CLINICAL FEATURES: Malaria is characterized by recurrent **paroxysms** of chills and high fever. They begin with chills and sometimes headache, followed by a high, spiking fever, with tachycardia, nausea, vomiting and abdominal pain. The high fever produces marked vasodilation and is often associated with orthostatic hypotension. The patient defervesces after several hours and is usually exhausted and drenched in sweat.

A period of 2–3 days follows, during which the patient feels well, only to be followed by a new paroxysm. Paroxysms recur for weeks, eventually subsiding as an immune response is mounted. Each paroxysm reflects the rupture of infected erythrocytes and release of daughter merozoites. As the mononuclear macrophage system responds to the infection, patients develop hepatosplenomegaly. Indeed, some of the largest spleens on record are the result of chronic malaria. Hypersplenism can exacerbate the anemia of malarial infection. As the level of parasitemia grows, fever may become virtually continuous. Ischemic brain injury causes symptoms from somnolence, hallucinations and behavioral changes to seizures and coma. CNS disease has a mortality of 20%–50%.

Malaria is diagnosed by demonstrating the organisms on Giemsa-stained blood smears. The several species are distinguished by their appearance in infected erythrocytes. Malarias other than falciparum malaria are treated with oral chloroquine, sometimes with primaquine. Therapy for falciparum malaria varies, as widespread chloroquine resistance requires new treatments.

BABESIOSIS

Babesiosis is a malaria-like infection caused by protozoa of the genus *Babesia,* which is transmitted by hard-bodied ticks.

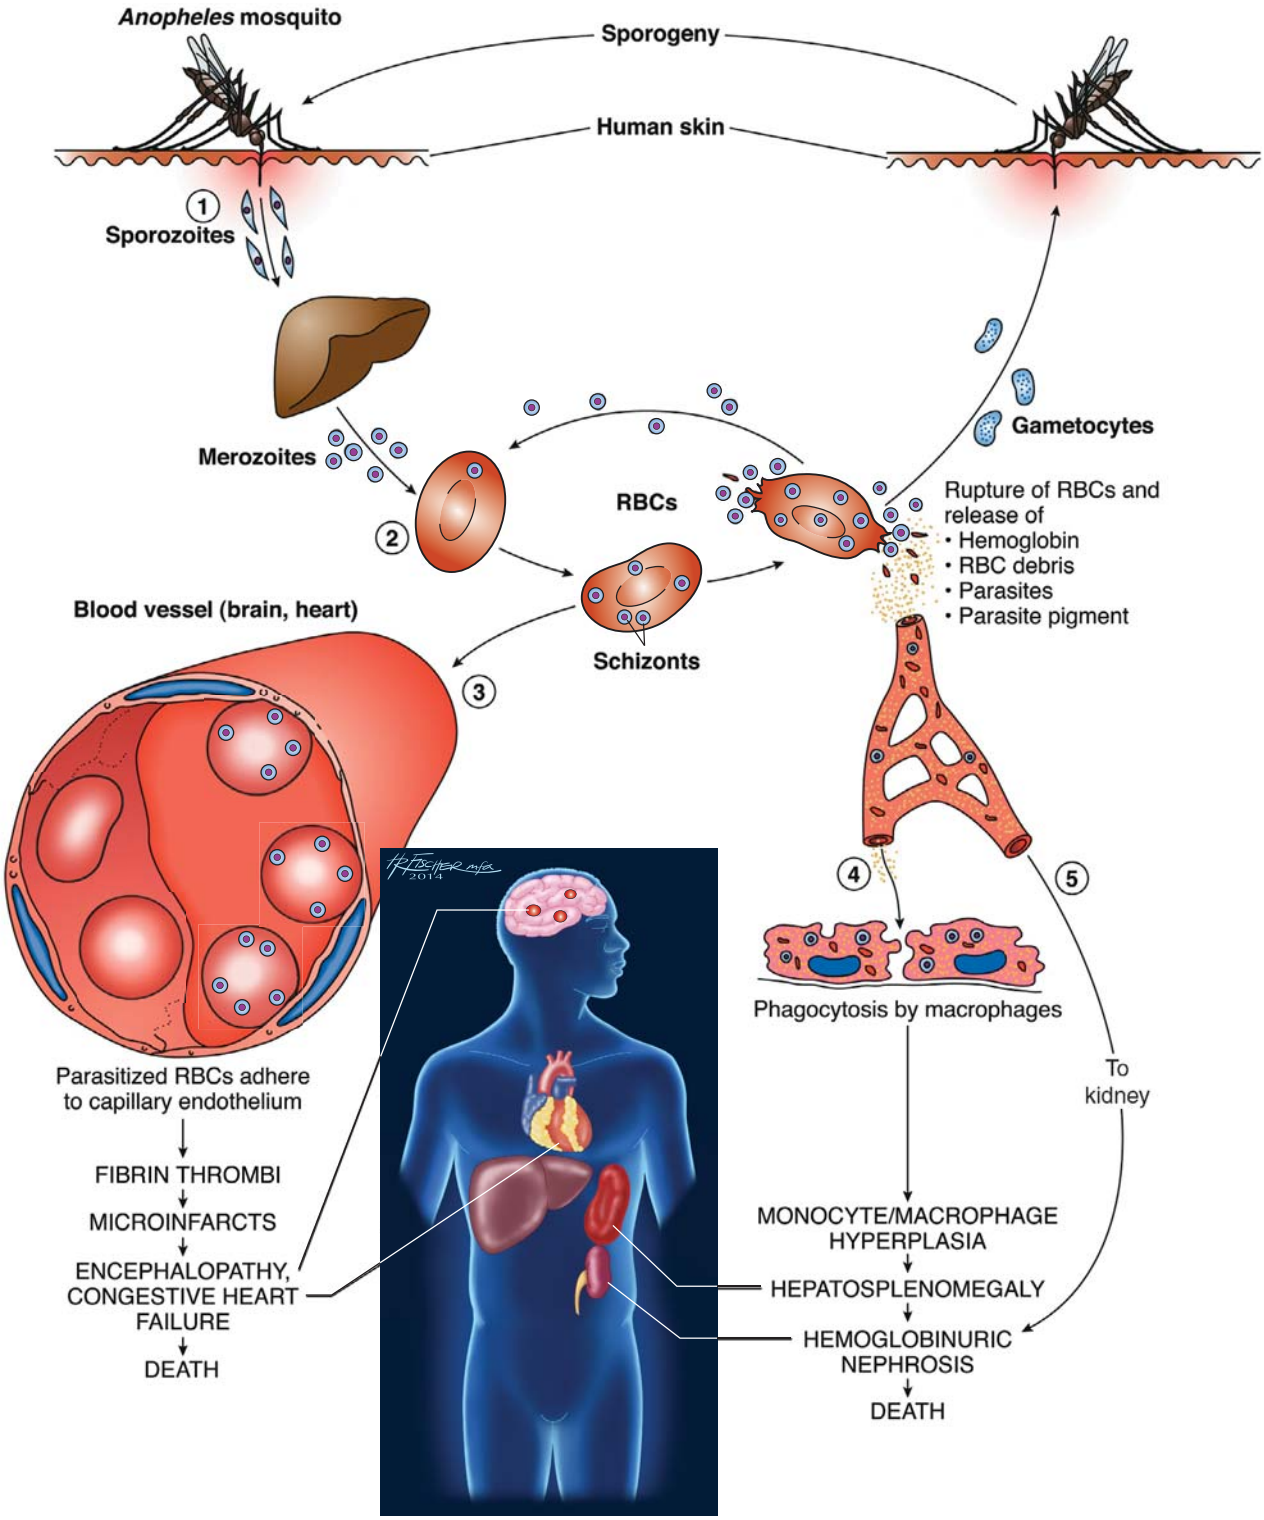

FIGURE 9-70. Life cycle of malaria. An *Anopheles* mosquito bites an infected person, taking blood that contains micro- and macrogametocytes (sexual forms). In the mosquito, sexual multiplication (sporogony) produces infective sporozoites in the salivary glands. **(1)** During the mosquito bite, sporozoites are inoculated into the bloodstream of the vertebrate host. Some sporozoites leave the blood and enter the hepatocytes, where they multiply asexually (exoerythrocytic schizogony) and form thousands of uninucleated merozoites. **(2)** Rupture of hepatocytes releases merozoites, which penetrate erythrocytes and become trophozoites, which then divide to form numerous schizonts (intraerythrocytic schizogony). Schizonts divide to form more merozoites, which are released on the rupture of erythrocytes and reenter other erythrocytes to begin a new cycle. After several cycles, subpopulations of merozoites develop into micro- and macrogametocytes, which are taken up by another mosquito to complete the cycle. **(3)** Parasitized erythrocytes obstruct capillaries of the brain, heart, kidney and other deep organs. Adherence of parasitized erythrocytes to capillary endothelial cells causes fibrin thrombi, which produce microinfarcts. These result in encephalopathy, congestive heart failure, pulmonary edema and frequently death. Ruptured erythrocytes release hemoglobin, erythrocyte debris and malarial pigment. **(4)** Phagocytosis leads to monocyte/macrophage hyperplasia and hepatosplenomegaly. **(5)** Released hemoglobin produces hemoglobinuric nephrosis, which may be fatal. *RBCs* = red blood cells.

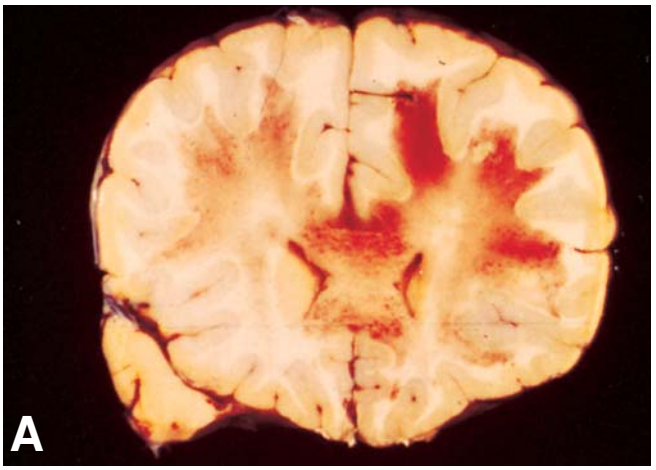

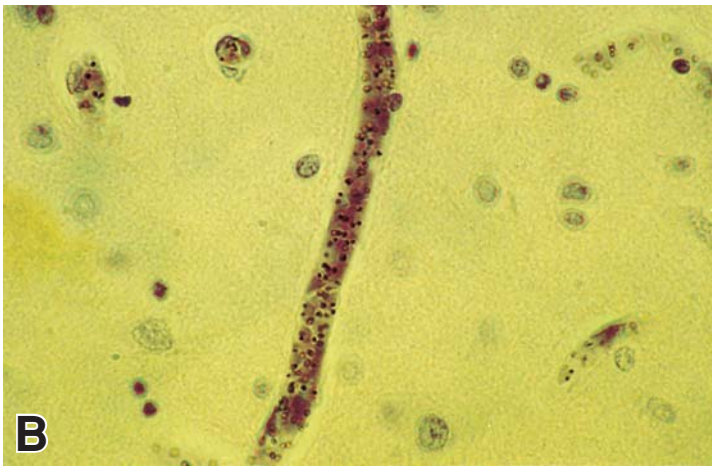

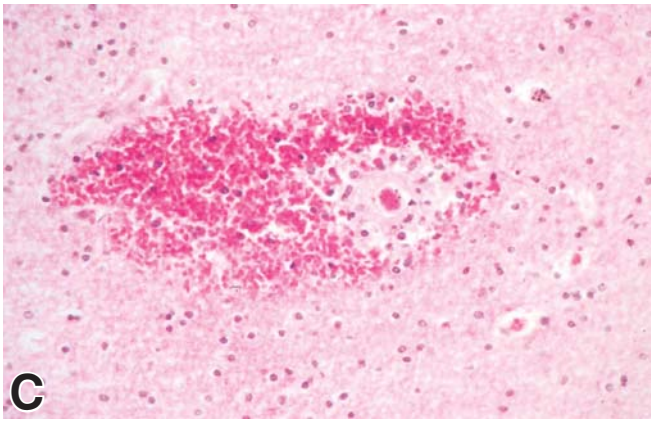

FIGURE 9-71. Acute falciparum malaria of the brain. A. There is severe diffuse congestion of the white matter and focal hemorrhages. **B.** A section of **(A)** shows a capillary packed with parasitized erythrocytes. **C.** Another section of **(A)** displays a ring hemorrhage around a thrombosed capillary, which contains parasitized erythrocytes in a fibrin thrombus.

EPIDEMIOLOGY: *Babesia* infections are common in animals and in some locations are responsible for serious economic losses to the livestock industry. By contrast, human babesiosis is almost a medical curiosity, with the parasites infecting humans only when people intrude into the zoonotic cycle between the tick vector and its vertebrate host. Human babesiosis is reported only in Europe and North America. Infections in the United States have been concentrated in islands off the New England coast. The organisms invade and destroy erythrocytes, causing hemoglobinemia, hemoglobinuria and renal failure. The disease is usually self-limited, but uncontrolled infections can be fatal. *Babesia* spp. are resistant to most antiprotozoal drugs.

TOXOPLASMOSIS

Toxoplasmosis is a worldwide infectious disease caused by a protozoan, *Toxoplasma gondii*. Most infections are asymptomatic, but if they occur in a fetus or immunocompromised host, devastating necrotizing disease may result.

EPIDEMIOLOGY AND ETIOLOGIC FACTORS: In some areas (e.g., France), the prevalence of *T. gondii* infection exceeds 80% of adults; in other regions (e.g., the southwestern United States), few people are affected. *T. gondii* infects many mammals and birds as intermediate hosts. The only final host is the cat, which becomes infected by ingesting toxoplasma cysts in tissues of an infected mouse or other intermediate host. In the cat's intestinal epithelium, five multiplicative stages end with shedding of oocysts. Oocysts sporulate in feces and soil and differentiate into sporocysts, which contain sporozoites. These are ingested by intermediate hosts, such as birds, mice or humans, and develop in the intermediate host to complete the life cycle.

T. gondii has two stages in tissue, tachyzoites and bradyzoites, both crescent shaped and 2×6 μm. In acute infection, tachyzoites multiply rapidly to form "groups" within intracellular vacuoles of parasitized cells, eventually causing the cells to rupture. Tachyzoites spread from the gut through lymphatics to regional lymph nodes, and through the blood to the liver, lungs, heart, brain and other organs. During chronic infection, the organisms, now called "bradyzoites," multiply slowly. The bradyzoites store PAS-positive material, and hundreds of organisms are tightly packed in "cysts." The cysts originate in intracellular vacuoles, enlarge beyond the usual size of the cell and push the nucleus to the periphery.

Except for congenital infection, toxoplasmosis is acquired by eating infectious forms of the organism. In the tropics, where infection is generally acquired in childhood, oocysts in contaminated soil are the main source of infection. In developed countries, the major mechanism of infection is eating incompletely cooked meat (lamb and pork) that carries *Toxoplasma* tissue cysts. Another source of infection is cat feces; oocysts contaminate the hands and food of people who live in close proximity to cats. **Congenital infection** is acquired by transplacental transmission of infectious forms from an acutely infected (usually asymptomatic) mother to the fetus.

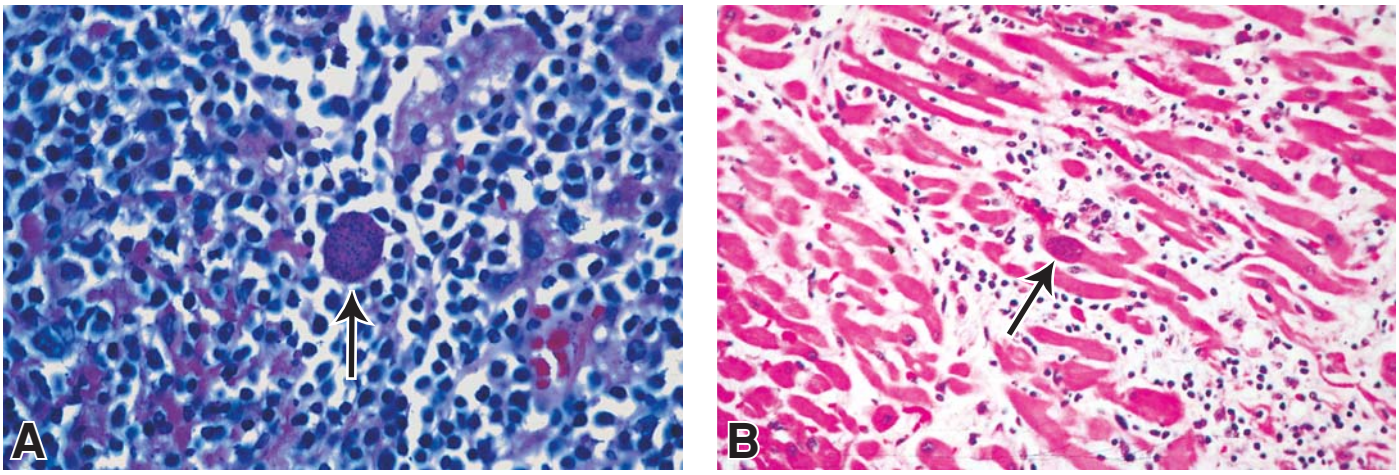

FIGURE 9-72. Toxoplasmosis. A. A photomicrograph of an enlarged lymph node reveals bradyzoites of *Toxoplasma gondii* within a cyst (*arrow*). **B.** A section of heart shows a cyst of bradyzoites of *T. gondii* within a myofiber (*arrow*), with edema and inflammatory cells in the adjacent tissue.

The active infection is usually terminated by the development of cell-mediated immune responses. In most *T. gondii* infections, little significant tissue destruction occurs before the immune response brings the active phase of the infection under control, and those infected suffer few clinical effects. *T. gondii* establishes latent infection, however, by forming dormant tissue cysts in some infected cells. These survive for decades in host cells. If an infected individual loses cell-mediated immunity, the organism can emerge from its encysted form and reestablish a destructive infection.

Toxoplasma Lymphadenopathy Occurs in Immunocompetent Persons

PATHOLOGY: The most common manifestation of *T. gondii* infection in immunocompetent hosts is lymphadenopathy (see Chapter 26). Virtually any lymph node group may be involved, but enlarged cervical nodes are most readily apparent. The histologic appearance of affected lymph nodes is distinctive, with numerous epithelioid macrophages surrounding and encroaching on reactive germinal centers.

CLINICAL FEATURES: In *Toxoplasma* lymphadenitis (Fig. 9-72A), patients present with nontender regional lymph node enlargement, sometimes accompanied by fever, sore throat, hepatosplenomegaly and circulating atypical lymphocytes. Hepatitis, myocarditis (Fig. 9-72B) and myositis have been documented. Lymphadenopathy usually resolves spontaneously in several weeks to several months, and therapy is seldom required.

Congenital *Toxoplasma* Infections Principally Affect the Brain

T. gondii infection in a fetus is far more destructive than is postnatal infection (see Chapter 6).

PATHOLOGY: The fetus lacks the immunologic capacity to contain *T. gondii* infection. The developing brain and eye are readily infected, leading to a necrotizing meningoencephalitis, which in the most severe cases causes loss of brain parenchyma, cerebral calcifications (Fig. 9-73) and marked hydrocephalus. Ocular infection results in chorioretinitis (i.e., necrosis and inflammation of the choroid and retina).

CLINICAL FEATURES: The most severe fetal disease is associated with infection early in pregnancy and often terminates in spontaneous abortion. In infants born with congenital toxoplasmosis, the effects of brain involvement range from severe mental retardation and seizures to subtle psychomotor defects. Ocular involvement may cause congenital visual impairment. Latent ocular infection established in utero may also recrudesce later in life to produce visual loss. Some newborns have *Toxoplasma* hepatitis, with large areas of necrosis and giant cells. Adrenal necrosis is also occasionally observed. Congenital toxoplasmosis requires therapy with antiprotozoal agents.

Toxoplasmosis in Immunocompromised Hosts Produces Encephalitis

Devastating *T. gondii* infections occur in people with impaired cell-mediated immunity (e.g., patients with AIDS or receiving immunosuppressive therapy). In most cases, the

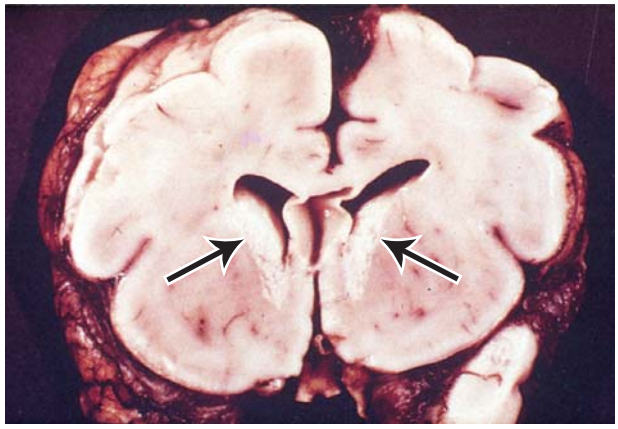

FIGURE 9-73. Congenital toxoplasmosis. The brain of a premature infant reveals subependymal necrosis with calcification appearing as bilaterally symmetric areas of whitish discoloration (*arrows*).

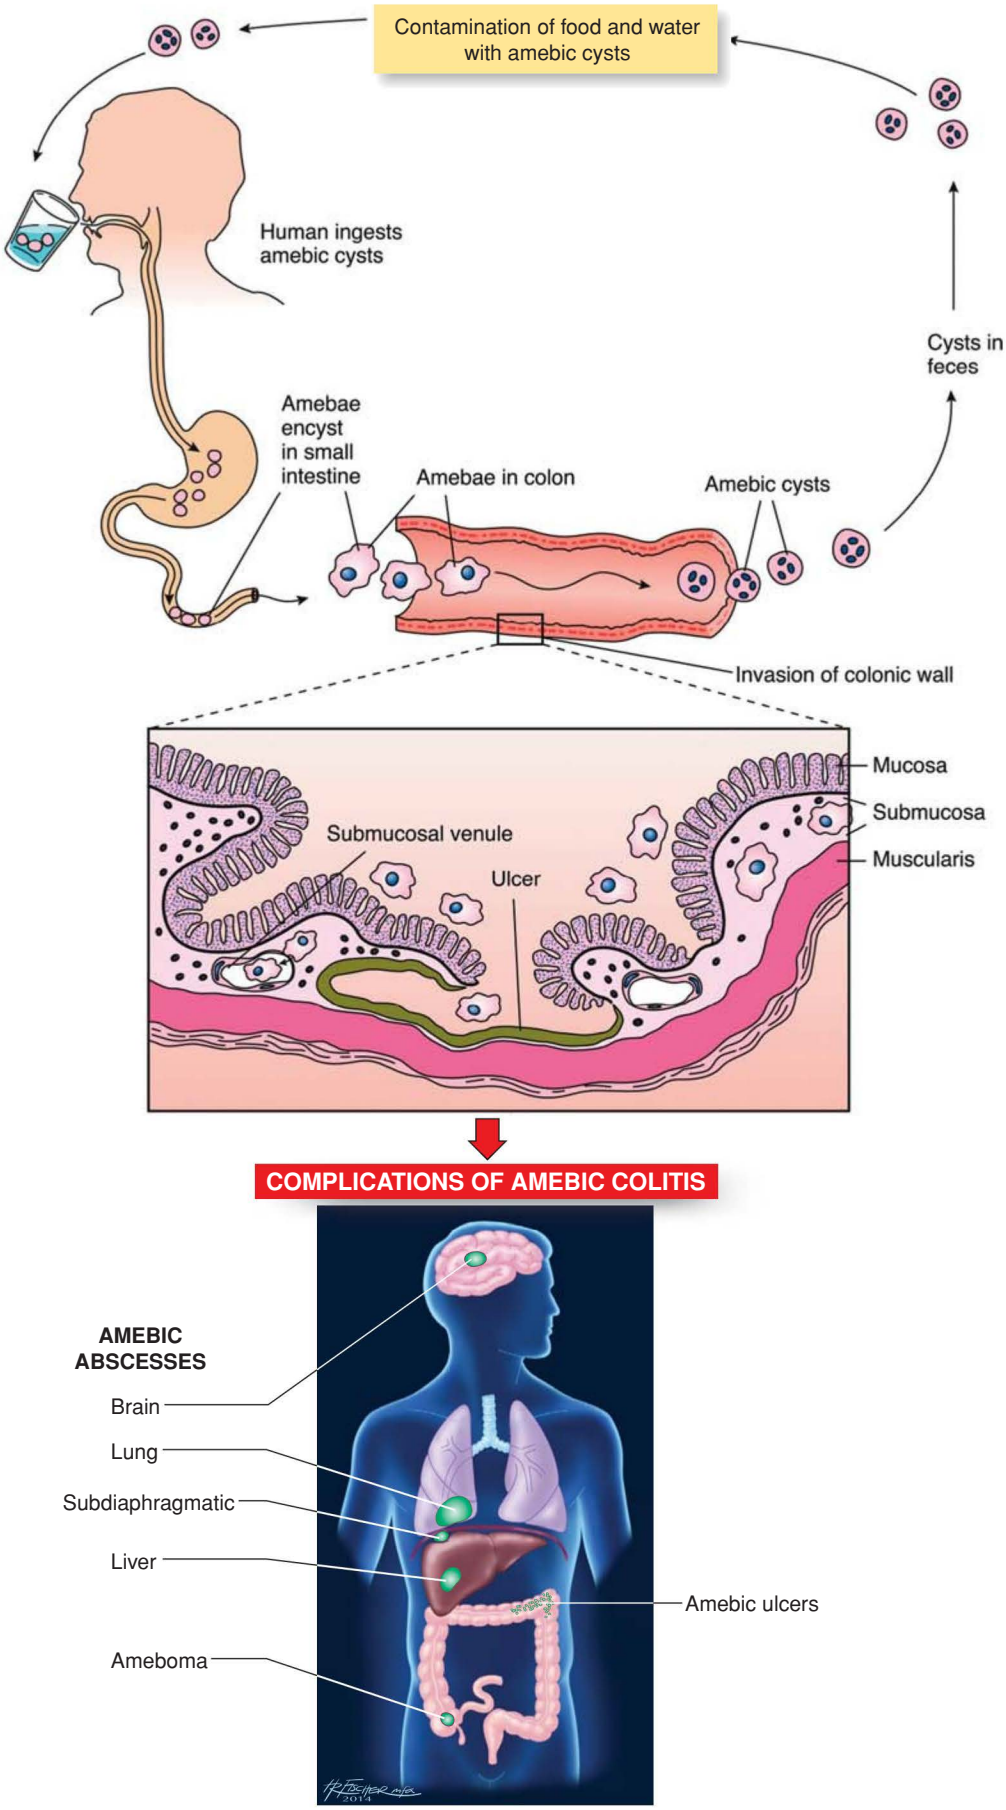

FIGURE 9-74. Amebic colitis and its complications. Amebiasis results from the ingestion of food or water contaminated with amebic cysts. In the colon, the amebae penetrate the mucosa and produce flask-shaped ulcers of the mucosa and submucosa. The organisms may invade submucosal venules, thereby disseminating the infection to the liver and other organs. The liver abscess can expand to involve adjacent structures.

disease reflects reactivation of a latent infection. The brain is most commonly affected, and infection with *T. gondii* produces a multifocal necrotizing encephalitis. Patients with encephalitis present with paresis, seizures, alterations in visual acuity and changes in mentation. *Toxoplasma* encephalitis in immunocompromised patients is fatal if not treated with antiprotozoal agents.

AMEBIASIS

Amebiasis is infection with *Entamoeba histolytica,* which principally involves the colon and occasionally refers to the liver. The parasite is named for its lytic actions on tissue. Intestinal infection ranges from asymptomatic colonization to severe invasive infection with bloody diarrhea. On occasion, the organisms spread beyond the colon to involve other organs. The most common site of extraintestinal disease is the liver, where *E. histolytica* causes slowly expanding, necrotizing abscesses.

EPIDEMIOLOGY: Humans are the only known reservoir for *E. histolytica,* which reproduces in the colon and passes in the feces. Although amebiasis is found worldwide, it is more common and more severe in tropical and subtropical areas, where poor sanitation prevails. ***Amebiasis is acquired by ingestion of materials contaminated with human feces.***

ETIOLOGIC FACTORS: *E. histolytica* has three distinct stages: the trophozoite, the precyst and the cyst.

Amebic trophozoites, 10–60 µm across, are found in stools of patients with acute symptoms. They are spherical or oval and have a thin cell membrane, a single nucleus, condensed chromatin on the interior of the nuclear membrane and a central karyosome. The trophozoites sometimes contain phagocytosed erythrocytes. PAS stains the cytoplasm of the trophozoites and makes them stand out in tissue sections. In the colon, trophozoites develop into cysts through an intermediate form, the **precyst.** During this process, trophozoites stop feeding, become round and nonmotile, lose some digestive vacuoles and form glycogen masses and chromatoidal bodies.

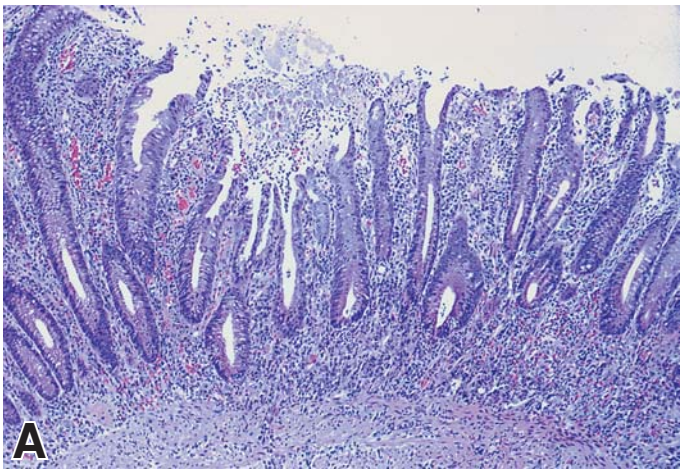
Amebic cysts are the infecting stage and are found only in stools, since they do not invade tissue. They are spherical, have thick walls, measure 5–25 µm across and usually have four nuclei. From the stools, the cysts contaminate water, food or fingers (Fig. 9-74). On ingestion, cysts traverse the stomach and excyst in the lower ileum. A metacystic ameba containing four nuclei divides to form four small, immature trophozoites, which then grow to full size. These organisms thrive in the colon and feed on bacteria and human cells. They may colonize any part of the large bowel, but the cecum is most affected. Patients with symptomatic amebic colitis pass both cysts and trophozoites. The latter survive only briefly outside the body and are also destroyed by gastric secretions. Host factors, such as nutritional status, coexistent colonic flora and immunologic status, also affect the course of *E. histolytica* infection. Invasion begins with attachment of a trophozoite to a colonic epithelial cell. The parasite kills target cells by elaborating a lytic protein that breaches the cell membrane. Progressive death of mucosal cells produces a superficial ulcer.

Intestinal Amebiasis Is an Ulcerating Disease of the Colon

PATHOLOGY: Amebic lesions begin as small foci of necrosis that progress to ulcers (Fig. 9-75A). Undermining of the ulcer margin and confluence of expanding ulcers lead to irregular sloughing of the mucosa. The ulcer bed is gray and necrotic, with fibrin and cellular debris. The exudate raises the undermined mucosa, producing chronic amebic ulcers, whose shape has been described as resembling a flask or a bottle neck.

Trophozoites are found on the ulcer surface, in the exudate and in the crater (Fig. 9-75B). They are also frequent in the submucosa, muscularis propria, serosa and small veins of the submucosa. There is little inflammatory response in early amebic ulcers. However, as the ulcers enlarge, acute and chronic inflammatory cells accumulate.

An **ameboma** is an infrequent complication of amebiasis, occurring when amebae invade through the intestinal wall. It is an inflammatory thickening of the bowel wall that resembles colon cancer and tends to form a "napkin-ring constriction." It consists of granulation tissue, fibrosis and clusters of trophozoites.



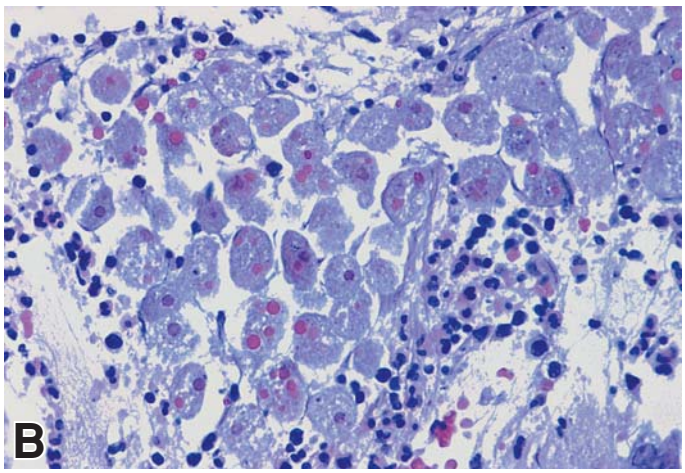


FIGURE 9-75. Intestinal amebiasis. A. The colonic mucosa shows superficial ulceration beneath a cluster of trophozoites of *Entamoeba histolytica.* The lamina propria contains excess acute and chronic inflammatory cells, including eosinophils. **B.** Higher-power view shows numerous trophozoites in the luminal exudate.

CLINICAL FEATURES: Intestinal amebiasis ranges from completely asymptomatic to a severe dysenteric disease. The incubation period for acute amebic colitis is 8–10 days. Gradually increasing abdominal discomfort, tenderness and cramps are accompanied by chills and fever. Nausea, vomiting, malodorous flatus and intermittent constipation are typical features. Liquid stools (up to 25 a day) contain bloody mucus, but diarrhea is rarely prolonged enough to cause dehydration. Amebic colitis often persists for months or years, and patients may become emaciated and anemic. Clinical features are often bizarre and sometimes must be differentiated from those of appendicitis, cholecystitis, intestinal obstruction or diverticulitis. In severe amebic colitis, massive destruction of colonic mucosa may lead to fatal hemorrhage, perforation or peritonitis. Therapy for intestinal amebiasis includes metronidazole, which acts against trophozoites, and diloxanide, which is effective against cysts.

Amebic Liver Abscess Is a Major Complication of Intestinal Amebiasis

PATHOLOGY: *E. histolytica* trophozoites that have invaded submucosal veins of the colon enter the portal circulation and reach the liver. Here the organisms kill hepatocytes, producing a slowly expanding necrotic cavity, which is filled with a dark brown, odorless, semisolid material, reported to resemble "anchovy paste" in color and consistency (Fig. 9-76). Neutrophils are rare within the cavity and trophozoites are found along the edges adjacent to hepatocytes.

Amebic liver abscesses may expand or rupture through the capsule. In the latter case, infestation extends into the peritoneum, diaphragm, pleural cavity, lungs or pericardium. Rarely, a liver abscess, or even a lesion in the colon, may spread amebae to the brain by a hematogenous route to form large necrotic lesions.

CLINICAL FEATURES: Patients with amebic liver abscess present with severe right upper quadrant pain, low-grade fever and weight loss. Only a minority of patients give a history of an antecedent diarrheal illness, and *E. histolytica* is demonstrated in the feces of less than one third of patients with extraintestinal disease. The diagnosis is usually made by radiologic or ultrasound demonstration of the abscess, in conjunction with serologic testing for antibodies to *E. histolytica.* Amebic abscess is treated by percutaneous or surgical drainage and antiamebic drugs.

FIGURE 9-76. Amebic abscesses of the liver. The cut surface of the liver shows multiple abscesses containing "anchovy paste" material.

CRYPTOSPORIDIOSIS

Cryptosporidiosis is an enteric infection with protozoa of the genus *Cryptosporidium* that cause diarrhea in persons with compromised immunity. The infection varies from a self-limited gastrointestinal infection to a potentially life-threatening illness. It is acquired by ingesting *Cryptosporidium* oocysts, which are shed in feces of infected humans and animals. Most infections probably result from person-to-person transmission, but many domesticated animals harbor the parasite and are a reservoir for human infection.

ETIOLOGIC FACTORS AND PATHOLOGY: *Cryptosporidium* oocysts survive passage through the stomach and release forms that attach to the microvillous surface of the small bowel. Unlike *Toxoplasma* and other coccidia, *Cryptosporidia* remain extracellular. They reproduce on the luminal surface of the gut, from stomach to rectum, forming progeny that also attach to the epithelium.

In immunocompetent people, infection is terminated by immune responses. Patients with AIDS and some congenital immunodeficiencies cannot contain the parasite and develop chronic infections, which may spread from the bowel to involve the gallbladder and intrahepatic bile ducts.

Cryptosporidiosis produces no grossly visible alterations. The organisms are visible microscopically as round, 2–4-μm blebs attached to the luminal surface of the epithelium (Fig. 9-77). In the small intestine, moderate or severe chronic inflammation in the lamina propria and villous atrophy are directly related to the density of the parasites. The colon has a chronic active colitis, with minimal architectural disruption.

CLINICAL FEATURES: Cryptosporidiosis presents as a profuse, watery diarrhea, sometimes accompanied by cramping abdominal pain or low-grade fever. Extraordinary volumes of fluid can be lost as diarrhea and intensive fluid replacement is required. In immunologically competent patients, diarrhea resolves spontaneously in 1–2 weeks. In immunocompromised persons, diarrhea persists indefinitely and may contribute to death.

GIARDIASIS

Giardiasis is an infection of the small intestine caused by the flagellated protozoan *Giardia lamblia* and is characterized by abdominal cramping and diarrhea.

EPIDEMIOLOGY: *G. lamblia* has a worldwide distribution, with a prevalence of infection from less than 1% to more than 25% in some areas with warmer climates and crowded, unsanitary environments. Children are more susceptible than adults. Giardiasis is acquired by ingesting infectious cyst forms of the organism, which are shed in the feces of infected humans and animals.

FIGURE 9-77. Cryptosporidiosis. A small intestinal biopsy stained with fluorescent antibody to *Cryptosporidium parvum* shows numerous sporozoites covering the villi and lining the crypts.

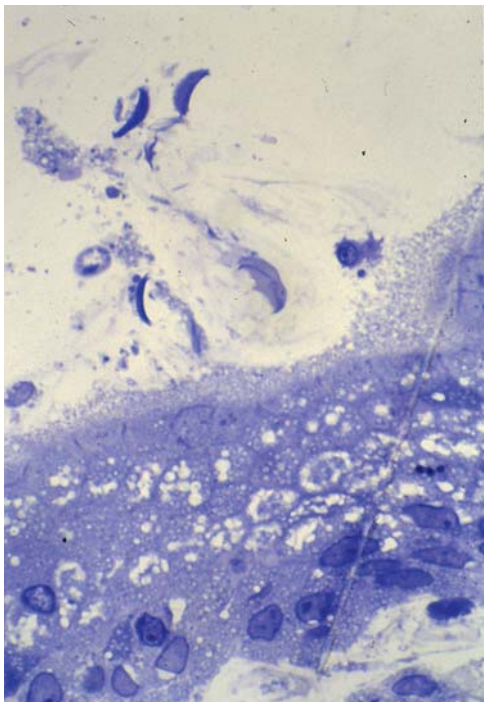

FIGURE 9-78. Giardiasis. Crescent-shaped trophozoites of *Giardia lamblia* are present overlying the small intestinal mucosa.

Infection spreads directly from person to person and also in contaminated water or food. *Giardia* can be acquired from wilderness water sources, where infected animals, such as beavers and bears, serve as the reservoir of infection. Infection may be epidemic, and outbreaks have occurred in orphanages and institutions.

ETIOLOGIC FACTORS AND PATHOLOGY: *G. lamblia* has two stages: trophozoites and cysts. The former are flat, pear-shaped, binucleate organisms with 4 pairs of flagella. They are most numerous in the duodenum and proximal small intestine. A curved, disc-like "sucker plate" on their ventral surface aids mucosal attachment. Ingested cysts contain 2 or 4 nuclei and revert to trophozoites on reaching the intestine. The stools usually contain only cysts, but trophozoites may also be present in patients with diarrhea.

Giardia cysts survive gastric acidity and rupture in the duodenum and jejunum to release trophozoites. These attach to small bowel epithelial microvilli and reproduce. Giardiasis produces no grossly visible alterations. Microscopic examination shows minimal associated mucosal changes, with crescentic or semilunar-shaped *Giardia* trophozoites on villous surfaces and within crypts (Fig. 9-78).

CLINICAL FEATURES: *G. lamblia* is usually a harmless commensal, but can cause acute or chronic symptoms. Acute giardiasis occurs with abrupt onset of abdominal cramping and frequent, foul-smelling stools. The infection is highly variable. In some patients, symptoms resolve spontaneously in 1–4 weeks. Others complain of persistent abdominal cramping and poorly formed stools for months. In children, chronic giardiasis may cause malabsorption, weight loss and retarded growth. The infection is treated effectively with various antibiotics, including metronidazole.

LEISHMANIASIS

Leishmaniae are protozoans that are transmitted to humans by insect bites and cause a spectrum of clinical syndromes, from indolent, self-resolving cutaneous ulcers to fatal disseminated disease. There are numerous *Leishmania* species, which differ in their natural habitats and the types of disease that they produce.

EPIDEMIOLOGY: Leishmaniasis is transmitted by *Phlebotomus* sandflies, which acquire the infection by feeding on infected animals. In many subtropical and tropical areas, leishmanial infection is endemic in animal populations; dogs, ground squirrels, foxes and jackals are reservoirs and potential sources for transmission to humans. It is mainly a disease of less developed countries where humans live in close proximity to animal hosts and the fly vector. There are estimated to be 20 million people infected worldwide.

ETIOLOGIC FACTORS: Infection begins when the organisms are inoculated into human skin by a sandfly bite. Shortly thereafter, leishmaniae are phagocytosed by mononuclear phagocytes and transformed into amastigotes, which reproduce within the macrophage. Daughter amastigotes eventually rupture from the cell and spread to other macrophages. Reproduction continues in this way, and eventually a cluster of infected macrophages forms at the site of inoculation.

From this initial local infection, the disease may take widely divergent courses depending on two factors: the immunologic status of the host and the infecting species of *Leishmania.* Three distinct clinical entities are recognized: (1) localized cutaneous leishmaniasis, (2) mucocutaneous leishmaniasis and (3) visceral leishmaniasis.

Localized Cutaneous Leishmaniasis Is an Ulcerating Disorder

Several *Leishmania* species in Central and South America, Northern Africa, the Middle East, India and China cause a localized skin disease, also known as "oriental sore" or "tropical sore."

PATHOLOGY: Localized cutaneous leishmaniasis begins as a collection of amastigote-filled macrophages that ulcerates the overlying epidermis. In tissue sections, the oval amastigotes measure 2 µm and contain two internal structures, a nucleus and a kinetoplast. Amastigotes in macrophages appear as multiple regular cytoplasmic dots, **Leishman-Donovan bodies**. With progressive development of cell-mediated immunity, macrophages are activated and kill the intracellular parasites. The lesion slowly becomes a more mature granuloma, with epithelioid macrophages, Langhans giant cells, plasma cells and lymphocytes. Over the course of months, the cutaneous ulcer heals spontaneously.

CLINICAL FEATURES: Cutaneous leishmaniasis begins as an itching, solitary papule, which erodes to form a shallow ulcer with a sharp, raised border. This ulcer can grow to 6–8 cm in diameter. Satellite lesions develop along draining lymphatics. The ulcers begin to resolve at 3–6 months, but healing may take a year or longer.

Diffuse cutaneous leishmaniasis develops in some patients who lack specific cell-mediated immune responses to leishmaniae. The disease begins as a single nodule, but adjacent satellite nodules slowly form, eventually involving much of the skin. These lesions so closely resemble lepromatous leprosy that some patients have been cared for in leprosaria. The nodule of anergic leishmaniasis is caused by enormous numbers of macrophages replete with leishmaniae.

Mucocutaneous Leishmaniasis Is a Late Complication of Cutaneous Leishmaniasis

Mucocutaneous leishmaniasis is caused by infection with *Leishmania braziliensis.* Most cases occur in Central and South America, where rodents and sloths are reservoirs.

PATHOLOGY AND CLINICAL FEATURES: The early course and pathologic changes of mucocutaneous leishmaniasis are like those of localized cutaneous leishmaniasis. A solitary ulcer appears, expands and resolves. Years afterward, an ulcer develops at a mucocutaneous junction, such as the larynx, nasal septum, anus or vulva. The mucosal lesion progresses slowly, is highly destructive and disfiguring and erodes mucosal surfaces and cartilage (Fig. 9-79). Destruction of the nasal septum sometimes produces a "tapir nose" deformity. The patient may die if the ulcers obstruct the airways. Mucocutaneous leishmaniasis requires treatment with systemic antiprotozoal agents.

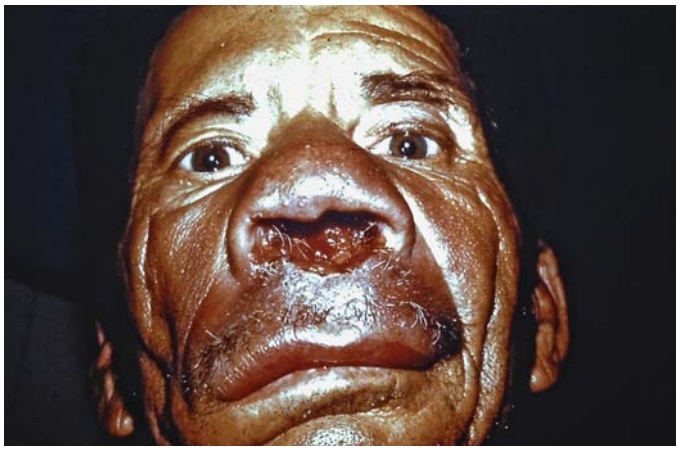

FIGURE 9-79. Mucocutaneous leishmaniasis. There is complete destruction of the basal septum and mucocutaneous ulceration.

Visceral Leishmaniasis (Kala Azar) Is a Potentially Fatal Infection

EPIDEMIOLOGY: Kala azar is produced by several subspecies of *Leishmania donovani.* Reservoirs of the agent and susceptible age groups vary in different parts of the world. Humans are the reservoir in India, and foxes in southern France and central Italy. Other canine and rodent species are reservoirs elsewhere in the world.

PATHOLOGY: Infection with *L. donovani* begins with localized collections of infected macrophages at the site of a sandfly bite (Fig. 9-80); these spread the organisms throughout the mononuclear phagocyte system. *L. donovani* are mostly destroyed by cell-mediated immune responses, but 5% of patients develop visceral leishmaniasis. Children and malnourished people are especially susceptible. The liver (Fig. 9-81A), spleen and lymph nodes become massively enlarged, as macrophages in these organs fill with proliferating leishmanial amastigotes (Fig. 9-81B). Normal organ architecture is gradually replaced by sheets of parasitized macrophages. Eventually, these cells accumulate in other organs, including the heart and kidney.

CLINICAL FEATURES: Patients with visceral leishmaniasis have persistent fever, progressive weight loss, hepatosplenomegaly, anemia, thrombocytopenia and leukopenia. Light-skinned people develop darkening of the skin; the Hindi name for leishmaniasis, *kala azar,* means "black sickness." Over the course of months, a patient with visceral leishmaniasis becomes profoundly cachectic and exhibits massive splenomegaly. The untreated disease is invariably fatal. Treatment entails systemic antiprotozoal therapy.

CHAGAS DISEASE (AMERICAN TRYPANOSOMIASIS)

Chagas disease is an insect-borne, zoonotic infection by the protozoan *Trypanosoma cruzi,* which causes a systemic infection of humans. Acute manifestations and long-term sequelae occur in the heart and gastrointestinal tract.

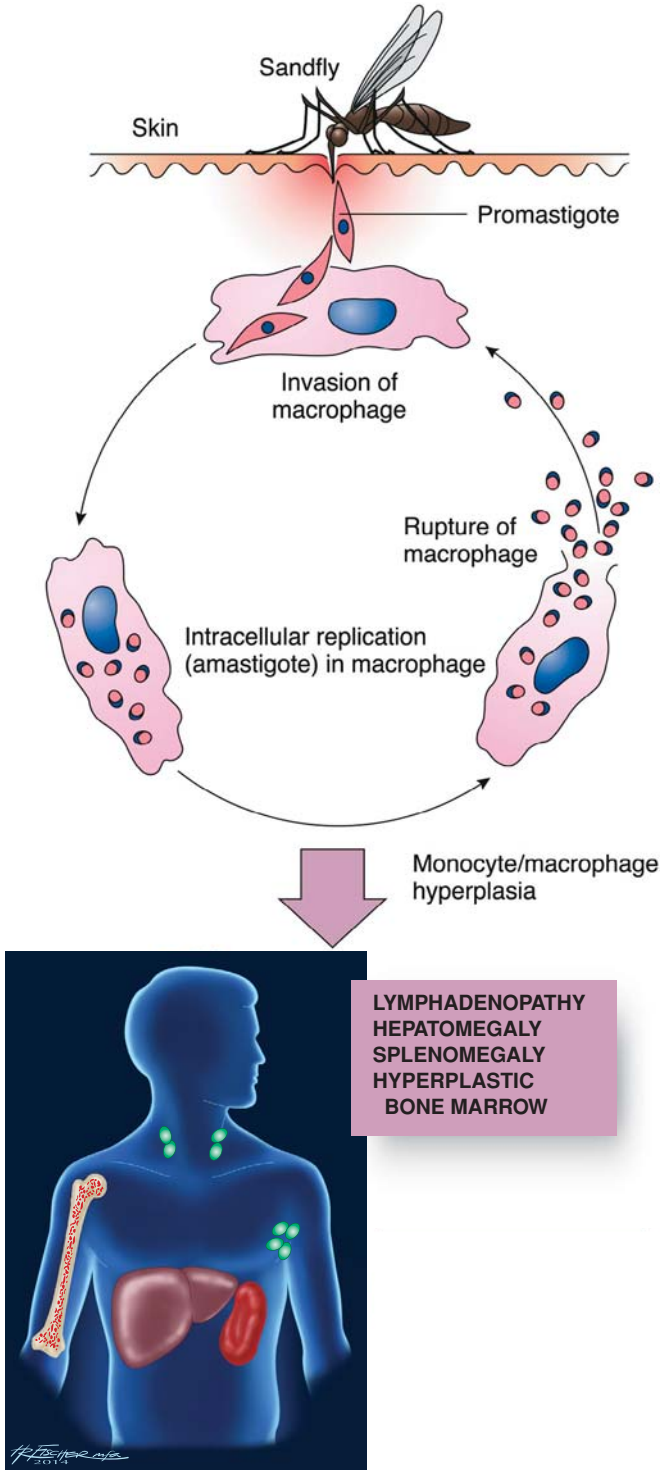

FIGURE 9-80. Leishmaniasis. Blood-sucking sandflies ingest amastigotes from an infected host. These are transformed in the sandfly gut into promastigotes, which multiply and are injected into the next vertebrate host. There they invade macrophages, revert to the amastigote form and multiply, eventually rupturing the cell. They then invade other macrophages, thus completing the cycle.

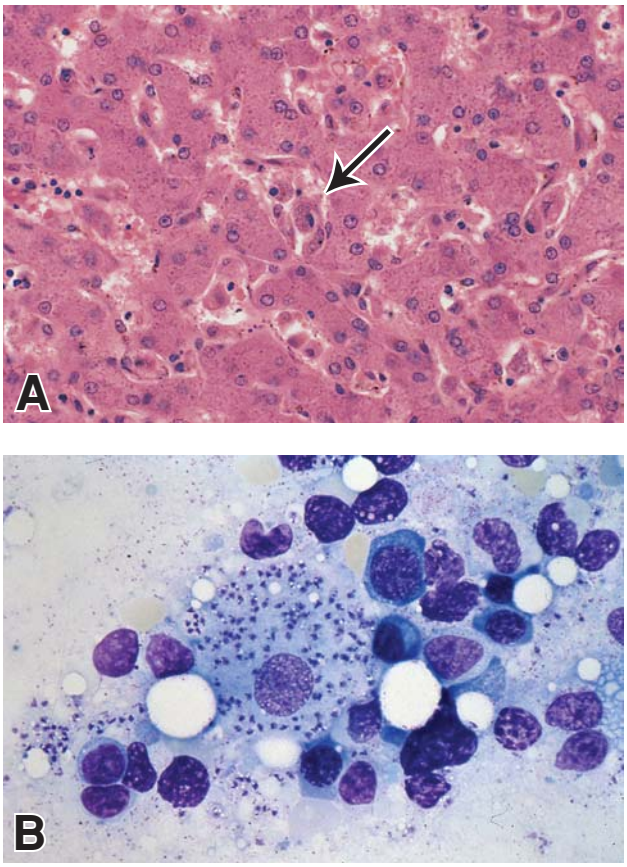

FIGURE 9-81. Visceral leishmaniasis. A. A photomicrograph of an enlarged liver shows prominent Kupffer cells distended by leishmanial amastigotes (*arrows*). **B.** A bone marrow aspirate from a patient with visceral leishmaniasis. Numerous leishmanial amastigotes are present, some of which are intracytoplasmic.

EPIDEMIOLOGY: *T. cruzi* infection is endemic in wild and domesticated animals (e.g., rats, dogs, goats, cats, armadillos) in Central and South America, where it is transmitted by the reduviid ("kissing") bug. Infection with *T. cruzi* is promoted by contact between humans and infected bugs, usually in mud or thatched dwellings of the rural and suburban poor. The bugs emerge at night and feed on sleeping victims. Congenital infection occurs upon passage of the parasite from mother to fetus. It is estimated that some 20 million people are infected with *T. cruzi*, more than half of them in Brazil. It is present in 18 nations on the American continents, with an estimated 300,000 infected people residing in the United States. Although exact figures are not known, it is thought that up to 50,000 deaths are attributable to Chagas disease every year.

ETIOLOGIC FACTORS: Infective forms of *T. cruzi* are discharged in the feces of the reduviid bug as it takes its blood meal. Itching and scratching promote contamination of the wound. The trypomastigotes penetrate at the site of the bite or at other abrasions, or may enter the mucosa of the eyes or lips. Once inside the body, they lose their flagella and undulating membranes, round up to become amastigotes and enter macrophages, where they undergo repeated divisions. Amastigotes also invade other sites, including cardiac myocytes and brain. Within host cells, amastigotes differentiate into trypomastigotes, which break out and enter the bloodstream (Fig. 9-82). Ingested in a subsequent bite of a reduviid bug, trypomastigotes multiply in the insect's alimentary tract and differentiate into metacyclic trypomastigotes, which congregate in the rectum of the bug and are discharged in the feces.

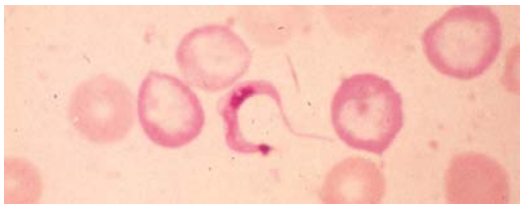

FIGURE 9-82. Chagas disease. A blood smear demonstrates a trypomastigote of *Trypanosoma cruzi* with its characteristic "C" shape, flagellum, nucleus and terminal kinetoplast.

T. cruzi infects and reproduces in cells at sites of inoculation, where they form localized nodular inflammatory lesions, **chagomas**. It then disseminates throughout the body via the bloodstream. Strains of *T. cruzi* differ in their predominant target cells; infections of cardiac myocytes, gastrointestinal ganglion cells and meninges cause the most significant disease. Parasitemia and widespread cellular infection are responsible for the systemic symptoms of acute Chagas disease. The onset of cell-mediated immunity eliminates the acute manifestations, but chronic tissue damage may continue. Progressive destruction of cells at sites of infection—particularly the heart, esophagus and colon—causes organ dysfunction, manifested decades after the acute infection.

Acute Chagas Disease May Cause Fatal Myocarditis

PATHOLOGY: *T. cruzi* circulates in the blood as a 20-µm long, curved flagellate that is easily recognized on blood films. Within infected cells, it reproduces as a nonflagellated amastigote, 2–4 µm in diameter. In fatal cases, the heart is enlarged and dilated, with a pale, focally hemorrhagic myocardium. Many parasites are seen in the heart, and amastigotes are evident within pseudocysts in myofibers (Fig. 9-83). There is extensive chronic inflammation and phagocytosis of parasites is conspicuous.

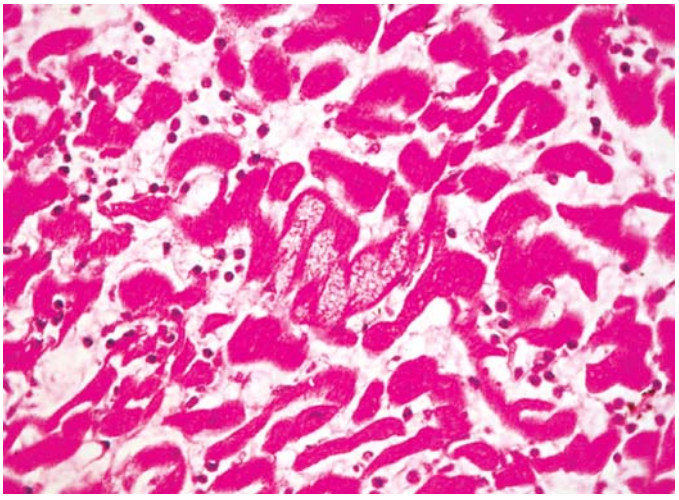

FIGURE 9-83. Acute Chagas myocarditis. The myofibers in the center contain numerous amastigotes of *Trypanosoma cruzi* and are surrounded by edema and chronic inflammation.

CLINICAL FEATURES: Acute symptoms develop 1–2 weeks after inoculation with *T. cruzi.* A chagoma (see above) develops at the site. Parasitemia appears 2–3 weeks after inoculation, usually associated with a mild illness characterized by fever, malaise, lymphadenopathy and hepatosplenomegaly. However, the disease can be lethal when there is extensive myocardial or meningeal involvement.

Chronic Chagas Disease Affects the Heart and Gastrointestinal Tract

The most frequent and most serious consequences of *T. cruzi* infection develop years or decades after acute infection. It is estimated that up to 40% of those acutely infected eventually develop chronic disease. In this phase of the illness, *T. cruzi* is no longer present in blood or tissue. Infected organs have been damaged, however, by chronic, progressive inflammation.

PATHOLOGY AND CLINICAL FEATURES: Chronic myocarditis is characterized by a dilated heart, prominent right ventricular outflow tract and dilation of the valve rings. The interventricular septum is often deviated to the right and may immobilize the adjacent tricuspid leaflet. There is extensive interstitial fibrosis, hypertrophied myofibers and focal lymphocytic inflammation, often involving the cardiac conduction system. Progressive cardiac fibrosis causes dysrhythmia or congestive heart failure. In endemic regions, chronic Chagas disease is a leading cause of heart failure in young adults.

Megaesophagus (i.e., dilation of the esophagus caused by failure of the lower esophageal sphincter [achalasia]) is common in chronic Chagas disease. It results from destruction of parasympathetic ganglia in the wall of the lower esophagus and leads to difficulty in swallowing, which may be so severe that the patient can consume only liquids.

Megacolon, which refers to massive dilation of the large bowel, is similar to megaesophagus in that the myenteric plexus of the colon is destroyed. The progressive aganglionosis of the colon causes severe constipation.

Congenital Chagas disease occurs in some pregnant women with parasitemia. Infection of the placenta and fetus leads to spontaneous abortion. In the infrequent live births, the infants die of encephalitis within a few days or weeks.

Antiprotozoal chemotherapy is effective for acute Chagas disease but not for its chronic sequelae. Cardiac transplantation has been effective in a number of patients.

AFRICAN TRYPANOSOMIASIS

African trypanosomiasis, popularly termed **sleeping sickness,** is an infection with *Trypanosoma brucei gambiense* or *Trypanosoma brucei rhodesiense* that leads to life-threatening meningoencephalitis. Gambian trypanosomiasis is a chronic infection often lasting more than a year. By contrast, East African (Rhodesian) trypanosomiasis is a rapidly progressive infection that kills the patient in 3–6 months. The organisms are curved flagellates, 15–30 µm in length. Although they can be demonstrated in blood or cerebrospinal fluid, they are difficult to find in infected tissues.

EPIDEMIOLOGY: *T. brucei gambiense* and *T. brucei rhodesiense* are hemoflagellate protozoa that are transmitted by several species of blood-sucking tsetse flies of the genus *Glossina.* The patchy distribution of African trypanosomiasis is related to the habitats of these flies. In Gambian trypanosomiasis, *T. brucei gambiense* is transmitted by tsetse flies of the riverine bush, mainly in endemic pockets of West and Central Africa. ***Humans are the only important reservoir for this trypanosome.***

In East African trypanosomiasis, *T. brucei rhodesiense* is spread by tsetse flies of the woodland savanna of East Africa. Antelope, other game animals and domestic cattle are natural reservoirs of the parasite. Infection of humans is an occupational hazard of game wardens, fishermen and cattle herders.

ETIOLOGIC FACTORS: While biting an infected animal or human, the tsetse fly ingests trypomastigotes with the blood (Fig. 9-84). These (1) lose their coat of surface antigen, (2) multiply in the midgut of the fly, (3) migrate to the salivary gland, (4) develop for 3 weeks through the epimastigote stage and (5) multiply in the fly's saliva as infective metacyclic trypomastigotes. During another bite, metacyclic trypomastigotes are injected into the lymphatics and blood vessels of a new host. They disseminate to the bone marrow and tissue fluids and some eventually invade the CNS. After replicating by binary fission in blood, lymph and spinal fluid, trypomastigotes are ingested by another fly to complete the cycle.

PATHOPHYSIOLOGY: African trypanosomiasis involves immune complex formation by variable trypanosomal antigens and antibodies. Autoantibodies to antigens of erythrocytes, brain and heart may participate in the pathogenesis of this disease. The trypanosome evades immune attack in mammals by periodically altering its glycoprotein antigen coat, which occurs in a genetically determined pattern, not by mutation. Thus, each wave of circulating trypomastigotes includes different antigenic variants that are a step ahead of the immune response.

PATHOLOGY: *T. brucei* multiplies at sites of inoculation, occasionally producing localized nodular lesions, termed "primary chancres." Generalized involvement of lymph nodes and spleen is prominent early in the disease. Affected nodes and spleen show foci of lymphocyte and macrophage hyperplasia. Infection eventually localizes to small blood vessels of the CNS, where replicating organisms elicit a destructive vasculitis, producing the progressive decrease in mentation characteristic of sleeping sickness. In *T. brucei rhodesiense* infection, the organisms also localize to blood vessels in the heart, sometimes causing a fulminant myocarditis.

Lesions in the lymph nodes, brain, heart and various other sites (including the inoculation site) show vasculitis of small blood vessels, with endothelial cell hyperplasia and dense perivascular infiltrates of lymphocytes, macrophages and plasma cells. The CNS vasculitis causes destruction of neurons, demyelination and gliosis. The perivascular infiltrate thickens the leptomeninges and involves the Virchow-Robin spaces (Fig. 9-85).

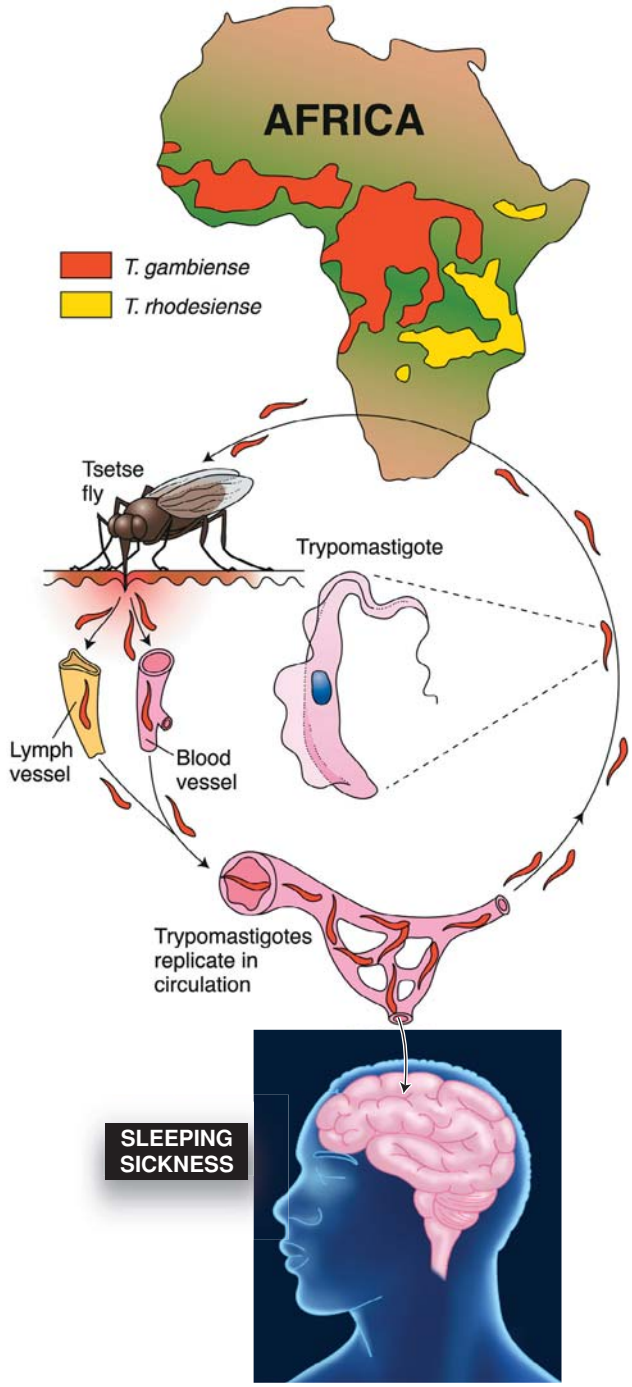

FIGURE 9-84. African trypanosomiasis (sleeping sickness). The distribution of Gambian and Rhodesian trypanosomiasis is related to the habitats of the vector tsetse flies (*Glossina* spp.). A tsetse fly bites an infected animal or human and ingests trypomastigotes, which multiply into infective, metacyclic trypomastigotes. During another fly bite, these are injected into lymphatic and blood vessels of a new host. A primary chancre develops at the site of the bite (stage 1a). Trypomastigotes replicate further in the blood and lymph, causing a systemic infection (stage 1b). Another fly ingests hypomastigotes to complete the cycle. In stage 2, invasion of the central nervous system by trypomastigotes leads to meningoencephalomyelitis and associated symptoms, including lethargy and daytime somnolence. Patients with Rhodesian trypanosomiasis may die within a few months. *T. gambiense* = *Trypanosoma brucei gambiense; T. rhodesiense* = *Trypanosoma brucei rhodesiense.*

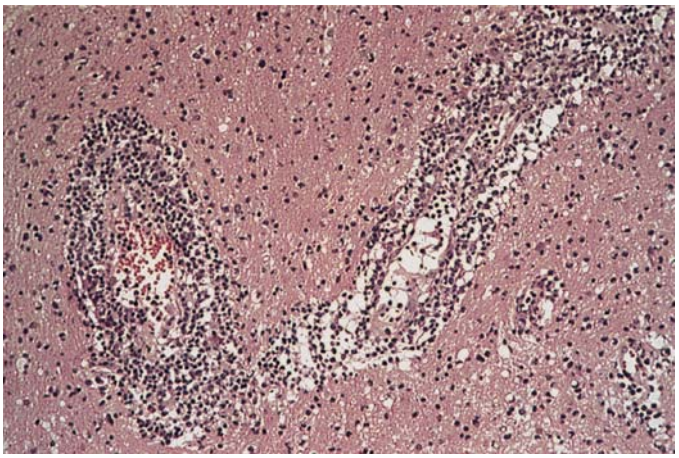

FIGURE 9-85. African trypanosomiasis. A section of brain from a patient who died from infection with *Trypanosoma brucei rhodesiense* shows a perivascular mononuclear cell infiltrate.

CLINICAL FEATURES: African trypanosomiasis is divided into 3 clinical stages:

1. **Primary chancre:** After 5–15 days, a 3–4-cm papillary swelling topped by a central red spot appears at the inoculation site. It subsides spontaneously within 3 weeks.
2. **Systemic infection:** Shortly after the appearance of the chancre (if any) and within 3 weeks of a bite, bloodstream invasion is marked by intermittent fever, for up to a week, often with splenomegaly and local and generalized lymphadenopathy. The evolving illness is marked by remitting irregular fevers, headache, joint pains, lethargy and muscle wasting. Myocarditis may be a complication and is more common and severe in Rhodesian trypanosomiasis. Dysfunction of the lungs, kidneys, liver and endocrine system occurs commonly in both forms of the disease.
3. **Brain invasion:** CNS invasion may occur early (weeks or months) in Rhodesian trypanosomiasis or late (months or years) in the Gambian form. Brain invasion is marked by apathy, daytime somnolence and sometimes coma. A diffuse meningoencephalitis is characterized by tremors of the tongue and fingers; fasciculations of the muscles of the limbs, face, lips and tongue; oscillatory movements of the arms, head, neck and trunk; indistinct speech; and cerebellar ataxia, causing problems in walking.

PRIMARY AMEBIC MENINGOENCEPHALITIS

Amebic meningoencephalitis, caused by *Naegleria fowleri*, is a fatal illness.

EPIDEMIOLOGY: *N. fowleri* is a free-living, soil ameba that inhabits ponds and lakes throughout tropical and subtropical regions but it is reported in temperate areas, including the United States. Primary amebic meningoencephalitis is rare (fewer than 300 reported cases), affecting people who swim or bathe in these waters.

ETIOLOGIC FACTORS AND PATHOLOGY: *N. fowleri* is inoculated into the nasal mucosa near the cribriform plate when a person swims in or dives into water containing high concentrations of the organism. Amebae invade the olfactory nerves, migrate into the olfactory bulbs and then proliferate in the meninges and brain.

The trophozoites are 8–15 µm across, with sharply outlined nuclei that stain deeply with hematoxylin. Grossly, the brain is swollen and soft, with vascular congestion and a purulent meningeal exudate, most prominent over the lateral and basal areas. The amebae invade the brain along the Virchow-Robin spaces and cause massive tissue damage. Thrombosis and destruction of blood vessels are associated with extensive hemorrhage. The olfactory tract and bulbs are enveloped and destroyed, and there is an exudate between the bulb and the inferior surface of the temporal lobe. Proliferation of *Naegleria* in the brain may produce solid masses of amebae (amebomas). Meningitis can extend the full length of the spinal cord.

CLINICAL FEATURES: Primary amebic meningoencephalitis due to *N. fowleri* begins suddenly with fever, nausea, vomiting and headache. Within hours, the patient suffers profound deterioration in mental status. Cerebrospinal fluid contains numerous neutrophils, blood and amebae. The disease is rapidly fatal.

Helminthic Infection

Helminths, or worms, are among the most common human pathogens. At any given time, 25%–50% of the world's population carries at least one helminth species. Although most do little harm, some cause significant disease. Schistosomiasis, for instance, is among the leading global causes of morbidity and mortality.

Helminths are the largest and most complex organisms capable of living within the human body. Their adult forms range from 0.5 mm to over 1 m in length. Most are visible to the naked eye. They are multicellular animals with differentiated tissues, including specialized nervous tissues, digestive tissues and reproductive systems. Their maturation from eggs or larvae to adult worms is complex, often involving multiple morphologic transformations (molts). Some undergo these metamorphoses in different hosts before attaining adulthood, and the human host may be only one in a series that supports this maturation process. Within the human body, the helminths frequently migrate from the port of entry through several organs to a site of final infection.

Most helminths that infect humans are well adapted to human parasitism, causing limited or no host tissue damage. They gain entry by ingestion, skin penetration or insect bites. With two exceptions, they do not multiply in the human body, so a single organism cannot become an overwhelming infection. The exceptions are *Strongyloides stercoralis* and *Capillaria philippinensis*, which can complete their life cycle and multiply within the human body.

Helminths cause disease in various ways. A few compete with their human host for certain nutrients. Some grow to block vital structures, producing disease by mass effect. Most, however, cause dysfunction through the destructive inflammatory and immunologic responses that they elicit. For example, morbidity in schistosomiasis, the most destructive helminthic infection, results from granulomatous responses to schistosome eggs deposited in tissue.

Eosinophils contain basic proteins toxic to some helminths and are a major component of inflammatory responses to these organisms. Parasitic helminths are categorized based on overall morphology and the structure of digestive tissues:

- **Roundworms (nematodes)** are elongate cylindrical organisms with tubular digestive tracts.
- **Flatworms (trematodes)** are dorsoventrally flattened organisms with digestive tracts that end in blind loops.
- **Tapeworms (cestodes)** are segmented organisms with separate head and body parts; they lack a digestive tract and absorb nutrients through their outer walls.

FILARIAL NEMATODES

Lymphatic Filariasis Results in Massive Lymphedema (Elephantiasis)

Lymphatic filariasis (bancroftian and Malayan filariasis) is an inflammatory parasitic infection of lymphatic vessels caused by the roundworms *Wuchereria bancrofti* and *Brugia malayi.* Adult worms inhabit the lymphatics, most frequently in inguinal, epitrochlear and axillary lymph nodes, testis and epididymis. There they cause acute lymphangitis and, in a minority of infected subjects, lymphatic obstruction, leading to severe lymphedema (Fig. 9-86). These and similar organisms are known as filarial worms, because of their thread-like appearance (from the Latin *filum,* meaning "thread").

EPIDEMIOLOGY: The elephantiasis characteristic of lymphatic filariasis was familiar to Hindi and Persian physicians as early as 600 BC. Humans, the only definitive host of these filarial nematodes, acquire infection from the bites of at least 80 species of mosquitoes of the genera *Culex, Aedes, Anopheles* and *Mansonia. W. bancrofti* infection is widespread in southern Asia, the Pacific, Africa and parts of South America. *B. malayi* is localized to coastal southern Asia and western Pacific islands. Worldwide, 100–200 million people are estimated to be infected.

ETIOLOGIC FACTORS: Mosquito bites transmit infectious larvae that migrate to lymphatics and lymph nodes. After maturing into adult forms over several months, worms mate and the female releases microfilariae into lymphatics and the bloodstream. The manifestations of filariasis result from inflammatory responses to degenerating adult worms in the lymphatics. Repeated infections are common in endemic regions and produce numerous bouts of lymphangitis (filarial fevers), which cause extensive scarring and obstruction of lymphatics over years. This blockage causes localized dependent edema, most commonly affecting legs, arms, genitalia and breasts. In its most severe form (<5% of the infected population), this is known as **elephantiasis**.

PATHOLOGY: The adult nematode is a white, thread-like worm that is very convoluted within lymph nodes. Females are 80–100 mm in length and 0.20–0.3 mm in width, twice the size of males. In blood films stained with Giemsa, the microfilariae appear as curved worms.

Lymphatic vessels harboring adult worms are dilated, and their endothelial lining is thickened. In adjacent tissues, worms are surrounded by chronic inflammation, including eosinophils. A granulomatous reaction may develop, and degenerating worms can provoke acute inflammation. Microfilariae are seen in blood vessels and lymphatics, and degenerating microfilariae also provoke a chronic inflammatory reaction. After repeated bouts of lymphangitis, lymph nodes and lymphatics become densely fibrotic, often containing calcified remnants of the worms.

CLINICAL FEATURES: In endemic areas, most of the infected population either has antifilarial antibodies with no detectable infection or asymptomatic microfilaremia. A smaller number develop recurrent episodes of filarial fevers, with malaise, lymphadenopathy and lymphangitis, which persist for 1–2 weeks and then resolve spontaneously. In a small subset, late manifestations of disease appear after two to three decades of recurrent bouts of filarial fevers. Lymphatic obstruction leads to chronic edema of dependent tissues. The overlying skin becomes thickened and warty. The diagnosis is made by identifying microfilariae in blood samples. Diethylcarbamazine and ivermectin are the agents effective against lymphatic filariasis.

Occult filariasis, characterized by indirect evidence of filarial infection (antifilarial antibodies), is the cause of **tropical pulmonary eosinophilia**. This condition is virtually restricted to southern India and some Pacific Islands. Patients present with cough, wheezing, diffuse pulmonary infiltrates and peripheral eosinophilia. The severity ranges from mild asthma to fatal pneumonia.

FIGURE 9-86. Bancroftian filariasis. Massive lymphedema (elephantiasis) of the scrotum and left lower extremity are present.

Onchocerciasis Causes Blindness

Onchocerciasis **("river blindness")** is a chronic inflammatory disease of the skin, eyes and lymphatics caused by the filarial nematode *Onchocerca volvulus.*

EPIDEMIOLOGY: Onchocerciasis is one of the world's major endemic diseases, afflicting an estimated 40 million people, of whom 2 million are blind. The disease is transmitted by bites of *Simulium damnosum* blackflies, which transmit infectious larvae to humans, who are the only definitive hosts. The flies require rapidly running water for breeding. Onchocerciasis is thus endemic along rivers and streams (hence, "river blindness") in parts of tropical Africa, southern Mexico, Central America and South America.

PATHOPHYSIOLOGY: Adult worms live as coiled tangled masses in deep fascia and subcutaneous tissues. They do not cause tissue damage or elicit inflammatory responses. However, gravid females release millions of microfilariae, which migrate into the skin, eyes, lymph nodes and deep organs, producing corresponding onchocercal lesions. Ocular onchocerciasis results from migration of microfilariae into all regions of the eye, from the cornea to the optic nerve head.

When microfilariae die, they incite vigorous inflammatory and immune responses. Inflammatory damage to the cornea, choroid or retina causes partial or total loss of vision. Cutaneous inflammation results in microabscess formation and chronic degenerative changes in the epidermis and dermis. In lymph nodes and lymphatics, responses to dying microfilariae produce chronic lymphatic obstruction and localized dependent edema.

PATHOLOGY: *Onchocerca volvulus* is a thin, very long nematode; the female is 400 × 0.3 mm and the male 30 × 0.2 mm. Masses of adult worms become encapsulated by a fibrous scar, forming discrete, 1–3-cm, **onchocercal nodules** in the deep dermis and subcutis. Nodules form over bony prominences of the skull, scapula, ribs, iliac crest, trochanter, sacrum and knee. Microscopically, these nodules have an outer fibrous layer and a central inflammatory infiltrate, which varies from suppurative to granulomatous. Active lesions in the eyes and lymphatics all show degenerating microfilariae surrounded by chronic inflammation, including eosinophils. Ocular involvement leads to sclerosing keratitis, iridocyclitis, chorioretinitis and optic atrophy. The femoral inguinal nodes become enlarged and then fibrotic.

CLINICAL FEATURES: Symptoms of onchocerciasis result from inflammatory responses to degenerating microfilariae. Skin manifestations begin with generalized pruritus, which becomes so intense that it can interfere with sleeping. Continuing damage produces areas of depigmentation, hypertrophy or atrophy of the skin. Progressive destruction of the cornea, choroid or uvea results in loss of vision. Chronic lymphadenitis is followed by localized edema, which may cause chronic swelling (elephantiasis) of the legs, scrotum or other dependent portions of the body. Systemic antihelminthic therapy, particularly with ivermectin, is effective.

Loiasis Principally Affects the Eyes and Skin

Loiasis is infection by the filarial nematode *Loa loa,* the African "eyeworm."

EPIDEMIOLOGY AND PATHOPHYSIOLOGY: Loiasis is prevalent in the rain forests of Central and West Africa. Humans and baboons are the definitive hosts, and infection is transmitted by mango flies. Adult worms (4 cm long) migrate in the skin and occasionally cross the eye beneath the conjunctiva, making the patient acutely aware of this infection (Fig. 9-87). Gravid worms discharge microfilariae, which circulate in the blood during the day but reside in capillaries of the skin, lungs and other organs at night.

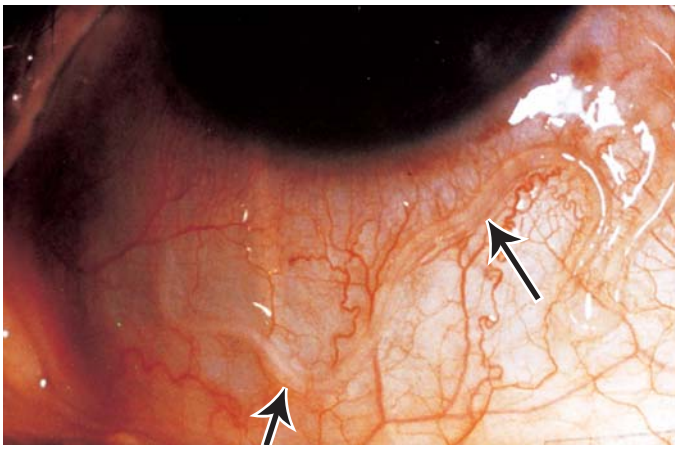

FIGURE 9-87. Loiasis. A thread-like *Loa loa* (*arrows*) is migrating in the subconjunctival tissues.

PATHOLOGY: Migrating worms cause no inflammation, but static ones are surrounded by eosinophils, other inflammatory cells and a foreign body giant cell reaction. Rarely, those infected may develop acute generalized loiasis, characterized by obstructive fibrin thrombi, containing degenerating microfilariae in small vessels of most organs. Brain involvement, with obstruction of vessels by filarial thrombi, may cause lethal and sudden diffuse cerebral ischemia.

CLINICAL FEATURES: Most infections are asymptomatic but persist for years. Some patients have pruritic, red, subcutaneous "Calabar" swellings, which may be a reaction to migrating adult worms or to microfilariae in the skin. Ocular symptoms include swelling of the eyelids, itching and pain. Worms may be extracted during their migration beneath the conjunctiva. Systemic reactions include fever, pain, itching, urticaria and eosinophilia. Dead worms in or near major nerves may cause paresthesia or paralysis. Treatment with microfilariacides may initiate massive death of microfilariae and provoke fever, meningoencephalitis and death.

INTESTINAL NEMATODES

The adult forms of several nematode species (Table 9-10) reside in the human bowel but rarely cause symptomatic disease. Clinical symptoms occur almost exclusively in patients with very large numbers of worms or who are immunocompromised. Humans are the exclusive or primary hosts for all of intestinal nematodes. Infection spreads from person to person via eggs or larvae passed in the stool or deposited in the perianal region. Infection is most prevalent in settings where hand washing and hygienic disposal of feces are lacking (e.g., less developed countries). Warm, moist climates are required for the infectious forms of many intestinal nematodes to survive outside the body. These worms are, thus, endemic in tropical and subtropical climates.

Ascariasis Is an Infestation of the Small Bowel

Ascariasis refers to infection by the large roundworm *Ascaris lumbricoides.* It is the most common helminthic infection of

TABLE 9-10
INTESTINAL NEMATODES

Species	Common Name	Site of Adult Worm	Clinical Manifestations
Ascaris lumbricoides	Roundworm	Small bowel	Allergic reactions to lung migration; intestinal obstruction
Ancylostoma duodenale	Hookworm	Small bowel	Allergic reactions to cutaneous inoculation and lung migration; intestinal blood loss
Necator americanus	Hookworm	Small bowel	Allergic reactions to cutaneous inoculation and lung migration; intestinal blood loss
Trichuris trichiura	Whipworm	Large bowel	Abdominal pain and diarrhea; rectal prolapse (rare)
Strongyloides stercoralis	Threadworm	Small bowel	Abdominal pain and diarrhea; dissemination to extraintestinal sites in immunocompromised persons
Enterobius vermicularis	Pinworm	Cecum, appendix	Perianal and perineal itching

humans, affecting at least 1 billion people, usually without causing symptoms. Infection is worldwide but is most common in areas with warm climates and poor sanitation.

PATHOPHYSIOLOGY: Adult worms live in the small intestine, where gravid females discharge eggs that pass in the feces. These eggs hatch when ingested. *Ascaris* larvae emerge in the small intestine, penetrate the bowel wall and reach the lungs through the venous circulation. They leave the pulmonary capillaries, enter the alveoli and then migrate up the trachea to the glottis, where they are swallowed and again reach the small bowel. There, they mature and live as adult worms within the lumen for 1–2 years.

PATHOLOGY AND CLINICAL FEATURES: Adult worms (15–35 cm long) usually cause no pathologic changes. Heavy infections may be complicated by vomiting, malnutrition and sometimes intestinal obstruction (Fig. 9-88). On rare occasions, worms enter the ampulla of Vater or pancreatic or biliary ducts, where they may cause obstruction, acute pancreatitis, suppurative cholangitis and liver abscesses. Eggs deposited in the liver or other tissues produce necrosis, granulomatous inflammation and fibrosis. *Ascaris* pneumonia, which may be fatal, develops when large numbers of larvae migrate within the air spaces.

Ascariasis is diagnosed by identifying eggs in the feces. Occasionally, adult worms may pass with the stools or even emerge from the nose or mouth. Ascaricidal drugs are effective.

Trichuriasis Is an Infestation of the Large Bowel

Trichuriasis is caused by the intestinal nematode *Trichuris trichiura* **("whipworm")**.

EPIDEMIOLOGY: Whipworm infection is found worldwide, affecting over 800 million people. Parasitism is most common in warm, moist places with poor sanitation, but over 2 million persons in the United States are infected. Children are especially susceptible. Adult worms live in the cecum and upper colon, where females produce eggs that pass in the feces. Eggs embryonate in moist soil and become infective in 3 weeks. Humans are infected by ingesting eggs in contaminated soil, food or drink.

PATHOPHYSIOLOGY: Larvae emerge from ingested eggs in the small bowel and migrate to the cecum and colon, where adult worms burrow their anterior portions into the superficial mucosa (Fig. 9-89). This invasion causes small erosions, focal active inflammation and continuous loss of small quantities of blood. *T. trichiura* measures 3–5 cm in length, with a long, slender anterior portion and a short, blunt posterior.

FIGURE 9-88. Ascariasis. This mass of over 800 worms of *Ascaris lumbricoides* obstructed and infarcted the ileum of a 2-year-old girl in South Africa.

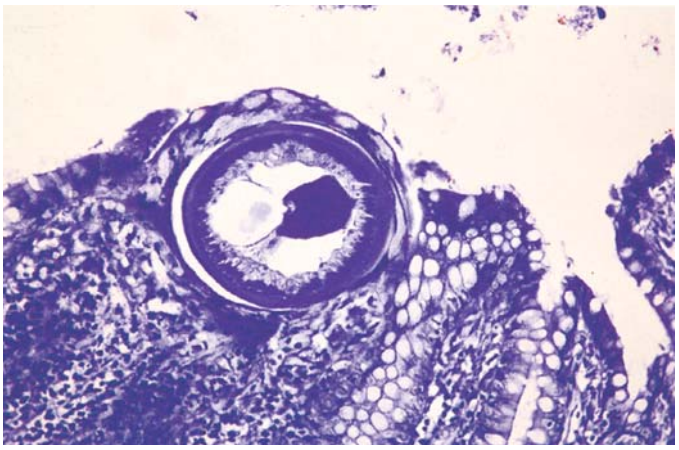

FIGURE 9-89. Trichuriasis. The anterior "whip" end of *Trichuris trichiura* is threaded into the mucosa of the colon.

CLINICAL FEATURES: Most *T. trichiura* infections are asymptomatic. Heavy infestation produces cramping abdominal pain, bloody diarrhea, weight loss and anemia. The diagnosis is made by finding the characteristic eggs in the stool. Mebendazole is effective therapy.

Hookworms Cause Intestinal Blood Loss and Anemia

Necator americanus and *Ancylostoma duodenale* ("hookworms") are intestinal nematodes that infect the human small bowel. They produce intestinal blood loss by lacerating the bowel mucosa, thereby resulting in anemia.

EPIDEMIOLOGY: Hookworm infections are found in moist, warm, temperate and tropical areas and cause serious public health problems worldwide. In fact, both *A. duodenale* ("Old World" hookworm) and *N. americanus* ("American" hookworm) prevail on most continents and have overlapping epidemiologic boundaries. More than 700 million people are infected with hookworms, including half a million people in the United States.

ETIOLOGIC FACTORS: Filariform larvae directly penetrate the human epidermis on contact and enter the venous circulation. They travel to the lungs and lodge in alveolar capillaries. After rupturing into the alveoli, larvae migrate up the trachea to the glottis and are then swallowed. They molt in the duodenum, attach to the mucosal wall with tooth-like buckle plates, clamp off a section of a villus and ingest it (Fig. 9-90). In extensive infestations, particularly with *A. duodenale*, blood loss can be sufficient to cause anemia. Hookworms are about 1 cm in length. They are grossly visible and are attached to the small bowel mucosa alongside punctate areas of hemorrhages. There is no attendant inflammation.

CLINICAL FEATURES: ***Although most people with hookworm infection have no symptoms, this parasite is the most important cause of chronic anemia worldwide.*** In people with heavy worm burdens (particularly women who consume a diet low in iron) and in populations with inadequate iron intake, chronic intestinal blood loss can produce severe iron-deficiency anemia. Skin penetration is sometimes associated with a pruritic eruption ("ground itch"), and the phase of larval migration through the lungs occasionally causes asthma-like symptoms.

Strongyloidiasis Is Disseminated in Immunocompromised Hosts

Strongyloidiasis is a small intestinal infection with a nematode, *Strongyloides stercoralis* ("threadworm"). ***Although most cases are asymptomatic, the infection can progress to lethal disseminated disease in immunocompromised persons.*** Infection is most frequent in areas with warm, moist climates and poor sanitation. Endemic pockets of strongyloidiasis still exist in the United States, particularly in the Appalachian region.

ETIOLOGIC FACTORS AND PATHOPHYSIOLOGY: *S. stercoralis* is the smallest of the intestinal nematodes, measuring 0.2–0.3 cm in length. Adult females are buried in the crypts of the duodenum or jejunum but produce no visible alterations. Microscopically, the coiled females, along with eggs and developing larvae, lie within the mucosa, usually with no associated inflammation (Fig. 9-91).

Parasitic females survive in the mucosa of the small intestine, where they lay eggs that hatch quickly and release rhabditiform larvae. These are passed in the feces, and in the soil become filariform, the infective stage that penetrates human skin. On entering the skin, *S. stercoralis* larvae pass in the bloodstream to the lungs and then to the small bowel, similarly to hookworms. The worms mature in the small bowel. Unlike other intestinal nematodes, *S. stercoralis* may reproduce in human hosts by a mechanism known as **autoinfection**. This occurs when rhabditiform larvae become infective (filariform) within a host's intestine and repenetrate either the intestinal wall or the perianal skin, thereby starting a new parasitic cycle within a single host.

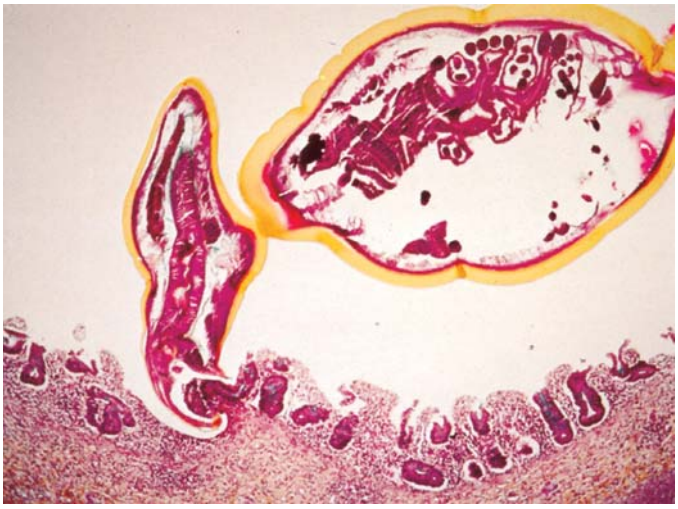

FIGURE 9-90. Ancylostomiasis. Section of the ileum shows two portions of a single adult worm, *Ancylostoma duodenale.* A plug of mucosa is in the buccal cavity of the hookworm.

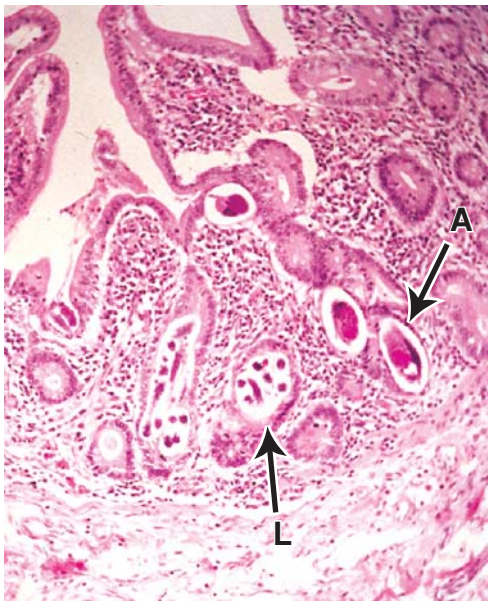

FIGURE 9-91. Strongyloidiasis. A section of jejunum shows adult worms, larvae and eggs of *Strongyloides stercoralis* in the mucosal crypts. The lamina propria is infiltrated with lymphocytes, plasma cells and eosinophils. The patient had a hyperinfected syndrome and presented with malabsorption.

CLINICAL FEATURES: Most infected people are asymptomatic, but moderate eosinophilia is common**. Disseminated strongyloidiasis** or **hyperinfection syndrome** occurs in patients with suppressed immunity, particularly those receiving corticosteroids. In such individuals, internal autoinfection is greatly increased, and extraordinary numbers of filariform larvae penetrate intestinal walls and disseminate to distant organs. In disseminated strongyloidiasis, the gut may show ulceration, edema and severe inflammation. Sepsis, usually with gram-negative organisms, and infection of parenchymal organs eventuate. Untreated, disseminated strongyloidiasis is fatal; even with prompt treatment with thiabendazole or ivermectin, only one third of patients survive.

Pinworm Infection (Enterobiasis) Leads to Perianal Itching

Enterobius vermicularis ("pinworm") is a worldwide intestinal nematode, most often encountered in temperate zones. Although people can be infected at any age, parasitism is most common among young children. More than 200 million people are estimated to be infected with *E. vermicularis* worldwide, including some 5 million school-age children in the United States.

The adult female worm resides in the cecum and appendix but migrates to the perianal and perineal skin to deposit eggs. The eggs stick to fingers, bed linens, towels and clothing and are readily transmitted from person to person. Ingested eggs hatch in the small bowel to yield larvae that mature into adult worms. Some infected people are asymptomatic, but most complain of perineal pruritus, caused by migrating worms depositing eggs. Several agents, including mebendazole, are effective against pinworms.

TISSUE NEMATODES

Trichinosis Is Myositis Acquired by Eating Pork

Trichinosis is produced by the roundworm *Trichinella spiralis.*

EPIDEMIOLOGY: Infection with *T. spiralis* occurs worldwide. Humans acquire trichinosis by eating inadequately cooked meat with encysted *T. spiralis* larvae. The larvae are found in the skeletal muscles of various carnivorous or omnivorous wild and domesticated animals, including pigs, rats, bears and walruses. Pork is the most common source of human trichinosis (Fig. 9-92).

Animals acquire trichinosis by feeding on the flesh of other infected animals. Infection is common among some wild animal populations and can be readily introduced into domesticated animals, such as pigs, when they feed on garbage or uncooked meat. Meat inspection programs and restriction of feeding practices have largely eliminated *T. spiralis* from domesticated pigs in many developed countries. Only about 100 cases of trichinosis are reported in the United States annually, but these represent only the most severely symptomatic cases, and infection is probably much more common.

ETIOLOGIC FACTORS: In the small bowel, *T. spiralis* larvae emerge from the ingested tissue cysts and burrow into the intestinal mucosa, where they develop into adult worms. The adults mate, and the female liberates larvae that invade the intestinal wall and enter the circulation. Production of larvae may continue for 1–4 months, until the worms are finally expelled from the intestine. The larvae can invade nearly any tissue but can survive only in striated skeletal muscle, where they encyst and remain viable for years. The resulting myositis is especially prominent in the diaphragm, extrinsic ocular muscles, tongue, intercostal muscles, gastrocnemius and deltoids. Sometimes the CNS or heart is also inflamed, causing meningoencephalitis or myocarditis.

PATHOLOGY: Skeletal muscle is the major site of tissue damage in trichinosis. When a larva infects a myocyte, the cell undergoes basophilic degeneration and swelling. Early myocyte infection elicits an intense inflammatory infiltrate rich in eosinophils and macrophages. Larvae grow to 10 times their initial size, fold on themselves and develop a capsule. With encapsulation, inflammation subsides. Several years later, the larvae die and the cysts calcify. The small bowel is grossly unremarkable but adult worms may be found on microscopic examination at the base of villi in heavy infestations, and may be associated with an inflammatory infiltrate.

CLINICAL FEATURES: Most human infections with *T. spiralis* involve small numbers of cysts and are asymptomatic. Symptomatic trichinosis is usually self-limited and patients recover in a few months. If large numbers of cysts are eaten, abdominal pain and diarrhea may result from small bowel invasion by the worms. Major symptoms, in the form of fever, weakness and severe pain and tenderness of affected muscles, usually develop several days later. **Eosinophilia may be extreme (over 50% of all leukocytes).** Involvement of extraocular muscles produces periorbital edema. Infection of the brain or myocardium can

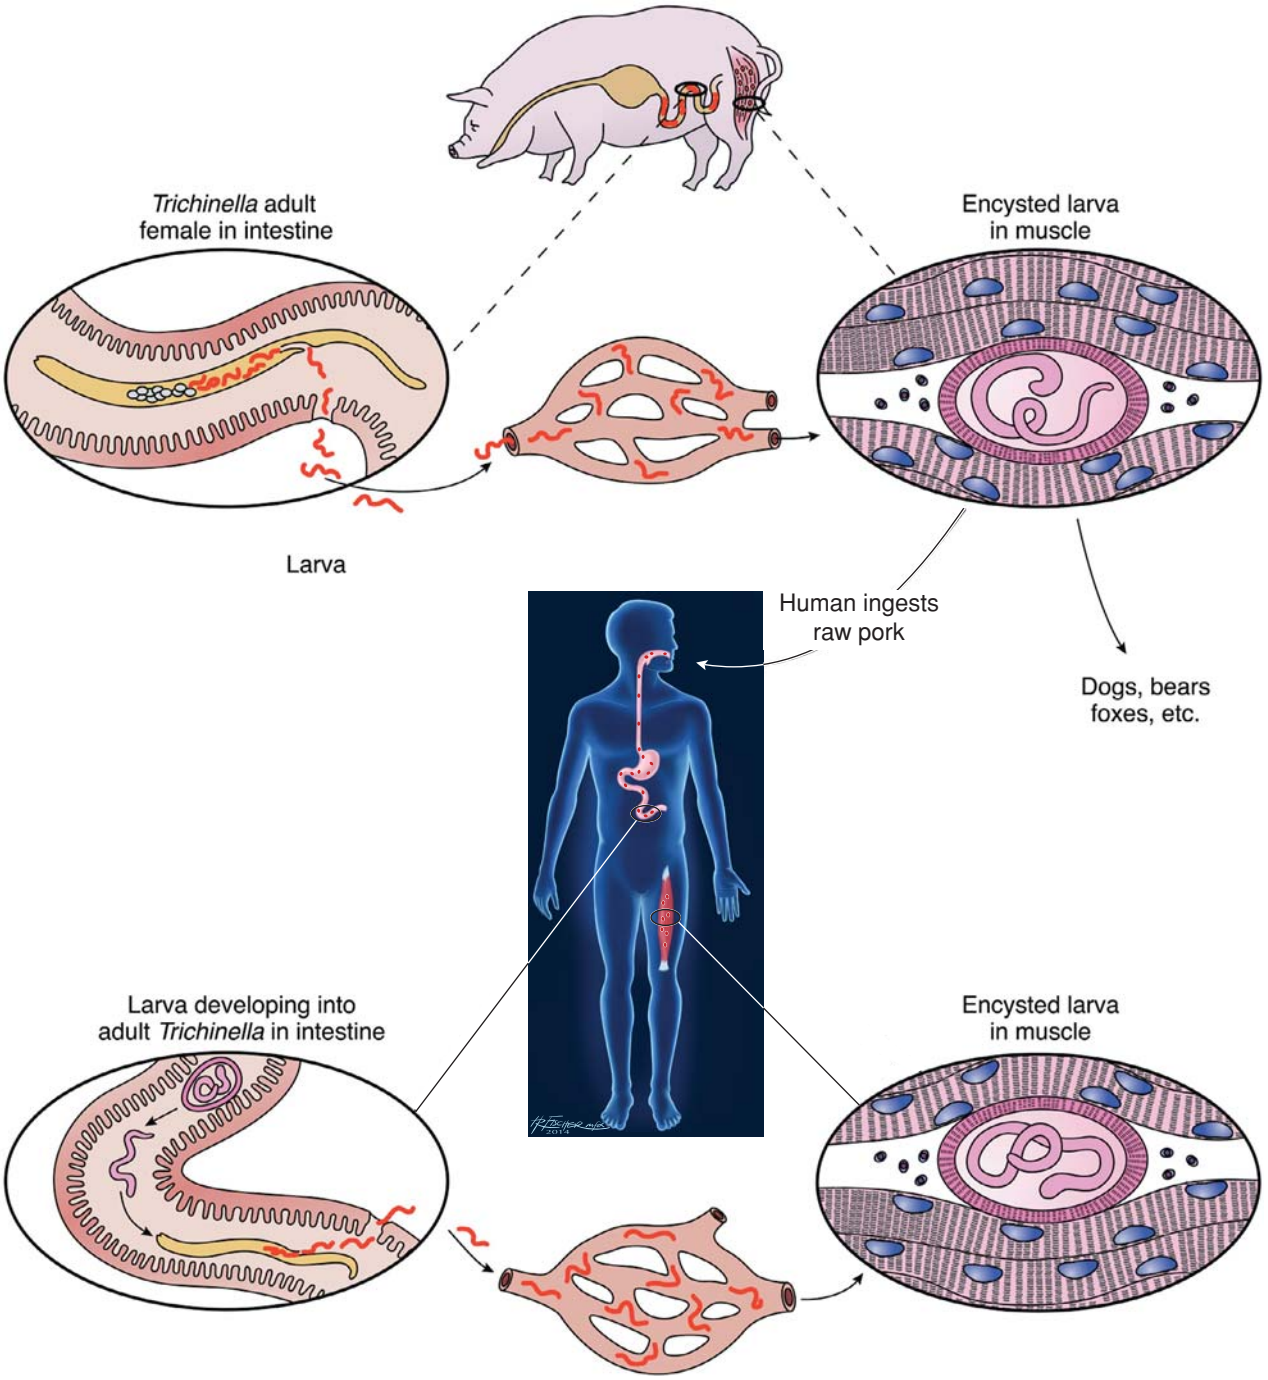

FIGURE 9-92. Trichinosis. After being ingested by the pig, cysts of *Trichinella* are digested in the gastrointestinal tract, liberating larvae that mature to adult worms. Female worms release larvae that penetrate the intestinal wall, enter the circulation and lodge in striated muscle, where they encyst. When humans ingest inadequately cooked pork, the cycle is repeated, resulting in the muscle disease characteristic of trichinosis.

be fatal. Severe trichinosis is treated with corticosteroids to attenuate the inflammation. Antihelminthic drugs are required to remove adult worms from the intestine.

Visceral Larva Migrans (Toxocariasis) Is Transmitted by Cats and Dogs

Toxocariasis is an infection of deep organs by helminthic larvae migrating in aberrant hosts.

ETIOLOGIC FACTORS: The infestation is a sporadic disease, mainly of young children, typically in the setting of overcrowded dwellings, living with dogs and cats. The most common causes of visceral larva migrans are *Toxocara* species, especially *T. canis* and *T. cati*. These roundworms live in the intestines of dogs and cats, and infection is transmitted to humans by ingestion of embryonated ova. Eggs hatch and larvae invade the intestinal wall. They are carried to the liver, from where a few

emerge to reach the systemic circulation and may be carried to any part of the body. In tissues, larvae die and elicit small granulomas, which eventually heal by scarring.

CLINICAL FEATURES: Many cases of visceral larva migrans are asymptomatic, but any infection can potentially cause severe disease. The typical symptomatic patient is a child with hypereosinophilia, pneumonitis and hypergammaglobulinemia. In these patients, ocular manifestations are common, and the chief complaint is often loss of vision in one eye. In fact, eyes with toxocaral endophthalmitis have been mistakenly enucleated for retinoblastoma. The infection is generally self-limited and symptoms disappear within a year. It is treated with diethylcarbamazine and thiabendazole.

Cutaneous Larva Migrans Is a Pruritic Eruption

Cutaneous larva migrans is caused by larval nematodes migrating through the skin, where they provoke severe inflammation that appears as serpiginous urticarial trails (Fig. 9-93). The names applied to cutaneous larva migrans are as varied as the organisms that cause it and include creeping eruptions, sand worm, plumber's itch, duck hunter's itch and epidermis linearis migrans. The more common larval nematodes include *Strongyloides stercoralis, Ancylostoma braziliensis* and *Necator americanus.* Dogs and cats infected with hookworms are the major source of the disease. Outbreaks of cutaneous larva migrans occur at subtropical and tropical beaches. Plumbers who crawl under houses and animal caretakers are frequently infected. Thiabendazole is the treatment of choice.

Dracunculiasis Features Long Adult Worms beneath the Skin

Dracunculiasis (guinea worm) is an infection of connective and subcutaneous tissues with the guinea worm, *Dracunculus medinensis.*

EPIDEMIOLOGY: Dracunculiasis is common in rural areas of sub-Saharan Africa, the Middle East, India and Pakistan, where it is estimated that 10 million people are infected. The disease is transmitted in drinking water contaminated with the intermediate host, a microscopic aquatic crustacean of the genus *Cyclops.*

FIGURE 9-93. Cutaneous larva migrans. The skin shows a creeping eruption with the characteristic serpiginous, raised lesion.

FIGURE 9-94. Dracunculiasis. A female guinea worm is seen emerging from the foot, which is swollen because of secondary bacterial infection.

ETIOLOGIC FACTORS AND PATHOLOGY: The adult female nematode resides in subcutaneous tissues and releases numerous larvae through an ulcerated blister. When the blister is immersed in water, larvae are ingested by the *Cyclops* crustaceans, which are in turn ingested by humans.

About a year after ingestion of infected crustaceans, systemic allergic symptoms appear, including a pruritic urticarial rash. A reddish papule, often around the ankles, develops and vesiculates. Beneath this sterile blister is the anterior end of the female worm. The blister bursts upon contact with water and the female worm, now measuring up to 120 cm and containing 3 million larvae, partially emerges (Fig. 9-94). The worm then spews myriad larvae into the water. Secondary infection of the blister, often with spreading cellulitis, is common. Dead worms provoke an intense inflammatory response, causing debilitation in many patients with dracunculosis. The worm is often extracted by local practitioners by progressively twisting it onto a small stick. Treatment also includes anthelminthic drugs.

TREMATODES (FLUKES)

Schistosomiasis Produces Diseases of the Liver and Bladder

Schistosomiasis (bilharziasis) is the most important human helminthic disease. Intense inflammatory and immune responses damage the liver, intestine or urinary bladder. Three species of schistosomes, *Schistosoma mansoni, Schistosoma haematobium* and *Schistosoma japonicum,* are the causative agents.

EPIDEMIOLOGY: ***Schistosomiasis causes greater morbidity and mortality than all other worm infections.*** It affects about 10% of the world's population and is second only to malaria as a cause of disabling disease. The three schistosomal pathogens affect distinct geographic regions, as dictated by the distribution of

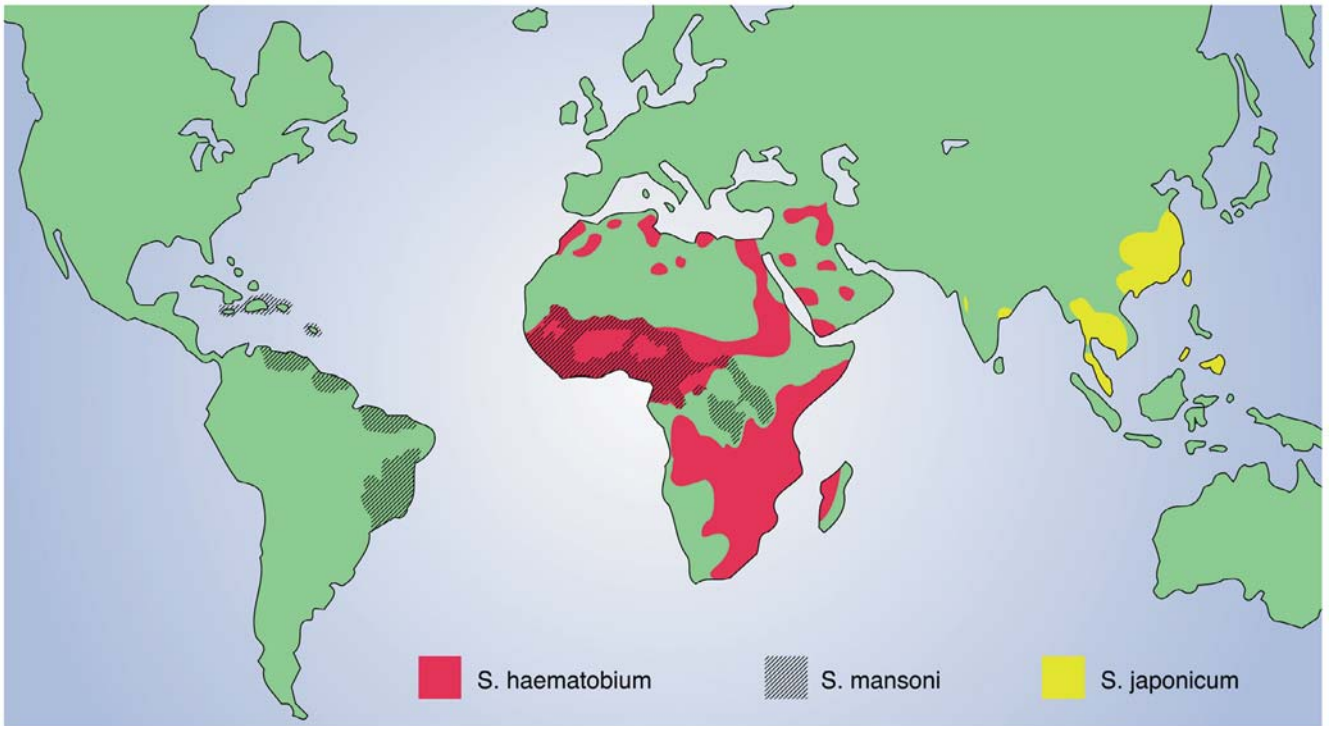

FIGURE 9-95. Distribution of schistosomiasis caused by *Schistosoma mansoni, Schistosoma haematobium* and *Schistosoma japonicum*.

their specific host snail species (Fig. 9-95). *S. mansoni* is found in much of tropical Africa, parts of southwest Asia, South America and the Caribbean islands. *S. haematobium* is endemic in large regions of tropical Africa and parts of the Middle East. *S. japonicum* occurs in parts of China, the Philippines, Southeast Asia and India.

ETIOLOGIC FACTORS: Schistosomes have complicated life cycles, alternating between asexual generations in their invertebrate host (snail) and sexual generations in the vertebrate host (Fig. 9-96). A schistosome egg hatches in fresh water, liberating a motile **miracidium** that penetrates a snail, where it develops into the final larval stage, the **cercaria**. Cercariae escape into the water and penetrate human skin, during which process they lose their forked tails and become "schistosomula." These migrate through tissues, penetrate blood vessels and migrate to the lungs and liver. In intestinal venules of the portal drainage, schistosomula mature, forming pairs of male and female worms. Female *S. mansoni* and *S. japonicum* deposit eggs in intestinal venules, whereas *S. haematobium* lays eggs in those of the urinary bladder. Embryos develop as the eggs pass through these tissues. The larvae are mature when eggs pass through the wall of the intestine or the bladder and are discharged in feces or urine. They hatch in fresh water, liberating miracidia and completing the life cycle.

PATHOLOGY: ***The basic lesion is a circumscribed granuloma or a cellular infiltrate of eosinophils and neutrophils around an egg.*** Adult schistosomes provoke no inflammation while alive in the veins. Granulomas that form about the eggs also obstruct microvascular blood flow and produce ischemic damage to adjacent tissue. The result is progressive scarring and dysfunction in affected organs.

Female worms deposit hundreds or thousands of eggs daily for 5–35 years. Most infected people harbor fewer than 10 adult females. However, if the worm burden is large, the granulomatous response to the enormous number of eggs poses significant problems. The site of involvement is determined by the tropism of the particular schistosome species.

- *S. mansoni* inhabits the branches of the inferior mesenteric vein, thereby affecting the distal colon and liver.
- *S. haematobium* winds its way to the veins serving the rectum, bladder and pelvic organs.
- *S. japonicum* deposits eggs predominantly in the branches of the superior mesenteric vein, thereby damaging the small bowel, ascending colon and liver.

Liver disease caused by *S. mansoni* or *S. japonicum* begins as periportal granulomatous inflammation (Fig. 9-97) and progresses to dense periportal fibrosis **(pipestem fibrosis)** (Fig. 9-98). In severe hepatic schistosomiasis, this causes obstruction of portal blood flow and portal hypertension. *S. mansoni* and *S. japonicum* also damage the intestine, where granulomatous responses produce inflammatory polyps and foci of mucosal and submucosal fibrosis.

In **urogenital schistosomiasis,** caused by *S. haematobium*, eggs are most numerous in the bladder, ureter and seminal vesicles, although they may also reach the lungs, colon and appendix. Eggs in the bladder and ureters provoke a granulomatous reaction, inflammatory protuberances and patches of mucosal and mural fibrosis. These may obstruct urine flow, and so cause secondary inflammatory damage to the bladder, ureters and kidneys. Bladder disease produced by *S. haematobium* may lead to **squamous cell carcinoma of the bladder**. In areas where *S. haematobium* is prevalent, this is the most common form of cancer.

The granulomas of schistosomiasis surround schistosome eggs. Eosinophils often predominate in early granulomas.

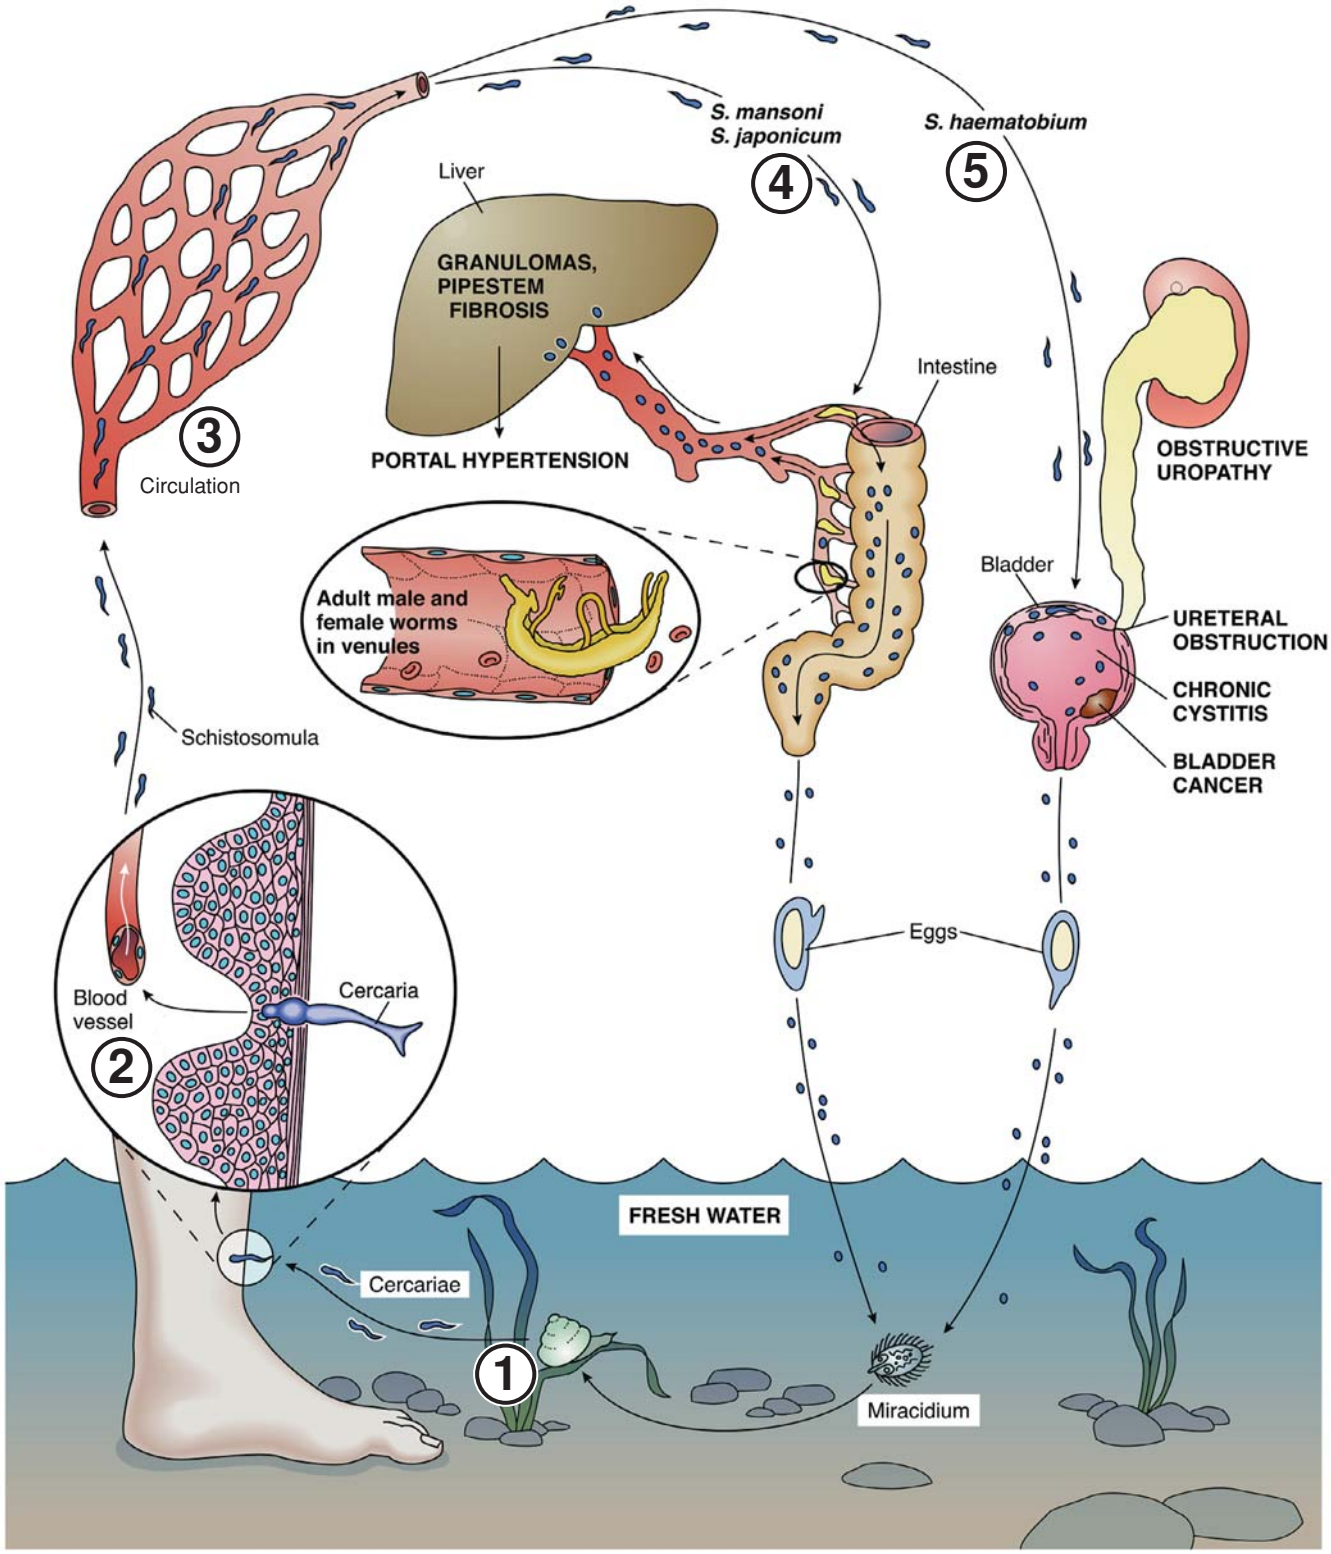

FIGURE 9-96. Life cycle of *Schistosoma* and clinical features of schistosomiasis. The schistosome egg hatches in water, liberates a miracidium that penetrates a snail and develops through two stages to a sporocyst to form the final larval stage, the cercaria. **(1)** The cercaria escapes from the snail into water, "swims" and penetrates the skin of a human host. **(2)** The cercaria loses its forked tail to become a schistosomulum, which migrates through tissues, penetrates a blood vessel and **(3)** is carried to the lung and later to the liver. In hepatic portal venules, the schistosomula become sexually mature and form pairs, each with a male and a female worm, the female worm lying in the gynecophoral canal of the male worm. The organism causes lesions in the liver, including granulomas, portal ("pipestem") fibrosis and portal hypertension. **(4)** The female worm deposits immature eggs in small venules of the intestine and rectum (*Schistosoma mansoni* and *Schistosoma japonicum*) or **(5)** of the urinary bladder (*Schistosoma haematobium*). The bladder infestation leads to obstructive uropathy, ureteral obstruction, chronic cystitis and bladder cancer. Embryos develop during passage of the eggs through tissues, and larvae are mature when eggs pass through the wall of the intestine or urinary bladder. Eggs hatch in water and liberate miracidia to complete the cycle.

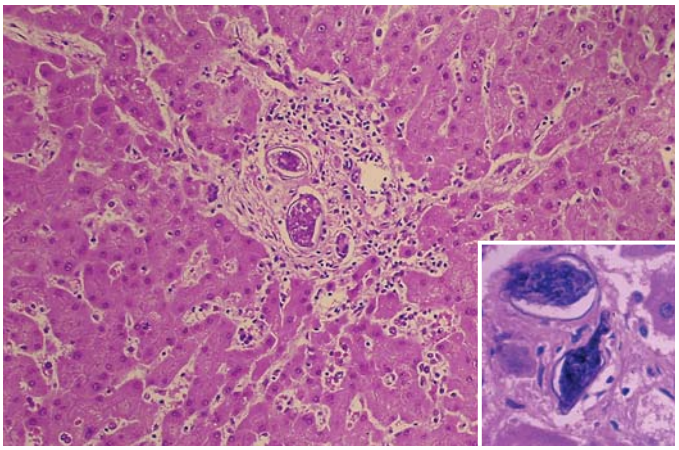

FIGURE 9-97. Hepatic schistosomiasis. A hepatic granuloma surrounds a degenerating egg of *Schistosoma mansoni.* A higher power of the organism is shown in the inset.

In older granulomas, epithelioid macrophages and giant cells are prominent and the oldest granulomas are densely fibrotic. The eggs of the various schistosomal species are identified on the basis of their size and shape.

CLINICAL FEATURES: Skin penetration by the schistosome larvae is sometimes associated with a self-limited, intensely pruritic rash. Most cases are dominated by the manifestations of chronic granulomatous tissue damage. Hepatic involvement is accompanied by portal hypertension, splenomegaly, ascites and bleeding esophageal varices. Intestinal disease is usually only minimally symptomatic, but some patients have abdominal pain and bloody stools. Schistosomiasis of the bladder is complicated by hematuria, recurrent urinary tract infections and sometimes progressive urinary obstruction, leading to renal failure. Identification of schistosome eggs in the urine or feces establishes the diagnosis. Schistosomes are effectively killed by systemic antihelminthic agents, but structural changes due to extensive scarring are irreversible.

Clonorchiasis Leads to Biliary Obstruction

Clonorchiasis is an infection of the hepatic biliary system by the Chinese liver fluke, *Clonorchis sinensis.* Although the fluke usually causes only mild symptoms, it is sometimes associated with bile duct stones, cholangitis and bile duct cancer.

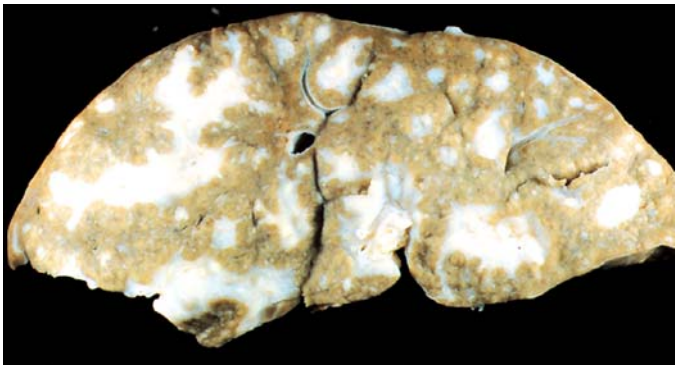

FIGURE 9-98. Hepatic schistosomiasis. Chronic infection of the liver with *Schistosoma japonicum* has led to the characteristic "pipestem" fibrosis.

EPIDEMIOLOGY: Clonorchiasis is endemic in east Asia, from Vietnam to Korea, where uncooked freshwater fish is common fare. In parts of these regions, over 50% of the adult population is infected. Human infection is acquired by ingesting inadequately cooked freshwater fish containing *C. sinensis* larvae.

Adult worms are flat and transparent, live in human bile ducts and pass eggs to the intestine and feces. After ingestion by a specific snail, the egg hatches into a miracidium. Cercariae escape from the snail and seek out certain fish, which they penetrate and in which they encyst. When humans eat the fish, cercariae emerge in the duodenum, enter the common bile duct through the ampulla of Vater and mature in the distal bile ducts to adult flukes.

PATHOPHYSIOLOGY AND PATHOLOGY: The presence of *Clonorchis* in the bile ducts elicits an inflammatory response that does not eliminate the worm, but causes dilation and fibrosis of the ducts. Sometimes the worms cause calculus formation in the hepatic bile ducts, leading to ductal obstruction. The adult *Clonorchis* persists in the ducts for decades, and long-standing infection is associated with an increased incidence of bile duct carcinoma **(cholangiocarcinoma)**.

In heavy *Clonorchis* infections, the liver may be up to three times normal size. Dilated bile ducts are seen through the capsule, and the cut surface is punctuated with thick-walled dilated bile ducts (Fig. 9-99). Flukes (up to 2.5 cm), sometimes in the thousands, can be expressed from the bile ducts. Microscopically, the epithelial duct lining is initially hyperplastic and then metaplastic. Surrounding stroma is fibrotic. Secondary bacterial infection is common and may be associated with suppurative cholangitis. Eggs deposited in the liver parenchyma elicit a fibrous and granulomatous reaction. Masses of eggs may lodge in the bile ducts and cause cholangitis. Pancreatic ducts may also be invaded, dilated and thickened; lined by metaplastic epithelium; and eventually surrounded by fibrosis.

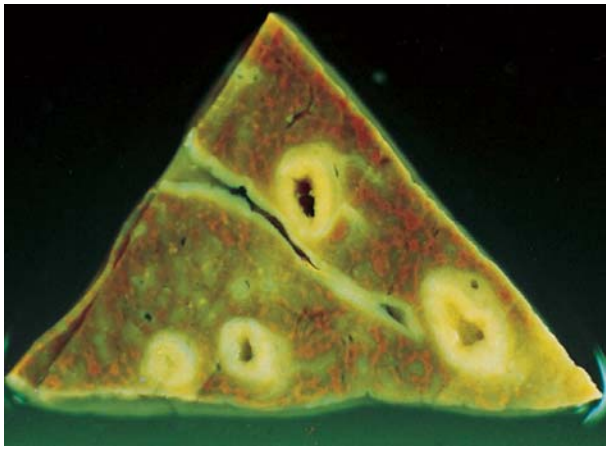

FIGURE 9-99. Clonorchiasis of the liver. The bile ducts are greatly thickened and dilated because of the presence of adult flukes (*Clonorchis sinensis*).

CLINICAL FEATURES: Migration of *C. sinensis* into the bile ducts causes transient fever and chills, but most infected persons are asymptomatic. Patients with clonorchiasis may die of a variety of complications, including biliary obstruction, bacterial cholangitis, pancreatitis and cholangiocarcinoma. The diagnosis is made by identifying eggs of *C. sinensis* in stools or duodenal aspirates. The infestation is treated effectively with systemic antihelminthic agents.

Paragonimiasis Is a Lung Disease

Paragonimiasis is a pulmonary infection by several species of the genus *Paragonimus,* the oriental lung fluke. The most common human pathogen is *Paragonimus westermani*, which is common in Asian countries (Korea, the Philippines, Taiwan and China), where uncooked, lightly salted or wine-soaked fresh crabs are delicacies. Use of raw crab juices as medicines or seasonings also has been associated with the infection.

CLINICAL FEATURES: Pulmonary paragonimiasis is frequently misdiagnosed as tuberculosis. It manifests as fever, malaise, night sweats, chest pain and cough. However, unlike tuberculosis, peripheral eosinophilia is common. The sputum is sometimes blood tinged and chest radiographs reveal transient diffuse pulmonary infiltrates. The prognosis in pulmonary paragonimiasis is good, but ectopic lesions of the brain may be fatal. Eggs in the sputum or stools provide the definitive diagnosis.

Fascioliasis Is a Biliary Disease Acquired from Sheep

Fascioliasis is an infection of the liver by the sheep liver fluke, *Fasciola hepatica.* Humans may acquire the infection wherever sheep are raised. People become infected by eating vegetation, such as watercress, that is contaminated with the cysts passed by sheep.

ETIOLOGIC FACTORS: After reaching the duodenum, cysts liberate metacercariae that pass into the peritoneal cavity, penetrate the liver and migrate through the hepatic parenchyma into the bile ducts. The larvae mature to adults and live in both the intrahepatic and extrahepatic bile ducts. Later, the adult flukes penetrate the wall of the bile ducts and wander back into the liver parenchyma, where they feed on liver cells and deposit their eggs.

PATHOLOGY AND CLINICAL FEATURES: Eggs of *F. hepatica* lead to hepatic abscesses and granulomas. The worms induce hyperplasia of bile duct epithelium, portal and periductal fibrosis, proliferation of bile ductules and varying degrees of biliary obstruction. Eosinophilia, vomiting and acute gastric pain are characteristic. Severe untreated infections may be fatal. The diagnosis is made by recovering eggs from the stools or biliary tract.

Fasciolopsiasis Is an Infestation of the Small Intestine

Fasciolopsiasis is caused by the giant intestinal fluke, *Fasciolopsis buski.* The disease is common in the Orient. Humans are infected by eating aquatic vegetables contaminated with encysted cercariae. The large worm (3 × 7 cm) attaches to the duodenal or jejunal wall, which may ulcerate, become infected and cause pain like that of a peptic ulcer. Acute symptoms may also be due to intestinal obstruction or by toxins released by large numbers of worms. The diagnosis is made by identifying *F. buski* eggs in the stool. Treatment is with systemic antihelminthic agents.

TABLE 9-11
TAPEWORM INFECTIONS

Species	Human Disease	Source of Human Infection
Taenia saginata	Adult tapeworm in intestine	Beef
Taenia solium	Adult tapeworm in intestine; cysticercosis	Pork; human feces
Diphyllobothrium latum	Adult tapeworm in intestine	Fish
Echinococcus granulosus	Hydatid cyst disease	Dog feces

CESTODES: INTESTINAL TAPEWORMS

Taenia saginata, Taenia solium and *Diphyllobothrium latum* are tapeworms that infect humans, growing to their adult forms within the intestine (Table 9-11). Presence of these adult worms rarely damages the human host.

EPIDEMIOLOGY: Intestinal tapeworm infections are acquired by eating inadequately cooked beef (*T. saginata*), pork (*T. solium*) or fish (*D. latum*) containing larvae. Tapeworm life cycles involve cystic larval stages in animals and worm stages in the human. The life cycles of beef and pork tapeworms require that the animals ingest material tainted with infected human feces. The cystic larval forms develop in the animals' muscles. Modern cattle and pig farming practices, plus meat inspection, have largely eliminated beef and pork tapeworms in industrialized countries, but infection remains common in the underdeveloped world. Fish tapeworm infection is prevalent in areas where raw, pickled or partly cooked freshwater fish are common fare. Tapeworm infections are usually asymptomatic, although it may be distressing when an infected person passes portions of the worm in the stool. The fish tapeworm (*D. latum*) takes up vitamin B_{12}, and a small number (<2%) of infected persons develop pernicious anemia (see Chapter 26).

Cysticercosis Is a Systemic Infection by the Larvae of the Pork Tapeworm

Adult *T. solium* is acquired by eating undercooked pork infected with cysticerci (measly pork).

PATHOPHYSIOLOGY: Pigs acquire cysticerci by ingesting eggs of *T. solium* in human feces. This cycle, although a public health concern, is essentially benign for both humans and pigs.

However, when humans accidentally ingest tapeworm eggs from human feces and become infected with cysticerci, the consequences may be catastrophic. The eggs release oncospheres, which penetrate the gut wall, enter the bloodstream, lodge in tissue, encyst and differentiate to cysticerci.

PATHOLOGY: The cysticercus is a spherical, milky white cyst, about 1 cm in diameter, containing fluid and an invaginated scolex (head of the worm) with birefringent hooklets. Cysts can remain viable for an indefinite period and provoke no inflammation; rather, as they grow, they compress adjacent tissues. Degenerating cysts are the ones usually responsible for symptoms. They attach to tissue and are densely inflamed with eosinophils, neutrophils, lymphocytes and plasma cells. Multiple cysticerci in the brain may impart a "Swiss cheese" appearance to the tissue (Fig. 9-100).

CLINICAL FEATURES: Cysticercosis of the brain manifests as headaches or seizures, and symptoms depend on the sites affected. Massive cerebral cysticercosis causes convulsions and death. Cysticerci in the retina blind the patient. In the heart, they may cause arrhythmias and sudden death. Depending on the site involved, cysticercosis is treated with surgery or antihelminthic therapy.

Echinococcosis Features Cysts of the Liver and Lungs

Echinococcosis (hydatid disease) is a zoonotic infection caused by larval cestodes of the genus *Echinococcus.* The most common offender is *Echinococcus granulosus,* which causes cystic hydatid disease. Rarely, *Echinococcus multilocularis* and *Echinococcus vogeli* infect humans.

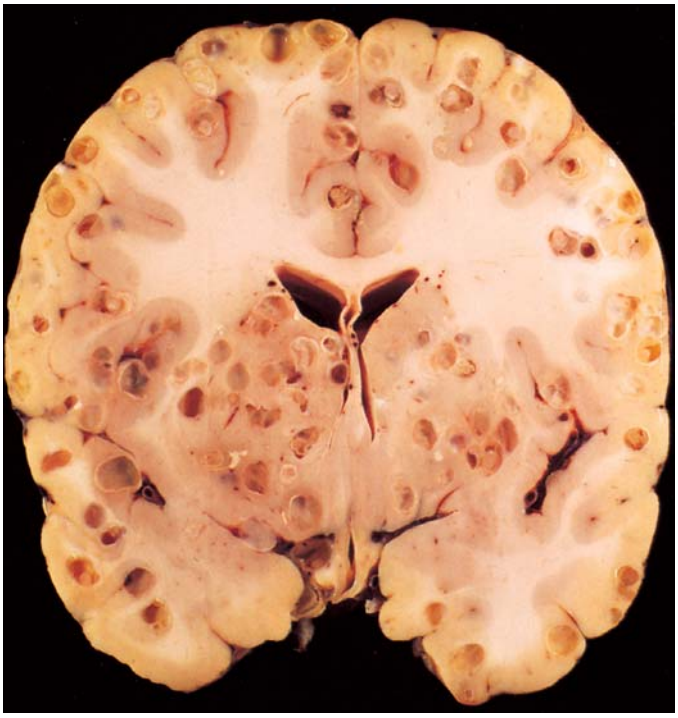

FIGURE 9-100. Cysticercosis. A cross-section of the brain from a patient infected with the larvae of *Taenia solium* shows many cysticerci in the gray matter, imparting a "Swiss cheese" appearance.

EPIDEMIOLOGY: Infestation with the tapeworm *E. granulosus* is endemic in sheep, goats and cattle, as well as their attendant dogs. Dogs contaminate their habitats (and their human keepers) with infectious eggs. Humans become infected when they inadvertently ingest the tapeworm eggs. The resulting hydatid disease is present worldwide among herding populations who live in close proximity to dogs and herd animals, especially Australia, New Zealand, Argentina, Greece and herding countries of Africa and the Middle East. In the United States, hydatid cyst disease is seen among immigrants and among the indigenous sheep-herding populations of the southwest.

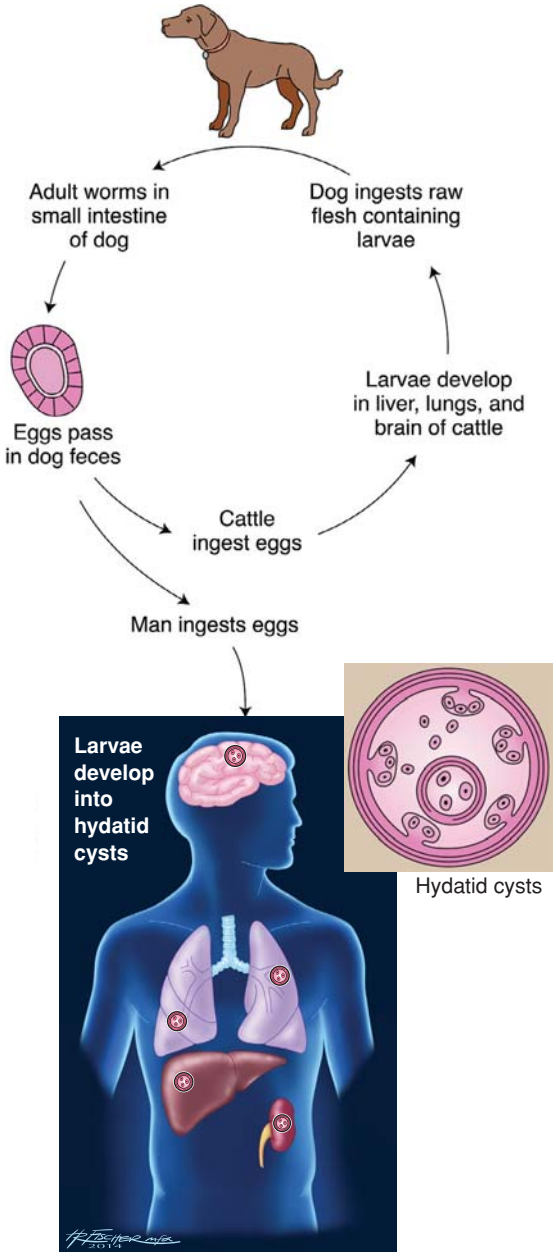
E. multilocularis causes alveolar hydatid disease in humans. Dogs and cats are domestic definitive hosts; the domestic intermediate host is the house mouse. Rare infections by *E. multilocularis* have been reported in Germany, Switzerland, China and the republics of the former Soviet Union.

Dogs are definitive hosts for *E. vogeli.* Humans may become accidental intermediate hosts for *E. vogeli* by ingesting eggs shed by domestic dogs. Polycystic hydatid disease caused by *E. vogeli* has been reported in Central and South America.

ETIOLOGIC FACTORS: The adult tapeworms (2–6 mm long) live in the small intestines of carnivorous hosts (e.g., wolves, foxes, etc.; Fig. 9-101). *E. granulosus* has a scolex with suckers and numerous hooklets to attach to intestinal mucosa. A short neck is followed by three segments (proglottids). The terminal gravid proglottid breaks off and releases eggs, which are eliminated in feces. Contaminated herbage is then eaten by herbivorous intermediate hosts, such as cattle and sheep. Humans are also infected by ingesting plant material contaminated by cestode eggs. Larvae released from the eggs penetrate the gut wall, enter the bloodstream and disseminate to deep organs, where they grow to form large cysts containing brood capsules and scolices. If the flesh of the herbivore is eaten by a carnivore, scolices develop into sexually mature worms in the latter, thereby completing the cycle.

PATHOLOGY AND CLINICAL FEATURES: The slowly growing hydatid cyst is found by chance or becomes obvious when its size and position interfere with normal functions. A hepatic cyst may manifest as a palpable right upper quadrant mass. Compression of intrahepatic bile ducts by the cyst leads to obstructive jaundice. Pulmonary cysts (Fig. 9-102) are often asymptomatic and discovered incidentally on a chest radiograph.

A major complication of cyst rupture is seeding of adjacent tissues with brood capsules and scolices. When these "seeds" germinate, they produce many additional cysts, each with the growth potential of the original cyst. Traumatic rupture of a hydatid cyst of the liver or other abdominal organ results in severe diffuse pain, resembling that of peritonitis. Rupture of a pulmonary cyst may cause pneumothorax and empyema. Moreover, when a hydatid cyst ruptures into a body cavity, release of cyst contents can cause fatal allergic



Adult worms in small intestine of dog

Larvae develop into hydatid cysts
Hydatid cysts

FIGURE 9-101. Life cycle of *Echinococcus granulosus* and cystic hydatid disease. The adult cestode lives in the small intestine of a dog (the definitive host). A gravid proglottid ruptures, releasing cestode eggs into the dog's feces. Cestode eggs are ingested by cattle or sheep (the intermediate hosts), hatch in the intestine and release oncospheres that penetrate the wall of the gut, enter the bloodstream, disseminate to various deep organs and grow to form hydatid cysts, containing brood capsules and scolices. When another dog ingests raw flesh from the cattle or sheep, the scolices are ingested and develop into mature worms in the dog's intestine to complete the cycle. A person who ingests cestode eggs in contaminated plant material becomes an accidental intermediate host. The larvae increase in size, but the parasite reaches a "dead end" without developing into an adult tapeworm. Hydatid cysts in humans occur predominantly in the liver but may also involve lung, kidney, brain and other organs.

reactions. Treatment of echinococcal cysts requires careful surgical removal: cysts must be sterilized with formalin before drainage or extirpation to prevent intraoperative anaphylactic shock.

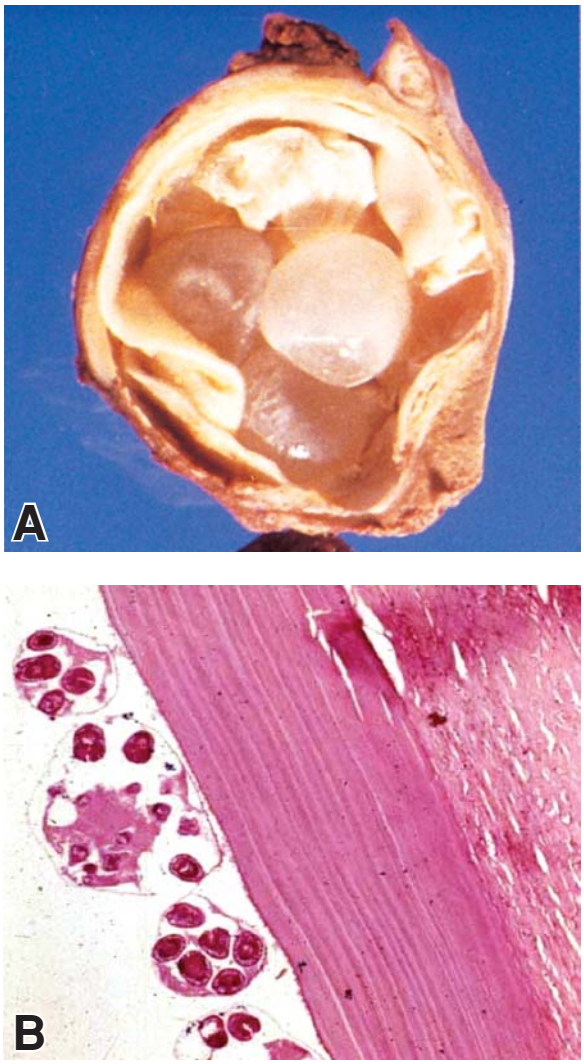

FIGURE 9-102. Echinococcal cyst. A. An echinococcal cyst showing daughter cysts was resected from the liver of a patient infected with *Echinococcus granulosus*. **B.** A photomicrograph of the cyst wall shows (*from right to left*) a laminated, nonnuclear layer, a nucleated germinal layer with brood capsules attached and numerous scolices in the cyst cavity.

Emerging and Reemerging Infections

Several decades ago, the antibiotic revolution, vaccinations and modern public health measures understandably led to the notion that the traditional global scourges of infectious diseases had been brought to bay. However, in the last few decades, we have witnessed the reemergence of microbial threats, including resurgent well-known agents (e.g., cholera, dengue fever, influenza, anthrax), as well as previously unknown pathogens. Antibiotic resistance among organisms, particularly communicable ones, such as tuberculosis, presents a new set of challenges.

Equally important has been the discovery of new pathogens belonging to all classes: viruses, bacteria, parasites and fungi. AIDS and hepatitis C were unknown in the 1970s and alone have caused many millions of deaths, despite

SARS = severe acute respiratory syndrome; SARS-CoV = severe acute respiratory syndrome-associated corona virus.

therapeutic advances. The resilience of influenza virus as a pathogen is underscored by the global influenza pandemics (e.g., H1N1, H5N1).

Table 9-12 is a partial list of newly recognized human infections. It should serve as a reminder that the equilibrium between humans and the pathogens that confront them is a dynamic one: continuous vigilance is obligatory, and complacency invites disaster. The reader is referred to other sources for those infections not discussed above.

AGENTS OF BIOWARFARE

Biological agents have been used as weapons since ancient times. The earliest documentation of use of biological weapons is described in Hittite texts from 1500 to 2000 BC, in which victims of plague were driven into enemy lands. The great Carthaginian warrior, Hannibal, first delivered bioweapons in 184 BC when, in preparing for a naval battle against King Eumenes of Pergamum, his army filled earthenware pots with serpents and hurled them to the decks of the Pergamene ships. In 1346, the Tatars lay siege to the Genoese-controlled seaport of Caffa (modern-day Feodosiya, Ukraine). During the siege, the Tatars were ravaged by plague. The Tatar leader catapulted his own dead soldiers, victims of the disease, into the besieged town to spread the epidemic, and forced the Genoese army to flee to Italy. Similar tactics were used at Karlstein in Bohemia in 1422 and by Russian troops in fighting Swedish forces in Reval in 1710.

Smallpox was used as a biological weapon by Francisco Pizarro in his conquest of South America in the 15th century when he presented variola-contaminated clothing as gifts. The English used a similar tactic in the French-Indian War in 1763, when Sir Jeffrey Amherst presented smallpox-laden blankets to the Delaware Indians loyal to the French. During the Revolutionary War, there were accusations of the potential use of smallpox as a weapon of terror from both sides. There was a plan by the British and their colonial allies to spread smallpox among the revolutionary American colonists (Fig. 9-103). In addition, a smallpox outbreak was spreading through the Northern Continental Army. By 1777, General George Washington ordered mandatory smallpox inoculation of all military recruits who had not had the disease.

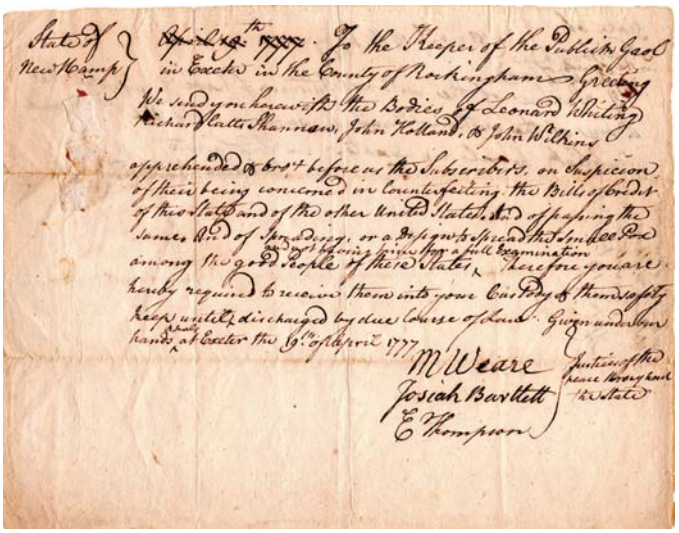

FIGURE 9-103. American Revolutionary War handwritten document describing the arrest and transport of three men "… *on Suspicion of their being concerned in Counterfeiting the Bills of Credit of this State and of the other United States, and of passing the same* ***And of Spreading or a Design to spread the Small Pox among the good People of these States…,"*** dated April 19, 1777 and signed by Josiah Bartlett, a famed New Hampshire physician and signer of the Declaration of Independence. This letter describes the threat of deliberate biowarfare by British sympathizers (Loyalists) in the War of Independence, and led to General George Washington's order for smallpox inoculation of the Continental Army.

TABLE 9-13
POTENTIAL BIOLOGICAL AGENTS OF WARFARE AND BIOTERROR

Bacteria
Bacillus anthracis
Brucella abortus, Brucella suis, Brucella melitensis
Listeria monocytogenes
Vibrio cholerae
Rickettsia prowazekii, Rickettsia rickettsii
Burkholderia mallei, Burkholderia pseudomallei
Coxiella burnetii, Francisella tularensis, Yersinia pestis
Clostridium botulinum and botulinum neurotoxin-producing species of *Clostridium*
Viruses
Arenaviruses—Lassa, Machupo, Sabia, Junin, Guanarito
Bunyaviruses—Rift Valley fever virus, Congo-Crimean hemorrhagic fever virus
Filoviruses—Ebolavirus, Marburg virus
Flaviviruses—Kyasanur Forest disease
Influenza
Kumlinge, Omsk hemorrhagic fever, Russian spring-summer encephalitis, tick-borne encephalitis
Poxviruses—smallpox (variola) and monkeypox
Togaviruses—eastern equine encephalitis virus
Venezuelan equine encephalitis virus
Biological Toxins
Botulinum, *Clostridium perfringens* ε toxin
Staphylococcal enterotoxin B
Shigatoxin
Conotoxins
Abrin
Ricin
Tetrodotoxin
Saxitoxin
T-2 toxin
Diacetoxyscirpenol
Microcystins
Aflatoxins
Satratoxin H
Palytoxin
Anatoxin A

Allegations of biowarfare surfaced in World War I. The Germans were reported to spread cholera to Italy, plague to St. Petersburg and anthrax and glanders to the United States and elsewhere. Although the League of Nations following the war found no definite proof of any of these actions by Germany, the psychological impact of the potential use of biological weaponry in inducing terror was firmly established in modern times. The United States established Camp Detrick in Maryland in 1942–1943 to investigate biological weapons.

The 20th century has unfortunately witnessed many national bioweapons programs, mainly covert, and a few notorious for human experimentation. During the Sino-Japanese War, 1937–1945, Japanese Army Unit 731 conducted bioweapons experimentation on many thousands of Chinese civilians, as well as Russian and American prisoners of war. The Japanese Army used bioweapons during military campaigns against Chinese soldiers and civilians. In 1940, Japanese planes bombed Ningbo with ceramic bombs containing plague-infested fleas. It is estimated that 400,000 Chinese died as a direct result of this use of biological weapons.

Accidental biological contamination has also occurred. In 1942, Gruinard Island off the northwest coast of Scotland was rendered uninhabitable for almost 50 years after British field trials of anthrax. In 1979, accidental release of anthrax from a Sverdlovsk (now Yekaterinburg) military facility, Compound 19, was perhaps the largest biological weapons accident known; sheep developed anthrax 200 kilometers from the release point and over 60 people died.

There is legitimate fear in modern times over the use of bioweapons as a terrorist tool. In September 1984, an outbreak of salmonella gastroenteritis was caused by followers of the Indian guru Bagwan Shree Rajneesh in Oregon, infecting over 700 people. In 1993, an apocalyptic Japanese cult group sprayed anthrax spores from a high-rise building in Tokyo, but no one was injured. The same cult group was found to be preparing vast quantities of *C. difficile* spores for terrorist use. In 1995, the American Type Culture Collection (ATCC), a nonprofit organization that supplies biological specimens to scientists, shipped a package containing three vials of *Y. pestis* to the home of a political extremist in Ohio. A search of his home revealed a variety of explosive devices, detonating fuses and triggers. Most recently, dried anthrax was mailed in letters through the U.S. postal system, causing five deaths.

Only a few biological agents have been considered or proven to be effective as weapons of biowarfare or bioterrorism (Table 9-13). Key factors that make an infectious agent suitable for large-scale biowarfare include (1) ease of large-scale production; (2) ability to cause death or incapacity of humans at doses that are deliverable; (3) appropriate particle size as an aerosol; (4) ease of dissemination; (5) stability during storage, in the environment or during placement into a delivery system; and (6) susceptibility of intended victims, but nonsusceptibility of friendly forces. Some biological weapons are potentially extremely lethal: 1 gram of purified botulinum toxin could kill 10 million people.

BIOLOGICAL AGING

Questions related to aging and death have obsessed humanity since the dawn of recorded history. For example, after the debacle in the Garden of Eden, Adam and Eve were cursed with (among other problems) the certainty of mortality, implying predestined aging. ***Aging*** *can be defined as a process characterized by progressive dysfunction, frailty and increasing mortality.* Biological aging is distinct from disease, in that the latter represents an abnormal and unpredictable pathologic condition, whereas aging is both universal and inevitable. Yet, aging and disease are intimately related; aging represents a key risk factor—and in many cases the dominant risk factor—for many of the afflictions described elsewhere in this volume.

The insidious effects of aging can be detected in otherwise healthy persons. For example, in many sports, an athlete in his or her 30s is considered "old." Even in the absence of specific diseases or vascular abnormalities, beginning in the fourth decade of life, there is a progressive decline in many physiologic functions, including such measurable parameters as muscular strength, cardiac reserve, nerve conduction time, pulmonary vital capacity, glomerular filtration and vascular elasticity (Fig. 10-1). This functional deterioration is accompanied by structural changes. Lean body mass decreases and the proportion of fat rises. Connective tissue matrix constituents are increasingly cross-linked. Lipofuscin ("aging") pigment accumulates in organs such as the brain, heart and liver. At the cellular level, the challenges imposed by aging on postmitotic cells (e.g., neurons and cardiomyocytes) are likely quite different than those faced by rapidly dividing cells, such as those of the gut or skin.

Life Span Is Subject to Environmental and Genetic Influences

Considerable evidence shows that aging is subject to strong genetic and environmental influences. For example, it is now possible to achieve dramatic life span extension (up to 65%) in rodent models through single-gene mutations in specific signaling pathways, or even by administering certain small molecules. Reduced food intake without malnutrition (dietary restriction [DR]) promotes longevity in many species, from budding yeast to rodents and perhaps even nonhuman primates.

Those who live in advanced industrialized societies already benefit from a greatly increased life span, relative to our forebears. It is estimated that a typical age at death of Neolithic humans was 20–25 years, and the average life span today in some underdeveloped regions is often barely 10 years more. By contrast, female life expectancy at birth in industrialized countries over the past 160 years has risen

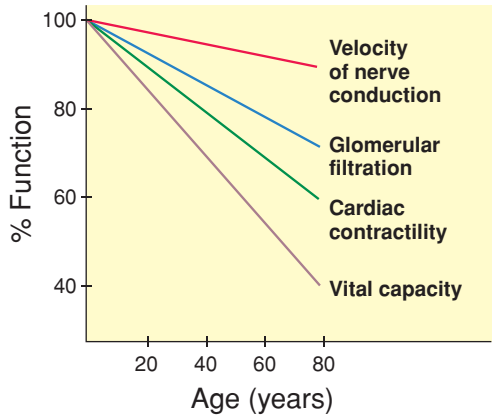

FIGURE 10-1. Decrease in human physiologic capacities as a function of age.

linearly by nearly 3 months a year, from about 45 years in the mid-19th century to nearly 85 years in the present day (women live 5–6 years longer than men, on average). This dramatic increase in life span stems mostly from reduced child mortality and improved public health measures, as well as advances in medical care. If current trends hold, life expectancy at birth in developed countries may reach 100 years by the mid-21st century. The **maximum** documented life span for any human is 122 years, and very few people live to be significantly older than 100.

Health Span

Health span is the *period of life spent free from major disease.* Remarkably, the prolongevity interventions described below not only extend life span but also delay or prevent many common diseases. For example, mice on a DR diet remain healthy into late old age, sometimes showing no evidence of clinically significant pathology at necropsy. By contrast, animals allowed to eat as much as they want typically show a diverse spectrum of advanced pathologies.

An Evolutionary Perspective on Aging

Why do we age at all? Once development has ceased, why do we not remain in good health and young perpetually? The notion that aging is programmed is an intuitively appealing explanation. That is to say, older individuals die to "make room" and free up resources for the next generation. However, from the standpoint of evolutionary biology, there are major conceptual problems with the notion of programmed aging. Among these is the issue of "cheating"—that is, if a gene existed whose sole purpose was to cause those possessing it to age and die, lucky individuals in whom that gene had been inactivated by chance would experience a selective breeding advantage and eventually take over the population. By similar reasoning, mutations that speed aging would confer selective disadvantages and so would not be maintained during evolution.

So if aging is not a strictly programmed process, akin to development, why does it occur? Evolutionary biology offers a conceptual answer to this question, if not a biological mechanism. We observe aging of organisms in the laboratory, or in other protected settings such as zoos. In this context, the maximal life span of animals in the wild is no different from the same animals in the zoo (Fig. 10-2).

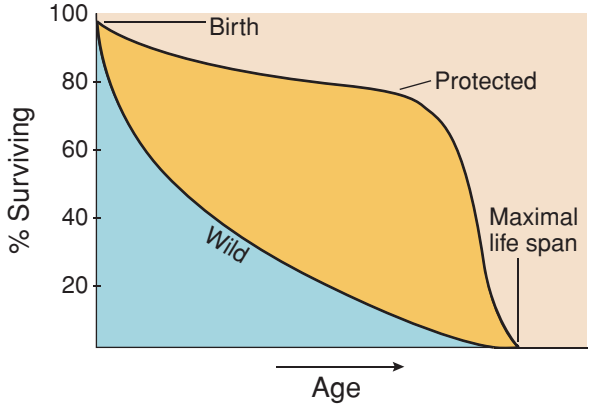

FIGURE 10-2. Life span of animals in their natural environment compared with that in a protected habitat. Note that both curves reach the same maximal life span.

In humans, aging is most evident in industrialized societies, where most people escape the ravages of infant mortality, infectious disease, trauma, starvation and other causes of early death. However, these sorts of protected environments differ greatly from those that occurred over the course of evolution. Most organisms evolved under conditions in which predation, infectious disease, competition for resources and environmental exposure eliminated most of the population early in life, independently of any effects of aging. For organisms evolving under such strong pressures, there was no evolutionary selective advantage in longevity, as most people died early from non-age-related causes. This idea generates several predictions that are borne out experimentally. For example, evolutionary biology predicts that species that evolve in relatively protected environments will inherently live longer than those evolving in less forgiving circumstances. In fact, this is the case. Birds, bats and flying squirrels, all of which can fly to escape from potential predators, are far longer lived than are mice. Other rodents that have evolved inherent protection against would-be predators (e.g., porcupines) or that live in safe environments underground (the naked mole rat) also live longer than their less fortunate exposed kin.

Antagonistic Pleiotropy

Evolutionary biology postulates **antagonistic pleiotropy,** that is, that *genes with deleterious effects at older ages may nevertheless be favorably selected if they confer some advantage early in life.* Thus, genes that improve reproductive efficiency, running speed or pathogen resistance in young adults would be greatly favored, even if they were associated with increases in the risks of cancer, neurodegeneration or other pathologies of old age.

Diverse Systems Exist to Study the Biology of Aging

Maximal life spans range from a few hours for adult forms of some insects, to a few weeks for the nematode *Caenorhabditis elegans* and fruitfly *Drosophila melanogaster,* to many decades for humans and other large mammals. At the upper end of longevity, there are clams that can live for centuries. A few species, such as hydra and lobster, may be entirely immune to aging. Key pathways that modulate longevity in invertebrates function similarly in rodents, and so potentially operate in the same way in humans.

Short-Lived Organisms and Mechanistic Insights into Aging

Model organisms have helped elucidate aging biology (Fig. 10-3). Brewer's yeast (*Saccharomyces cerevisiae*) reproduces by budding, producing a larger mother cell and a smaller daughter cell. Individual yeast cells can bud only a finite number of times before ceasing to divide, a point known as *senescence.* Several yeast genes (e.g., ***mTOR*** [mammalian target of rapamycin] and ***SIR2***) influence this process and also play key roles in modulating longevity in mammals. The roundworm (*C. elegans*) and the fruitfly (*Drosophila*) are more complex organisms that possess tissue types seen in higher organisms, such as skeletal muscle and a nervous system. As they age, they show degenerative effects like those in higher organisms, including decreased movement and lipofuscin accumulation.

Lifespan	Days	Weeks	Weeks	~ 3 Years	~ 80 Years
Genetically tractable	Yes	Yes	Yes	Yes	No

FIGURE 10-3. Model organisms commonly used in aging research.

Among mammals, the laboratory mouse (*Mus musculus*) is by far the most common system used in life span studies. Aged mice show many of the same pathologies as older humans. Thus, their small size, rapid generation time of roughly 12 weeks, and short life span of 2–3 years, make mice the prime system for studying mammalian aging. The ease with which mouse strains with specific genomic alterations can be produced has facilitated dissection of mechanisms of mammalian aging. Many diverse pathologies of old age in humans are also manifest in aged mice.

Scaling

Conserved aging phenotypes show a phenomenon called **scaling**—that is, they manifest at proportionately the same point in the lifespan, irrespective of absolute chronological time. Thus, cancer incidence increases at roughly the midpoint of life span in both mice and humans. However, in mice, this phenomenon occurs at 1–1½ years, whereas in humans, it occurs in the 5th decade. Although the biological basis of scaling is not well understood, it implies that interventions that slow the aging rate in humans would probably also delay the onset of age-associated disease and dysfunction.

CELLULAR SENESCENCE AND ORGANISMAL AGING

When human fibroblasts are passaged serially in culture, they do not replicate forever. Instead (like yeast), after many passages, they enter a nondividing state called **replicative senescence**. During this time, they remain postmitotic but are viable for an extended period. Senescent cells are characterized by (1) an enlarged, flattened appearance; (2) absence of molecular markers of proliferation; (3) persistent foci of unrepaired DNA damage; and (4) expression of senescence-associated β-galactosidase and $p16^{Ink4a}$ protein.

Telomere Shortening Promotes Replicative Senescence

In human cells, replicative senescence is largely due to attrition of **telomeres,** which are a series of short repetitive nucleotide sequences (TTAGGG in vertebrates) at the 3′ ends of chromosomes (see Chapters 1 and 5). DNA polymerase, the enzyme that replicates DNA, begins at the 5′ and works toward the 3′ end. It cannot copy linear chromosomes all the way to their distal ends, so telomeres tend to shorten with each cell division. Telomeres protect the genes that are near chromosomal termini from being lost with repeated cell divisions. Certain crucial cell types, such as stem cell populations, express an enzyme, **telomerase,** that restores sequences lost during replication and thus stabilizes the length of their telomeres. By contrast, most human somatic cells, such as fibroblasts, do not express significant levels of telomerase. Consequently, their telomeres shorten with each cell division, thus representing a "mitotic clock" that counts DNA replication events. Some types of cellular injury, such as oxidative stress, can directly damage telomeres, independent of replication.

Telomeres are normally protected by a protein complex termed **shelterin**. When telomeres shorten beyond a critical point, shelterin is released and telomeres are exposed, triggering a DNA damage response that can cause irreversible cell cycle arrest or apoptosis (Fig. 10-4). Telomere attrition can also lead to end-to-end chromosomal fusions and other types of genomic instability via breakage–fusion–bridge cycles (see Chapter 5). Reintroduction of telomerase into human fibroblasts enables them to bypass senescence, showing that telomere attrition is limiting for their growth in culture.

In addition to telomere shortening, other types of cellular injury also induce cellular senescence. These include many

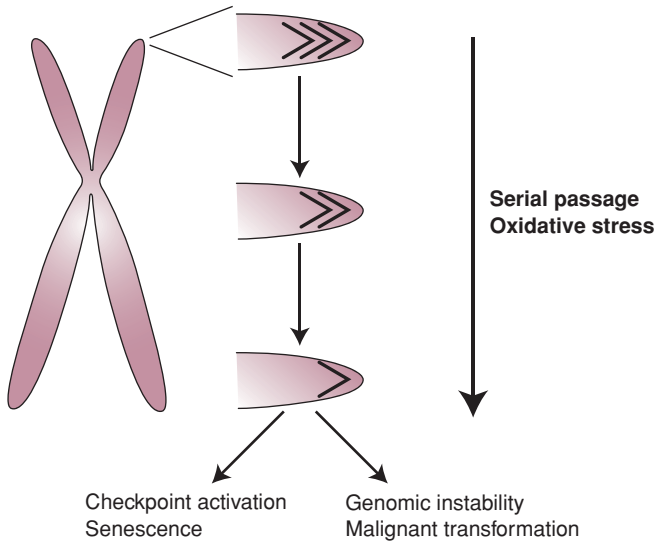

FIGURE 10-4. Deleterious consequences of telomere shortening in mammalian cells.

DNA-damaging agents, such as oxidative stress, excessive mitogenic stimulation like that associated with activated oncogenes (see Chapter 5), and chromatin disruption.

Senescence-Associated Secretory Phenotype

The link between cellular senescence and organismal aging is controversial and complex. There is solid evidence that senescence prevents replication of cells with potentially oncogenic mutations (oncogene-induced senescence; see Chapter 5), thereby helping protect from tumors. Senescent cells also secrete proinflammatory cytokines, proteases and other factors (the **senescence-associated secretory phenotype,** or **SASP**). Via SASP, senescent cells might potentially contribute to age-related pathologies, such as atherosclerosis, epidermal thinning, immune dysfunction and degenerative joint disease. Furthermore, it is possible that senescent cells create a microenvironment that promotes the growth of malignant cells, thus contributing to the increased rate of cancer observed in older people. Experimentally eliminating senescent cells can mitigate some effects of aging in mouse models.

Precise Molecular Mechanisms of Aging Remain Obscure

Many factors probably contribute to the degenerative manifestations of aging. Accumulated unrepaired macromolecular damage—to DNA, chromatin, proteins and lipids—eventually may induce cellular dysfunction, manifesting at the organismal level as aging. To counter the effects of such damage, cells have evolved elaborate, well-regulated mechanisms to repair many types of macromolecular lesions. Alternatively, cells with certain types of severe damage, such as to mitochondria and nuclear DNA, can also be removed by apoptosis (see Chapter 1). This damage-based model of aging predicts that mutant organisms with increased longevity should also show more robust resistance to damage-inducing stressors. This is in fact typically—though not always—observed. The model also predicts that cellular repair systems should be intimately related, genetically speaking, to prolongevity pathways. This is also observed empirically, as outlined in greater detail below.

Reactive Oxygen Species Contribute to Age-Associated Disease

A long-standing theory holds that macromolecular damage in the context of aging is caused by **reactive oxygen species (ROS),** generated mostly endogenously in mitochondria (see Chapter 1). Important ROS include superoxide, peroxide and nitric oxide. ROS can interact with and damage all cellular macromolecules, causing a diverse spectrum of lesions in nucleic acids, modifying and inactivating proteins and damaging lipids. Most ROS generation occurs in mitochondria, owing to "leakage" at complexes I and III of the electron transport chain. It is estimated that a single cell undergoes some 100,000 attacks on DNA per day by ROS, and that at any time 10% of protein molecules in the cell are modified by oxidative carbonyl adducts.

Antioxidants

To counter the potentially toxic consequences of ROS, cells possess a network of antioxidant defenses that detoxify ROS and repair ROS-related damage. These pathways include superoxide dismutase, catalase, glutathione peroxidase, thioredoxins, thioredoxin reductase and many others. An excess of ROS relative to cellular defenses is called **oxidative stress**. It is noteworthy that ROS play important physiologic roles, in addition to being a potential source of macromolecular damage. For example, ROS modulate kinase signaling, defend against microbial pathogens and regulate vascular tone. Thus, it is neither possible nor desirable to eliminate cellular ROS entirely. Yet most long-lived invertebrate mutants have enhanced antioxidant defenses. DR induces increased antioxidant defenses, concomitant with diminished ROS levels and reduced macromolecular oxidation products.

However, it is unlikely that ROS are the single major driver of age-associated damage. In many invertebrate models, *elevated* ROS levels are associated with *increased* longevity. Enhancement of ROS defenses in mouse models through genetic overexpression of antioxidant enzymes generally does not extend longevity. Studies in hundreds of thousands of people given supraphysiologic doses of antioxidant dietary supplements have not found any significant benefit on life span, disease development or health; indeed, adding certain antioxidants is associated with *increased* mortality.

A corollary to the free radical theory of aging, the **rate of living theory** aims to explain why larger species in general live longer and show a reduced metabolic rate than smaller ones. One current form of this idea postulates that each gram of tissue from any organism (shrew, human, elephant) can metabolize the same amount of total energy over the life span before losing function, presumably owing to accumulated ROS-related injury. Several observations have cast doubt on this theory: (1) some small creatures with high metabolic rates nevertheless live for a relatively long time (e.g., birds and bats); (2) *within* species, larger individuals tend to have a shorter life span than smaller ones (e.g., larger breeds of dogs are shorter lived than smaller ones); and (3) DR does not reduce overall metabolic rate but (counterintuitively) may actually *increase* it.

The Role of Telomere Maintenance in Longevity

The role of telomere erosion in aging is attributed to progressive cellular dysfunction and senescence, eventually leading to the overall phenomenon of organismal aging. However, laboratory mice have very long telomeres, and yet these animals age, so that (at least in mice) telomere attrition may not be needed for aging to occur. In humans, rare mutations in telomerase or shelterin components lead to shortened telomeres and aplastic anemia, skin and nail defects, infertility, pulmonary fibrosis and cancer. Even in people without such defects, shortened telomeres are also found in association with human diseases such as cirrhosis, atherosclerosis and ulcerative colitis, consistent with extended proliferative histories or high levels of oxidative stress in these conditions. Short telomere length in peripheral blood cells predicts susceptibility to coronary artery disease, neoplasia and overall mortality in older people. These findings suggest that eroded telomeres can indeed contribute to age-associated pathologies, if not necessarily to aging per se.

Genetically engineered mouse strains that cannot maintain telomeres show reduced longevity, as well as defects in tissues that require rapid cell proliferation and stem and

progenitor cell activity, principally bone marrow, skin, gut and testes. Altogether, these studies demonstrate that telomere maintenance contributes to cellular and organismal homeostasis, but that its role in human longevity is less clear.

Maintenance of Proteostasis May Contribute to Longevity

Increasing evidence points to maintenance of cellular protein homeostasis **(proteostasis)** as an important factor in longevity (see Chapter 1). All cellular proteins, collectively called the **proteome,** are subject to diverse challenges. Translational errors, oxidative damage, mutations and polymorphisms can lead to protein misfolding and aggregation, which can cause cellular injury. All of these mechanisms can be regulated by interventions that also promote longevity, thus suggesting an important relationship between proteostasis and life span. Moreover, older cells and organisms accumulate oxidatively damaged and cross-linked proteins. Studies of invertebrates suggest that collapse of proteostasis is an early, and perhaps causative, event in organismal aging. One proteostatic mechanism that is closely linked to aging is autophagy, a regulated process by which cells degrade damaged proteins, and even whole organelles, in lysosomes (see Chapter 1). In model organisms, autophagy is required for longevity induced by many environmental or genetic manipulations. Autophagic function declines with age in mammals and lower organisms, and restoration of autophagy in older mice can improve tissue function.

Mitochondrial Function Declines with Aging

With age, mitochondria produce less adenosine triphosphate (ATP) and generate more ROS. It is thought that this mitochondrial energetic decline contributes to age-associated conditions such as sarcopenia, insulin resistance and type 2 diabetes, cardiac dysfunction, neurodegeneration and so forth. The molecular basis for mitochondrial functional decline during aging is unclear; damage to the mitochondrial genome may play a role. Since mitochondrial DNA lies in close proximity to components of the respiratory chain, the mitochondrial genome is highly susceptible to ROS-induced DNA damage. However, the role of mitochondria in longevity is not that straightforward. In *C. elegans, Drosophila* and even rodents, certain mitochondrial defects present during development actually *extend* longevity. Mitochondria thus help determine organismal longevity, but via complex and uncertain mechanisms.

Stem Cell Function Declines with Aging

Adult stem cells in mammalian tissues are critical for proper organ function and for repair following injury. These stem cells may lose functionality with age, thus impairing tissue homeostasis and contributing to degenerative disease. This notion has been best evaluated in the context of hematopoietic stem cells (HSCs), which give rise to all mature cell types in the blood. Aging is not characterized by fewer HSCs, but it is associated with impaired HSC function. Clinically, it has long been known that HSC transplants from young donors are more likely to be successful than those from older donors. In aged people, HSCs increasingly follow myeloid, rather than lymphoid, differentiation. There are progressive defects in HSC mobilization and homing, and aged HSCs also accumulate unrepaired ROS-induced DNA damage.

As mentioned previously expression of the tumor suppressor $p16^{Ink4a}$ is induced in senescent cells. More generally, in aging tissues, $p16^{Ink4a}$ and the related gene $p19^{ARF}$ (the murine equivalent of human $p14^{ARF}$) are normally inhibited by Bmi-1, a protein required for renewal of all adult stem cell types. In aged mice, $p16^{Ink4a}$ limits proliferative capacity in different types of stem cells. Increased $p16^{Ink4a}$ in aging stem cells may be a defense against malignant transformation of these cells, at the expense of stem cell function, tissue repair and overall organismal homeostasis. Interestingly, genetic studies in humans have linked polymorphisms near the $p16^{Ink4a}$ locus to diverse age-associated pathologies (e.g., coronary atherosclerosis, type 2 diabetes and frailty). These data suggest that $p16^{Ink4a}$ or a closely linked gene product can regulate aging in humans in important ways, via effects on stem cells or other cell types.

In recent years, it has become possible to convert somatic cells into induced pluripotent stem cells (iPSCs). Remarkably, this process reverses many effects of aging, including senescence, telomere erosion and mitochondrial dysfunction. Although the mechanisms underlying these effects are poorly understood, it may eventually be possible to harness these processes to ameliorate the ravages of aging in differentiated cells.

Alternatives to the ROS-Centric Model of Aging

The free radical theory of aging dominated thinking in aging biology for decades, but aging is unlikely to have a single "root cause." As noted above, genetic data support the concept that **protein quality control** mechanisms are key to organismal longevity and health; hence, unrepaired damage to proteins may be a major cause of age-associated decline. As well, diverse chemicals **(xenobiotics)** in food and the environment may cause diverse types of macromolecular damage, thus contributing to the effects of aging. Xenobiotics are detoxified and chemically processed for eventual excretion by **xenobiotic metabolizing enzymes**. Intracellular signaling itself, in particular via mTOR kinase, may be central to organismal aging. Signaling through mTOR and its downstream targets significantly limits life span (see below). The mTOR-centric model postulates that this kinase drives inappropriate cellular hypertrophy and hyperplasia as organisms age, contributing to, or even causing, many of the manifestations of aging.

It seems likely that the protean effects of aging reflect multiple molecular causes, including diverse types of molecular damage and other phenomena, such as excess mTOR signaling. These effects may then converge to cause progressive dysfunction and eventual death. Processes underlying biological aging persist, since there has been little evolutionary pressure to weed them out. However, experimental biologists have now developed powerful means of extending life span; there is great promise that such tools will provide additional mechanistic insights into the aging process and eventually, perhaps, the means to extend healthy life spans in humans.

GENETIC DISEASES RESEMBLING PREMATURE AGING

There are rare diseases that seem to resemble accelerated aging **(progerias)**. The two best-studied such conditions are **Werner syndrome** (WS) and **Hutchinson-Guilford progeria syndrome** (HGPS).

FIGURE 10-5. Werner syndrome. The premature appearance of aging phenotypes is evident.

Werner Syndrome

WS is caused by recessive mutations in the *WRN* gene, encoding a DNA helicase involved in many aspects of DNA metabolism, including replication, repair and telomere maintenance. Patients with mutations in *WRN* show poor growth in adolescence, premature hair graying, thinning of the skin, cataracts, diabetes and atherosclerosis (Fig. 10-5). They also have a tendency to develop cancer, specifically sarcomas, leukemias and other malignancies. WS patients typically succumb to myocardial infarction or cancer by their 40s or 50s.

Despite the apparent similarities of WS to normal aging, this disease is by no means a perfect mimic of the aging process. For example, some disorders commonly associated with physiologic aging, such as Alzheimer disease, are not observed in WS. Thus, WS is an example of a **segmental progeria**—that is, a syndrome that recapitulates some, but not all, aspects of accelerated aging. Cultured WS fibroblasts show chromosomal instability, sensitivity to DNA cross-linking agents and a reduced replicative life span. This last observation has been used to argue for the validity of cellular senescence as a model system to study aging.

Hutchinson-Guilford Progeria Syndrome

HGPS is caused by autosomal dominant mutations in the *LMNA* gene, whose product is a protein, **lamin A**. These children show reduced growth, hair loss, scleroderma-like skin changes and atherosclerosis (Fig. 10-6). Patients with HGPS die at an average age of 13 years, typically from myocardial infarction or stroke. The most common mutation associated with HGPS causes missplicing of the LMNA transcript, leading to accumulation of **progerin,** a defective precursor of lamin A protein. Normally, lamin A is a key part of the nuclear lamina that provides structural integrity to the nucleus in differentiated cells. By contrast, progerin accumulates in the nucleus, resulting in a distorted nuclear outline and nuclear blebbing. The buildup of progerin interferes with chromatin organization, impairing gene expression and DNA repair. HGPS is at the severe end of a spectrum of disorders associated with mutations in the *LMNA* gene, collectively termed "**laminopathies**." These diseases are associated with defects in muscle, adipose tissue and peripheral nerves.

It is unclear whether and to what extent the study of WS, HGPS and related disorders improves understanding of the biology of aging. These conditions may represent disease phenotypes whose pathogenesis is unrelated to physiologic aging.

Defects in DNA Repair Cause Degenerative Phenotypes

WS and HGPS are members of a larger group of progerias that show accelerated appearance of degenerative, aging-like **(progeroid)** phenotypes. Since most of these conditions have been produced in the mouse by inactivation of genes involved in nuclear DNA repair, a model holds that DNA is an important target, perhaps the principal target, of age-associated damage. In this respect ROS are thought to represent one major source of aging-associated DNA damage (see above). This is an intuitively appealing notion; unlike other cellular macromolecules such as proteins and lipids, nuclear DNA cannot simply be replaced, but instead must be repaired once damaged. Consistent with this notion, increased levels of chromosomal aberrations, as well as more

FIGURE 10-6. Hutchinson-Guilford progeria syndrome. A 10-year-old girl shows typical features of this disease.

subtle mutations, occur in peripheral blood leukocytes and other mammalian tissues with advancing age.

Cells have evolved numerous systems to repair distinct DNA lesions (see Chapter 5). Double-strand breaks are repaired through (1) homologous recombination, (2) nonhomologous end-joining and (3) alternative end-joining. Single-strand lesions are mended via (1) nucleotide excision repair and its subsystems, (2) base excision repair and (3) mismatch repair. Unrepaired DNA damage activates cellular checkpoint responses, resulting in cell cycle arrest, apoptosis or senescence. Although defects in DNA repair systems cause dramatic harmful effects, that fact does not prove that DNA damage is at the root of physiologic aging. Thus, a connection between DNA repair and aging remains an attractive, but unproven hypothesis.

A related model implicates **epigenetic** alterations in aging. Gene expression is regulated by many mechanisms affecting DNA, histones, chromatin-binding factors, protein alterations and noncoding RNAs. DNA methylation and histone modifications change progressively with age, leading to less accurate regulation of gene expression. In invertebrate systems, genetic manipulations involving the epigenome can prolong life span. Increased cell-to-cell variation in gene expression has been observed with age in mammalian cardiomyocytes, arguing that age-associated epigenetic dysregulation may have deleterious consequences. Further studies are needed to elucidate the significance of epigenetic influences in mammalian aging.

REDUCED CALORIC INTAKE AND LONGEVITY

As noted above, DR promotes increased longevity in the vast majority of organisms in which it has been tested, from budding yeast to rodents. In mice, DR is typically achieved by reducing caloric intake by 30%–50%. This routinely extends life span by 25%–40%. Perhaps even more striking than its prolongevity effects, DR delays or prevents the onset of many age-associated conditions, including cancers, cardiovascular disease, neurodegeneration, diabetes, sarcopenia and many others. However, DR is not a "free ride"; in rodents, it impairs certain immune responses and delays wound healing. In humans, DR has been associated with reduced bone density and muscle mass, and with depression.

Prolonged Longevity with DR Is an Active Phenomenon

Longevity occurring in response to DR is not simply a passive consequence of reduced caloric intake. Even reduction of specific dietary constituents can dramatically prolong longevity. For example, in rodents, restriction of a particular amino acid, methionine, extends life span similarly to the prolongation that is seen with overall reduced caloric intake. Yet methionine-restricted animals actually consume *more* calories than do controls (Fig. 10-7).

In rodent models, DR initiated even in middle-aged adults has beneficial effects, although the increase in longevity is progressively less as DR is started later in life. Remarkably, in mice, DR imposed during the brief 3-week period from birth until weaning is sufficient to confer extended life span. This finding suggests that early DR may provoke long-lasting epigenetic changes that favor longevity.

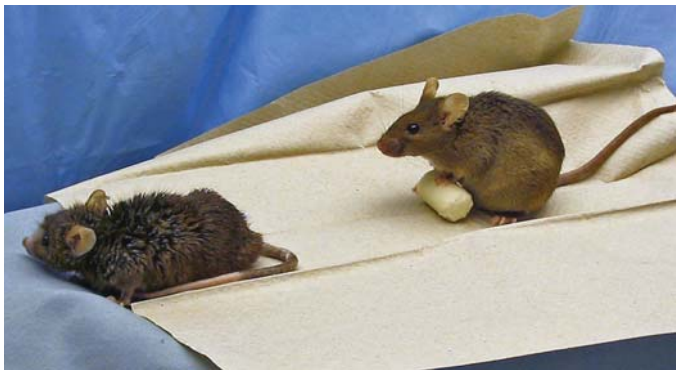

FIGURE 10-7. Methionine restriction extends mouse life span. Both mice are roughly 30 months old. The one in front is the last surviving member of a control group of mice fed regular chow. The one playing with the chalk was fed a low-methionine diet.

Can DR extend life span in humans? Studies of DR in our close cousins, rhesus monkeys, have so far yielded conflicting results as to its impact on longevity, though DR does have consistent health benefits in these animals. Until recently, residents of the Japanese island of Okinawa ate on average substantially fewer calories than did those on the Japanese mainland or the United States. This diet was associated with markedly reduced incidences of cardiac disease and cancer, and one of the world's largest populations of centenarians on a per capita basis. Members of the Calorie Restriction Society voluntarily limit their dietary intake and show improved serum lipid parameters, increased insulin sensitivity, reduced blood pressure and protection against obesity, type 2 diabetes, inflammation, carotid artery intimal hyperplasia and left ventricular diastolic dysfunction. Thus, DR in humans does confer dramatic protection against cardiovascular risk factors. Yet the overall lowest mortality rate in humans is associated with a body mass index (BMI) of roughly 25, corresponding to a normal to slightly overweight status; both lower and higher BMIs are associated with an increased risk of death. Thus, the low BMIs associated with DR in humans may have unforeseen negative consequences.

Hormesis

Conceptually, the longevity associated with DR represents an example of **hormesis:** a low-level stress such as reduced food intake may prime the organism to respond more effectively to other forms of stress, such as those linked to aging. As noted previously, DR is associated with reduced mitochondrial ROS production and decreased ROS-associated damage. It also reduces overall adiposity; visceral adiposity in particular has negative health effects. DR in rodents also increases insulin sensitivity in skeletal muscle and lowers serum levels of insulin and insulin-like growth factor-I (IGF-I). Genetic lesions in nutrient signaling pathways also extend longevity, providing a potential link between DR-induced and genetic longevity. DR modulates the activities of specific sirtuin proteins, NAD^+-dependent deacetylases that promote aspects of mammalian health span. DR also decreases inflammation and upregulates autophagy and DNA repair mechanisms. In sum, DR can extend health and life span. The molecular mechanisms underlying this effect are only beginning to be elucidated, but are likely to be complex.

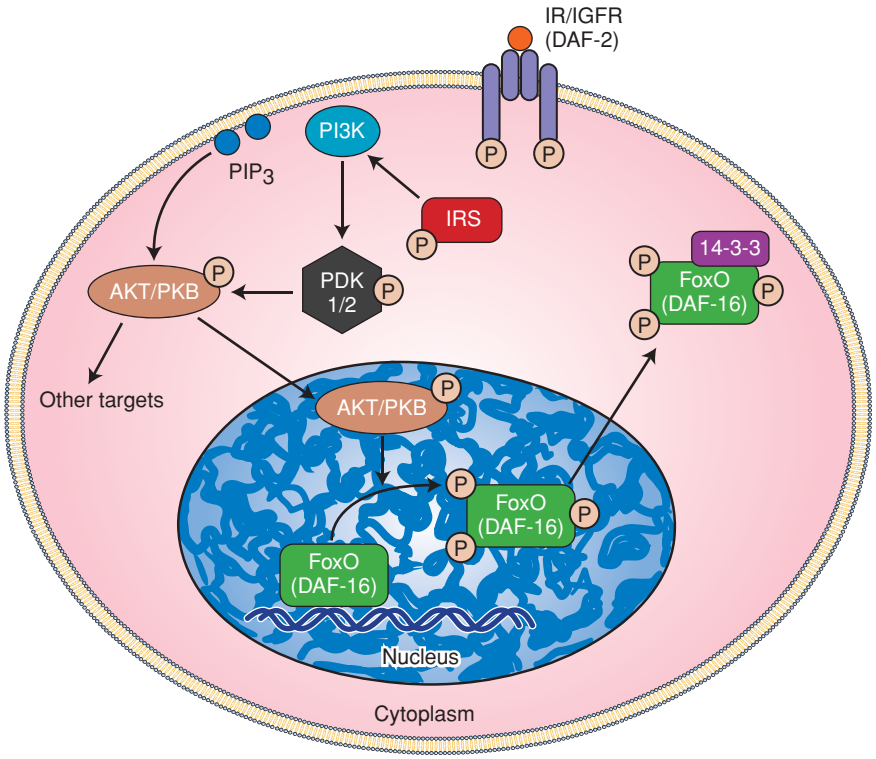

FIGURE 10-8. Insulin/insulin-like growth factor-I (IGF-I)-like signaling (IIS) pathway. IIS begins when insulin or IGF-I binds to its cell surface receptors, which are tyrosine kinases. This initiates an intracellular signaling cascade involving generation of phosphatidylinositol triphosphate by phosphatidylinositol-3-kinase (PI3K), in turn leading to activation of the downstream kinases PDK1 and Akt. FoxO transcription factors are key targets of this signaling pathway; in *C. elegans*, FoxO is termed DAF-16.

Insulin and IGF-I Signaling Shorten Life Span

Insulin/IGF-I-like signaling (IIS) negatively regulates longevity. IIS is initiated when insulin or IGF family members bind their cognate cell surface receptor tyrosine kinases (Fig. 10-8). These interactions activate the kinase Akt, which phosphorylates downstream proteins to regulate diverse processes, including cell survival, growth, cell cycle, metabolism and stress resistance. The FoxO transcription factors are key targets of Akt; when IIS is active, Akt phosphorylation sequesters FoxO factors in the cytoplasm, where they are transcriptionally inert.

In 1993, the first mutation that increased life span in any organism was characterized. Mutations in the *C. elegans* insulin receptor homolog *daf-2* were found to extend life span by more than twofold. This effect required the activity of a FoxO homolog. Subsequent work showed that genetic lesions that impair several IIS components also extend life span. Increased FoxO activity is a key element in longevity driven by reduced IIS. Surprisingly, detailed studies have revealed that increased FoxO activity in only a subset of tissues is sufficient to confer extended life span. These findings highlight the role of neuro endocrine signaling in controlling overall life span.

Two naturally occurring mouse mutants, the Snell and Ames dwarf lines, have pituitary defects that reduce growth hormone (GH) and IGF-I levels, along with greatly extended longevity and delayed onset of age-associated disease. Remarkably, these mice also show preserved cognition in old age. Although they have reduced levels of several pituitary-derived hormones, it is their GH deficiency that is critical for their long life span. Indeed, mutations in many genetically engineered strains of mice with increased longevity impinge upon IIS signaling. In dogs and horses, small breeds show low serum IGF-I levels and longer life spans, compared to their larger cousins. Collectively, these data point to a role for IIS in limiting mammalian life span.

Several mechanistic hypotheses have been proposed to explain how reduced IIS promotes longevity in mammals. In the Ames and Snell dwarf mice, as well as in some other long-lived mouse strains, cells show increased resistance to oxidative and other stressors. Insulin sensitivity is a feature of mice with reduced GH signaling, an improved metabolic profile that may contribute to their longevity, although some other IIS mutants paradoxically show insulin resistance. It has been proposed that reduced IIS contributes to the pro-longevity effects of DR, but mechanisms of longevity underlying DR and reduced GH–IGF-I–IIS overlap only partially.

Could reduced IIS contribute to longevity in humans as well? Since insulin *resistance* in humans is typically a pathologic condition associated with disease states (obesity, atherosclerosis, dyslipidemia, etc.; see Chapter 13), the intuitive response to this question might be no. Yet genetic studies in humans support the notion that under some circumstances, reduced IIS may provide health and even longevity benefits. Congenital mutations in the GH receptor and consequent low serum IGF-I levels are the basis of **Laron dwarfism**. Affected individuals show very short stature and striking protection from cancer and type 2 diabetes. In more typical populations, polymorphisms in the IGF-I receptor (IGFR), Akt and FoxO genes have been identified in centenarians. In the case of IGFR, these polymorphisms are associated with reduced IGF-I signaling. Overall, there is solid evidence that chronically reduced IGF-I signaling in humans protects against disease and potentially promotes longevity.

mTOR Signaling

mTOR is a protein kinase (see Chapters 1 and 5) with conserved roles in limiting longevity seen in widely divergent species. Through complex signaling pathways, mTOR phosphorylates many targets in the cell (Fig. 10-9). Genetic or pharmacologic inhibition of mTOR activity experimentally

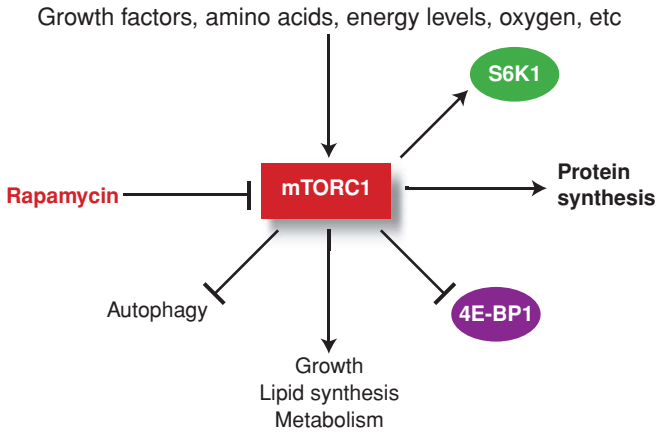

FIGURE 10-9. mTOR signaling. The mTOR kinase participates in two major complexes, termed mTORC1 and mTORC2. mTORC1 has been most closely linked to longevity. Multiple stimuli activate mTORC1. Two key downstream targets of mTORC1 are S6K1 and 4EBP1, through which mTORC1 promotes protein synthesis. Rapamycin acutely inhibits mTORC1 in a substrate-specific manner, but chronically can also inhibit mTORC2.

extends longevity in invertebrate models. As with IIS, DR may work in part through reduction of mTOR signaling. Genetic disruption of mTOR signaling components extends longevity in invertebrate models of female mice. Remarkably, the mTOR inhibitor rapamycin robustly extends mouse life span, even when treatment is initiated in older adults. Rapamycin also suppresses neoplasia (see Chapter 5) and several other phenotypes of aging in treated animals. Overall, these data indicate that mTOR signaling limits longevity in a manner that is conserved in many different organisms.

Sirtuins Are Linked to Health Span and Life Span

Sirtuins are a family of enzymes whose best-characterized biochemical function is NAD^+-dependent **deacetylation** of target proteins. Intracellular NAD^+ levels rise with nutrient deprivation and stress; hence, sirtuin activity is a means by which cells sense and respond to their environments, akin to IIS and mTOR signaling.

Interest in the potential involvement of sirtuins in longevity began with the observation that the prototypical sirtuin, SIR2, extends life span when overexpressed in *S. cerevisiae.* One mechanism by which SIR2 promotes yeast longevity is by deacetylating histones in repetitive genomic regions, thereby suppressing recombination and enhancing genomic stability. These observations have led to investigation of SIR2 homologs (i.e., sirtuins) in mammals (which possess seven sirtuins). Sirtuin function helps promote mammalian health span (Fig. 10-10) and, in the case of at least two sirtuins (SIRT6), longevity.

Most research on mammalian sirtuins has focused on SIRT1, the closest homolog of yeast SIR2. This protein deacetylates dozens of cellular proteins, including histones, p53, FoxO transcription factors, PGC-1α and many others, thus regulating key aspects of cell biology. SIRT1 attenuates many diseases associated with aging, including cardiac hypertrophy, neoplasia, glucose intolerance, neurodegeneration and others. SIRT1 overexpression in the hypothalamus increases mouse life span.

Acetylation on mitochondrial proteins is particularly abundant, and the mitochondrial sirtuin SIRT3 deacetylates and regulates many protein targets in mitochondria. It influences core organelle processes, promoting electron transport and suppressing ROS generation. SIRT3 also plays a key role in promoting cardiac health and suppressing tumors. Interestingly, mice normally lose hearing acuity progressively with age, a change blocked by DR. DR-driven preservation of hearing requires SIRT3, likely due to the function of this sirtuin in lowering ROS. Overall, SIRT3 is strongly linked to health span, and potentially to the DR response.

Mammalian SIRT6 has also been connected to the biology of aging. SIRT6 maintains chromosomal stability and metabolic homeostasis. Mice lacking SIRT6 suffer from a degenerative metabolic disorder and typically die by 1 month of age. SIRT6 protein is a histone deacetylase that suppresses the transcriptional output of key signaling pathways, in particular nuclear factor-κB (NF-κB) and hypoxia-induced factor-1α (HIF-1α). It also facilitates DNA repair through several different mechanisms. In mice, SIRT6 promotes cardiac health and suppresses hypertrophy and is a potent tumor suppressor. Overexpression of SIRT6 extends mouse life span.

Perspective: The Biology of Aging and Longevity

Although in some respects aging remains an enigma, we now have important molecular insights into its mechanisms, as well as environmental and genetic interventions that can dramatically slow the rate of aging in invertebrates and in mammals. Eventually, these efforts are likely to yield large dividends in medicine. In industrialized societies, most elderly persons suffer from multiple diseases of old age. Consequently, disease-specific interventions, against heart disease or cancer for example, actually have fairly modest payoffs in terms of years of life gained. For example, based on demographic data, it has been estimated that for a 50-year-old woman, curing all forms of cancer would extend her life expectancy by less than 3 years. Even curing cancer, heart disease, stroke and diabetes all simultaneously would add only 14 years of life, on average. These gains are fairly modest because deaths due to all causes of mortality rise exponentially with age. Thus, as she ages, our hypothetical 50-year-old woman will likely succumb to some other age-associated disease anyway (i.e., soon after she would have otherwise died from cancer, heart disease, stroke or diabetes). On the other hand, life span extension proportional to that observed in a typical rodent DR study would increase the life expectancy of a 50-year-old woman by roughly 40%, from 80 to about 112 years. Moreover, based on animal studies, most of those added years would likely be spent in good health. These figures illustrate how a deep, mechanistic understanding of the biology of aging may offer a powerful means to improve human health.

Mechanisms of Autoimmunity

Both the innate and adaptive immune systems have the capacity to injure host tissues. This process gives rise to a large number of human diseases, some entirely caused by self-reactivity, and others mediated secondarily by autoreactivity. Broadly speaking, human autoimmune diseases are divided into those affecting primarily one organ (e.g., myocarditis) and those whose effects extend to multiple body systems (e.g., systemic lupus). More recently, a third group of autoimmune illnesses caused by inappropriate activation of the innate immune system has been recognized.

Autoimmunity Is Specific Reactivity by the Adaptive Immune System against Self-Tissue

This includes recognition of self by autoantibodies and by self-reactive T cells. A broader definition of autoimmunity would include immune damage to tissues initiated by the innate immune system, for example, inflammation due to inappropriate activation of **inflammasomes** (see Chapter 2), key complexes of membrane-linked enzymes and adapter proteins that lead to generation of biologically active interleukin-1 (IL-1), with subsequent inflammation. Similar conditions of activation of innate immunity include activation of the complement system owing to faulty control proteins (such as factor H) or of the response to cytokines such as tumor necrosis factor-α (TNF-α) owing to an inappropriately sensitive receptor.

Autoimmunity is woven into the normal immune response. T cells normally recognize peptide antigens only when associated with self–major histocompatibility complex (MHC) molecules (see Chapter 4). Certain autoantibodies are present even in normal individuals (e.g., rheumatoid factor; see below) and play a housekeeping role in removing superfluous antigens. B cells that make autoantibodies constitute a very large part of the fetal, and even neonatal, repertoire. Such cells are lost or inactivated as a normal part of development (Fig. 11-1).

Humoral Autoimmunity

Autoantibodies are generated normally as a consequence of random association of VH and VL gene segments. B cells

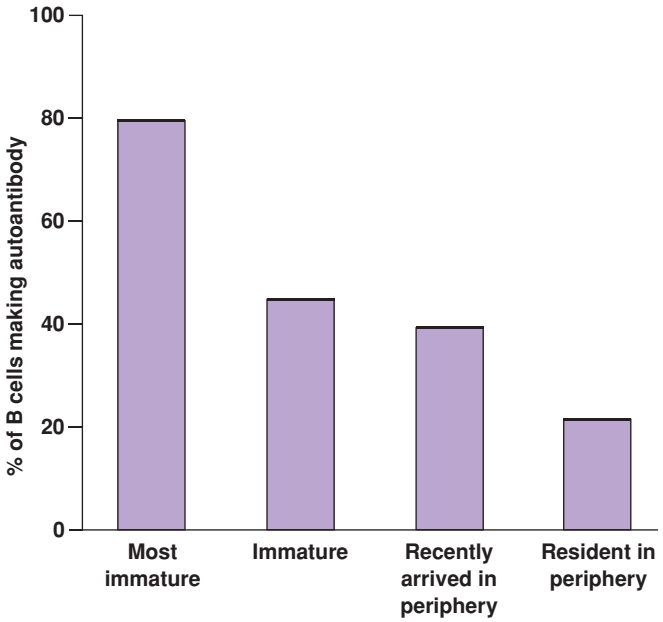

FIGURE 11-1. Autoantibody formation by normal B cells. Fractions of human B-cell lymphocytes produced autoantibodies, taken at different stages of development.

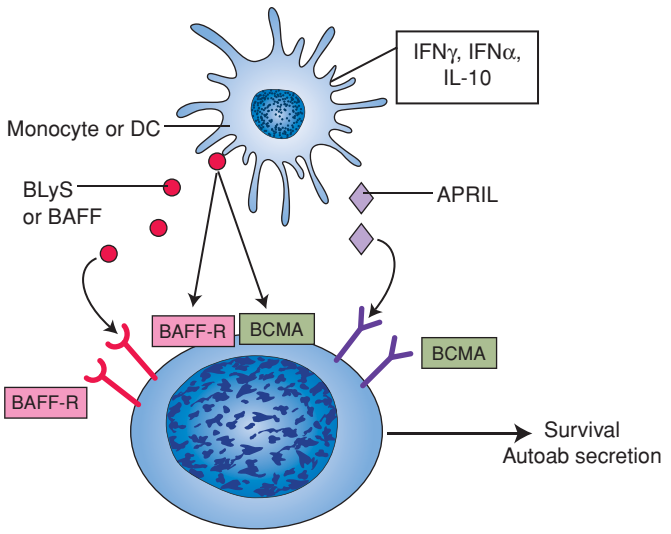

FIGURE 11-2. BAFF and APRIL binding to B lymphocytes. Monocytes and dendritic cells produce BAFF (BLys) and APRIL when driven by certain cytokines. These bind to receptors on B cells, promoting their survival.

that by chance are autoreactive must be eliminated or at least inactivated. Autoreactive B cells are vetted and removed or marginalized at multiple checkpoints in normal B-cell development. For example, heavy (H) or light (L) chains of autoreactive B cells are replaced by different H or L chains. This process, called **receptor editing,** changes the specificity of autoreactive B cells so that they are no longer autoreactive. Receptor editing is thought to be an important mechanism of avoiding autoreactivity. Another key mechanism is the action of BAFF (also known as BLyS), a cytokine derived mainly from monocytes, which regulates B-cell maturation (Fig. 11-2). Far more B cells are produced than are needed. BAFF (and a related molecule called APRIL) control the number of B cells that can mature by rescuing immature B cells from apoptosis. Overproduction of BAFF causes hypergammaglobulinemia and humoral autoimmunity.

T-Cell–Mediated Autoimmunity

Acquisition of a T-cell repertoire is a complex process involving both positive and negative selection in the thymus. The repertoire is further shaped by selection among peripheral T cells (i.e., mature T cells that have already exited the thymus). AIRE thymic transcription factor plays a crucial role in allowing many self-proteins to be expressed in the thymus so that potentially self-reactive T cells can be exposed to them and be eliminated (Fig. 11-3). Mutations in AIRE lead to a serious pediatric diffuse autoimmune disease (autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy [APECED]). T-cell autoreactivity is also controlled by regulatory T cells (T_{reg}), which dampen potentially harmful

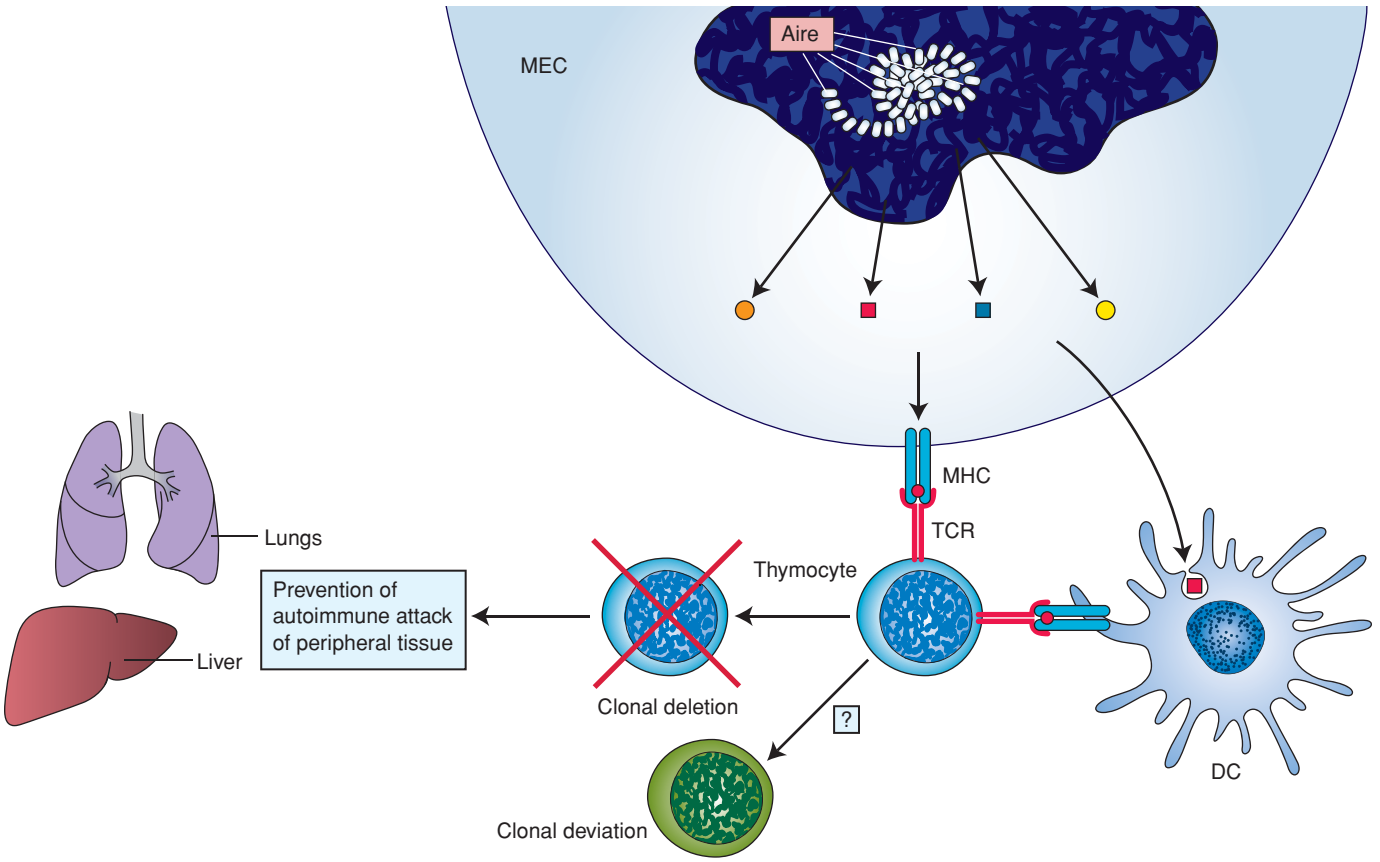

FIGURE 11-3. T-lymphocyte clonal deletion in tolerance. AIRE transcription factor activates expression of antigens normally expressed in peripheral tissues, so that they are expressed in thymic medulla epithelial cells (MEC). Antigens so regulated may include those of any tissue, the liver and lungs being shown here as representatives. Such self-antigens are presented to T lymphocytes developing in the thymus, directly by the MEC or by dendritic cells (DCs). The result is deletion of autoreactive T lymphocytes.

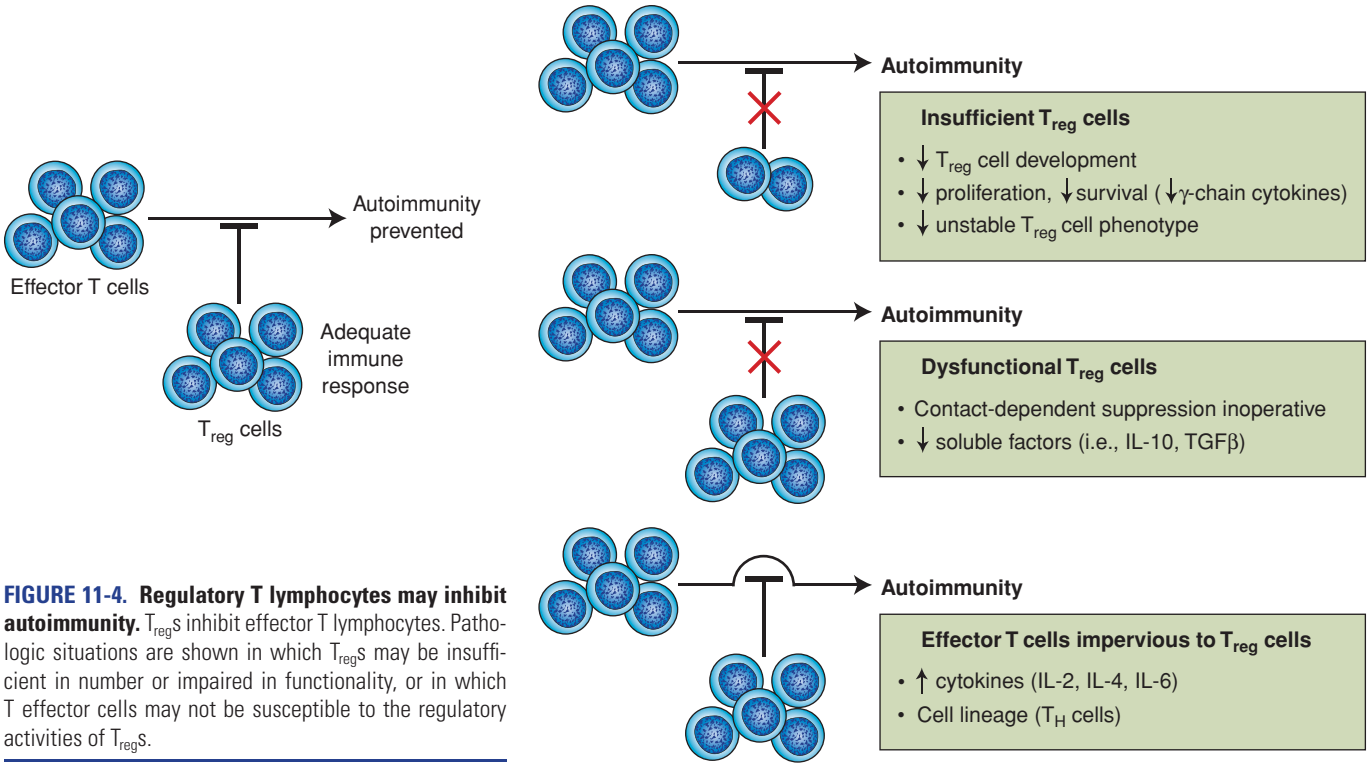

FIGURE 11-4. Regulatory T lymphocytes may inhibit autoimmunity. T_{reg}s inhibit effector T lymphocytes. Pathologic situations are shown in which T_{reg}s may be insufficient in number or impaired in functionality, or in which T effector cells may not be susceptible to the regulatory activities of T_{reg}s.

responses by other T cells. Mutations in FoxP3, a key transcription factor for regulatory T cells, lead to another serious autoimmune disease (immunodysregulation, polyendocrinopathy and enteropathy, X-linked [IPEX]) (Fig. 11-4).

Innate Immunity as a Form of Autoimmunity

Certain inflammatory diseases are caused by improper control of the innate immune system. The periodic fever syndromes, an important cause of morbidity in many parts of the world, are caused by genetic defects in the control of the **inflammasome** (see Chapter 2), a complex of proteins that regulates the conversion of prointerleukin-1 to interleukin-1 (Fig. 11-5). The "autoinflammatory" diseases also include several inherited disorders characterized by widespread inflammation, for example, neonatal onset multisystem inflammatory disease (NOMID), a condition in which a mutated cryopyrin protein (a key component of the inflammasome) is constitutively activated and leads to skin inflammation and arthritis. Mutations of TRAPS, a key intracellular protein involved in TNF signaling, also lead to inherited inflammatory conditions.

Inherited or acquired defects of complement control proteins (factor H and others) can result in severe microangiopathic disease (the hemolytic–uremic syndrome), and defects in red cell proteins that control complement activation can lead to paroxysmal nocturnal hemoglobulinuria, a serious form of anemia and hemolysis.

Causes of Autoimmunity

Thinking about autoimmunity is still influenced by a famous monograph by Paul Ehrlich, the father of modern immunology. He understood that animals generally did not make immune responses even when deliberately immunized with their own tissues, and he coined the term *horror autotoxicus* to indicate the terrible consequences that might occur if autoimmunity were allowed to happen. Yet we now recognize that autoimmunity is a common feature of the immune system, and that there are many diseases that appear to be a result of abnormal autoimmunity.

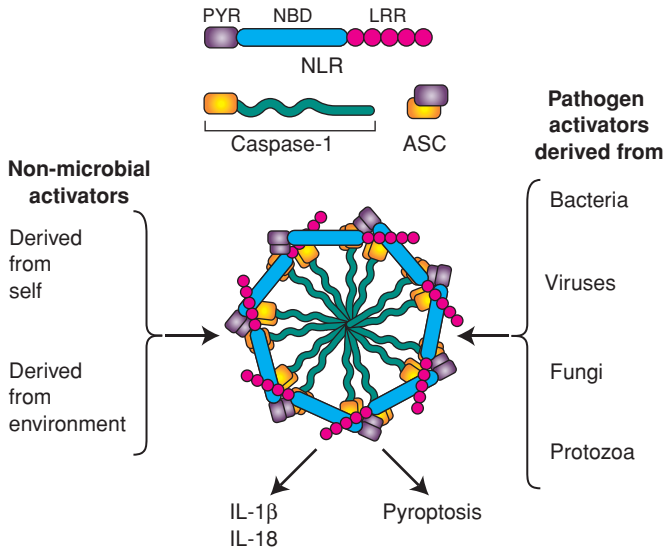

FIGURE 11-5. The inflammasome. The NLRP3 inflammasome, the best studied of these pro-inflammatory complexes, is a cluster of proteins (NLR, caspase 1, ASC) on macrophages and other innate immune cells. Several stimuli activate it to cause production of active interleukin-1 (IL-1) and IL-18 and to elicit cell death. *ASC* = apoptosis-associated speck-like protein containing a caspase recruitment domain; *CPPD* = calcium pyrophosphate dihydrate; *MDP* = muramyl dipeptide; *MSU* = monosodium urate; *NLR* = nucleotide-binding domain, leucine-rich repeat containing; *PAMP* = pathogen-associated molecule patterns.

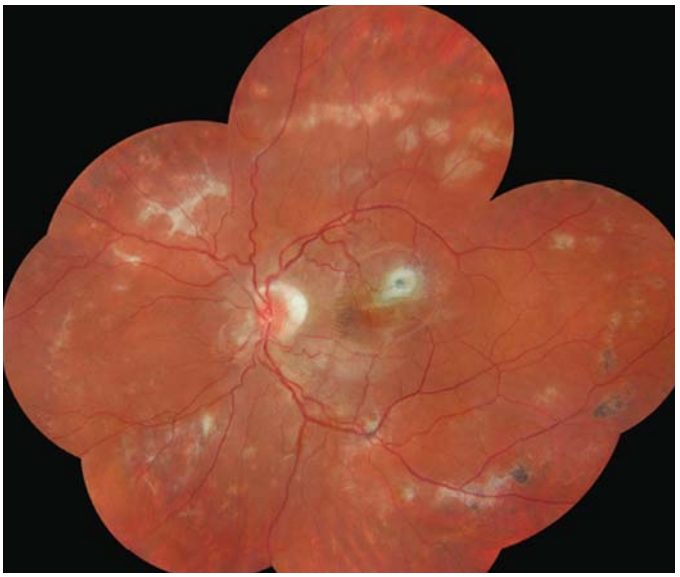

FIGURE 11-6. Sympathetic ophthalmitis after eye surgery. Optic fundus of the left eye of a patient who had a right eye vitrectomy several weeks previously. Retinal inflammation is seen, with optic disc swelling and pigment deposition. The immune system was activated by antigens from the left eye that were released as a consequence of the prior surgery. The result is damage in the previously normal right eye.

What are the causes of abnormal autoimmunity? In many cases, the answer is incompletely understood, but what follows are the principal views of scientists in this area of active investigation.

Breach of Immunologic Privilege

This is a rare cause of autoimmunity. Certain body areas (e.g., the anterior part of the eye) are immunologically "privileged": the immune system has little or no contact with these areas, and tolerance is not established to tissue-specific antigens there. This allows transplantation of foreign corneas, happily. But if "privileged" proteins should contact the immune system (through trauma, for instance), self-reactivity can occur. This accounts for **sympathetic ophthalmitis,** when trauma to one eye causes chronic autoimmune inflammation of both eyes because the immune system has become sensitized to ocular antigens it normally ignored. Post–myocardial infarction pericarditis may have a similar etiology (Fig. 11-6).

Postinfectious Autoimmunity and Molecular Mimicry

Acute rheumatic fever is a result of the immune response to group A *Streptococcus.* Certain microbial antigens share structural similarity to human antigens, so that immunity triggered by, and directed against, the infectious agent may elicit antibodies or T cells that react to self-tissues. In this vein, immunity that develops against certain streptococcal antigens is thought to stimulate antibodies that cross-react with tissue in joints, the nervous system and the heart. This causes an acute febrile illness with inflammation in and around the heart and in the joints, and sometimes in the brain (see Chapter 17). It may lead to scarring in heart valves and may recur with reinfection. Why some people are susceptible and others are not remains unclear (see below). **Guillain-Barré syndrome** is a postviral autoimmune neuropathy apparently resulting from immunity originally directed against viral products. A large number of viral diseases have been associated with autoimmune consequences—for example, postmeasles encephalomyelopathy. The extent to which this represents cross-reactivity with the host or other mechanisms is unclear (Fig. 11-7).

Polyclonal Activation and Autoimmunity

Certain environmental agents—famously, the lipopolysaccharide (LPS) that is part of the coating of gram-negative bacteria, but also many other substances—may diffusely activate the immune system. LPS acts by binding to Toll-like receptor 4 (TLR4; see Chapter 2). Many other activators of the innate immune system can also activate TLRs. Because B cells have certain TLRs, they can be powerfully activated by ligands binding these receptors. For B cells, the result is that many different clones are activated simultaneously, causing a burst of antibody formation that represents all the specificities possessed by available B cells, including autoantibodies. Autoantibodies can thus be stimulated by certain viral or bacterial infections. For example, Epstein-Barr virus (EBV) binds to and activates B cells, and autoantibodies are regularly present during acute EBV infection. Chronic bacterial infections, such as endocarditis and osteomyelitis, are also often accompanied by autoantibodies. In most cases, these are not pathogenic, but occasionally they cause clinical disease.

Drugs and Toxins as Causes of Autoimmunity

Certain drugs can provoke autoantibodies and even clinical autoimmunity in ways that are still ill-defined but that

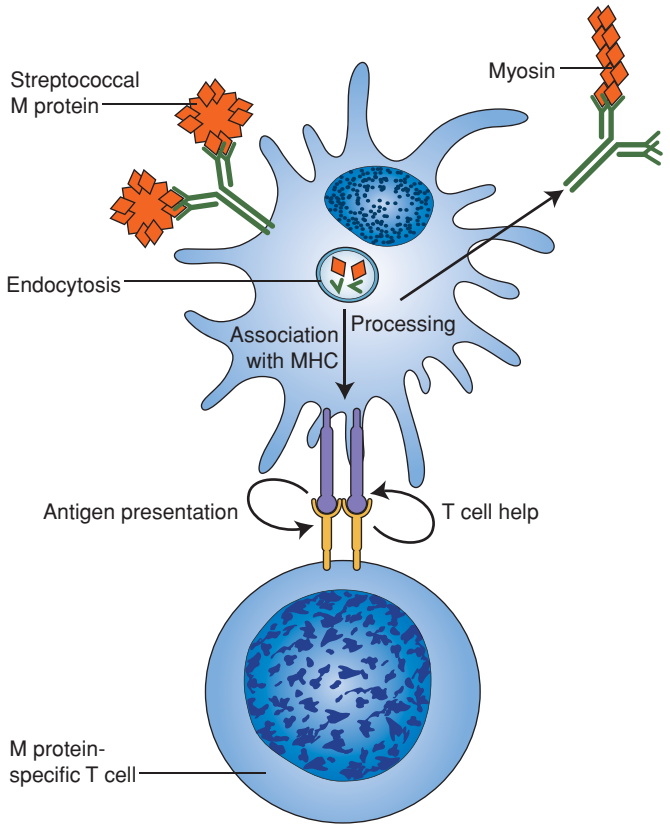

FIGURE 11-7. Molecular mimicry. In molecular mimicry, the immune system is sensitized by foreign proteins (here, *Streptococcus* M protein). M-protein–reactive T cells help B cells, which make antibody that cross-reacts with autologous cardiac myosin, to cause damage to the heart, as in rheumatic fever.

involve aberrations of tolerance. Well-known examples are antinuclear antibodies that follow treatment with hydralazine and procainamide, antierythrocyte autoantibodies from methyldopa and antiplatelet antibodies from quinine. Environmental toxins, notably mercury and other heavy metals, result in autoantibodies and immune-mediated renal and nervous system disease. There have been outbreaks of inflammatory connective tissue disease from contaminated tryptophan and other food supplements. Recently, it has been appreciated that cocaine, especially when taken with the antihelminth levamisole, may induce granulomatous vasculitis. Mechanisms are still obscure.

Genetics and Autoimmunity

Host genes profoundly affect susceptibility to autoimmune diseases. Concordance for certain autoimmune diseases among identical twins may reach 35%. As well, autoimmune disease patients frequently report that family members have or have had the same or similar autoimmune disorders. Except for rare inherited conditions (e.g., APECED), inheritance is complex and multiple genes are believed to conspire together with multiple environmental factors. Among the genetic links that influence development of autoimmune diseases are MHC alleles (mostly class II, but class I for the spondyloarthropathies), together with multiple genes involving the immune system, such as IL-7 and its receptor and IL-23. As well, TLR genes and other genes for cytokines, cytokine receptors and tyrosine kinases involved in immune cell activation are associated with development of immune responses to self-antigens.

Gender and Autoimmunity

Most autoimmune diseases occur more often in females. Female-to-male ratios range from up to 20:1 for autoimmune thyroiditis and lupus to perhaps 3:1 for rheumatoid arthritis and multiple sclerosis. The increased susceptibility of women to autoimmunity remains incompletely understood. A large but not conclusive body of evidence supports the notion that it is sex hormones, through their influence on the immune response, that account for the difference, but X-chromosome gene dosage effects are also possible.

Chance and Autoimmunity

Both B- and T-cell receptor formation involve random genetic recombination events. These are compounded by somatic mutation of receptors. The variability of autoimmunity—even in completely inbred susceptible animal strains—has led to the view that stochastic (random) events, probably in repertoire generation, may have a profound effect both on the normal immune repertoire and on the development of autoimmunity.

Apoptosis and Autoimmunity

Many autoantibodies—at least in systemic autoimmune diseases—recognize intracellular antigens, and in particular those that normally reside within the cell nucleus. Such intracellular antigens may gain access to the immune system during the process of cell death. Nuclear antigens can be demonstrated on the surfaces of dying cells and may be the source of immunization leading to autoantibodies. Apoptosis is characterized by cell death without inflammation (see Chapter 1). Apoptotic cells are phagocytosed whole, via a choreographed set of interactions with macrophages (Fig. 11-8). However, abnormalities of the mononuclear phagocyte system may lead to abnormal persistence of apoptotic cells and cause autoimmunity in experimental systems. Thus, mice lacking an apoptotic cell receptor–signaling intermediate develop a lupus-like syndrome (see below) because they cannot clear apoptotic debris. Along these lines, unengulfed apoptotic debris is detectable in human lupus and in other autoimmune diseases.

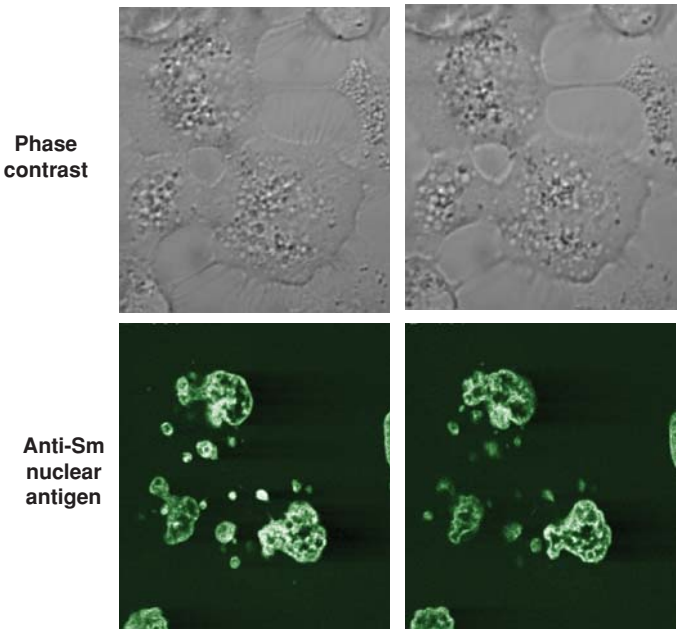

FIGURE 11-8. Expression and release of nuclear antigens by cells early (left) and late (right) in apoptosis. UV-irradiated skin cells became apoptotic, demonstrating the typical morphology (*upper panel*, phase contrast). Immunofluorescence staining was used to identify Sm nuclear antigen (*lower panel*). Sm was present on surface blebs. Such nuclear antigens may thus trigger autoimmune responses.

Graft-versus-Host Disease

Allogeneic T cells provoke inflammation when they recognize noncompatible tissue (as in recipients of allogeneic bone marrow; see Chapter 4). Autoantibodies may arise during chronic graft-versus-host disease (GVHD). This is believed to result in the abnormal interaction between the foreign T cells and host B cells, probably because the T cells have not been "educated" in the host thymus.

During Cycles of Remission and Exacerbation, Marker Autoantibodies May Provide Clues about Autoimmunity

Marker autoantibodies are disease-specific autoantibodies that are so tightly linked to certain diseases that their presence suffices to confirm the diagnosis. Some of these are very surprising; for instance, antibodies to transfer RNA (tRNA) synthetases (e.g., methionine tRNA synthetase) are virtually diagnostic of inflammatory myositis, and antibody to topoisomerase I (a DNA unwinding enzyme) is specific for scleroderma.

Remission–Exacerbation

Many autoimmune diseases, even if untreated, tend to flare and then to remit. Multiple sclerosis is especially

prone to exacerbations and remissions, but other diseases (lupus, rheumatoid arthritis, etc.) can show marked regression (usually not permanent). The reasons for this pattern of episodic peaks and valleys of disease activity are uncertain.

Systemic Autoimmune Diseases

It is customary to classify autoimmune diseases as organ specific (affecting a single organ or organ system)—for example, autoimmune thyroiditis—or as systemic, in which multiple organs are affected. Such distinctions are not absolute, as some diseases may be mainly organ specific in most cases but demonstrate systemic involvement in some individuals (e.g., rheumatoid arthritis; see below). As well, organ-specific autoimmune symptomatologies are often part of systemic autoimmune disease. Manifestations of autoimmune diseases in individual organs (e.g., autoimmune hepatitis) are mainly described in the chapters that focus on organ-based pathology. We address below systemic autoimmune diseases as they affect the whole patient. It should be emphasized that almost every organ can be afflicted with autoimmune disease.

Autoantibodies

Autoantibodies can be detected in normal individuals and may not cause disease. Some autoantibodies clearly induce pathology if given to normal individuals. (This is not done anymore but was done in the past for several autoimmune diseases.) Such antibodies may also cross the placenta and be pathogenic for the fetus. Other autoantibodies can transfer disease manifestations when given to experimental animals. For most autoimmune diseases, the inference that autoantibodies or autoreactive T cells are the cause of pathology is made based on the presence of autoantibodies or T cells in affected tissue, often together with complement components.

Autoimmune Diseases May Reflect Both T- and B-Cell–Mediated Autoreactivity

Demonstrating that antibodies cause an autoimmune disease is technically much easier than doing so for T cells, and many autoimmune diseases do seem to be largely caused by antibody. Some autoimmune diseases (e.g., lupus; see below) seem to involve both autoreactive T and B cells. Even today, there is debate about the relative importance of humoral versus cellular immunity for many autoimmune diseases. The surprising effectiveness of B-cell depletion (using anti-CD20) has provoked a reevaluation of the relative role of T cells in certain autoimmune diseases, notably multiple sclerosis.

For some autoimmune diseases, the target antigens are few and are well defined (e.g., α-gliadin in celiac disease, although, strictly speaking, this is not autoimmune because the antigen is in food). For others, it has been difficult to incriminate specific antigens, or the antigenic spectrum of certain autoimmune diseases may be highly complex.

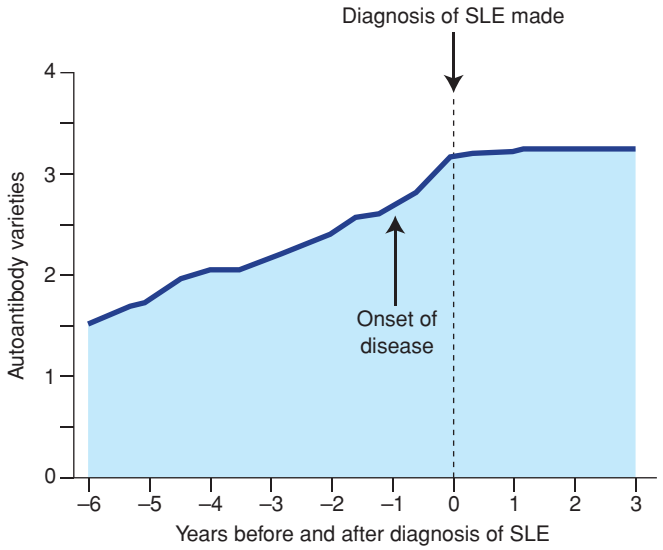

FIGURE 11-9. Time course of autoantibody formation in systemic lupus erythematosus (SLE). Average numbers of the different kinds of autoantibodies as a function of time of symptom onset and diagnosis in patients with SLE.

Immunity Is Usually Depressed in Patients with Autoimmune Diseases

People suffering from systemic autoimmune disorders have **reduced** immune responses to exogenous antigens (i.e., conventional antigens, such as in vaccines or natural infections). This observation is independent of immunosuppressive treatments they may be receiving. It is almost as if an immune system that is obsessed with responding to self cannot do its real job of defending against infection. This disease-associated reduction in immunocompetence has clinical implications.

The antibodies found in systemic autoimmune disease patients have all of the characteristics of mature, high-affinity immune responses. There are antibodies present against multiple epitopes on complex autoantigens, supporting the idea that the original autoantibody response was indeed antigen driven and not due to a fortuitous cross-reaction or an aberrancy in immune regulation (Fig. 11-9).

Autoantibodies Predate Disease Onset

Patients with systemic lupus and rheumatoid arthritis generally have significant levels of disease-specific autoantibodies in their sera years before the disease began to manifest clinically. Thus, at least in these instances, autoimmunity precedes disease, and autoantibodies most likely play causative roles in pathogenesis.

Autoantibody Specificities Are Skewed

The specificities of disease-related autoantibodies are not easily predictable. Of the thousands of proteins present in the nucleus, only a few are targets of autoantibodies. For example, the Smith (Sm) ribonuclear protein (RNP) complex, crucial to splicing of premessenger RNA (pre-mRNA), is a highly specific antibody for lupus, yet Sm RNP is not an abundant nuclear protein. Neither the amount nor the

location of an individual self-protein determines whether it will be a disease-related autoantigen. There is some evidence that the degree of molecular disorder positively correlates with autoantigenicity.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic Lupus Erythematosus Is a Multisystem Inflammatory Disease that May Involve Almost Any Organ

SLE characteristically affects the skin, joints, serous membranes, central nervous system and kidneys. Autoantibodies are formed against a variety of self-antigens, including plasma proteins (complement components, clotting factors) and protein–phospholipid complexes, cell surface antigens (lymphocytes, neutrophils, platelets, erythrocytes), intracellular cytoplasmic components (microfilaments, microtubules, lysosomes, ribosomes, RNA) and nuclear DNA, ribonucleoproteins and histones. The spectrum of intracellular autoantigens includes the proteins and DNA that make up chromatin, proteins of the spliceosome complex (small nuclear RNPs [snRNPs]) and the Ro/La small cytoplasmic ribonucleoprotein particle. The most important diagnostic autoantibodies are those against nuclear antigens—in particular, antibody to double-stranded DNA (dsDNA) and to a soluble nuclear antigen complex, Sm antigen, that is part of the spliceosome. In clinical context, high titers of these two **antinuclear antibodies** (ANAs) are very suggestive of SLE. Antigen–antibody complexes form or deposit in tissues, leading to characteristic vasculitis, synovitis and glomerulonephritis. SLE is a prototypical type III hypersensitivity reaction. Occasionally, directly cytotoxic antibodies are present, particularly antibodies against cell surface antigens of leukocytes and erythrocytes. There is also evidence that cell-mediated immune responses are involved.

EPIDEMIOLOGY: The prevalence of SLE varies worldwide. In North America and northern Europe, it is 40 in 100,000. In the United States, it appears to be more common and severe in blacks and Hispanics, although socioeconomic factors may in part be responsible. Nearly 90% of cases are in women of childbearing age, as many as 1 in 700 of whom may have this disease.

The etiology of SLE is unknown. Genetic, immunologic and environmental factors contribute (Fig. 11-10). The presence of numerous autoantibodies, particularly ANAs, suggests a loss of tolerance. Some manifestations of SLE result from tissue injury due to immune complex–mediated vasculitis, while other manifestations (e.g., thrombocytopenia or the secondary antiphospholipid syndrome) are caused by autoantibodies to cell membrane molecules or serum components. However, many diagnostically helpful ANAs are not incriminated in the pathogenesis of SLE.

MOLECULAR PATHOGENESIS: Unlike some other purely genetic diseases, the effects of a single gene do not dominate the genetics of lupus. Instead, susceptibility to lupus results from the sum of small effects of multiple genes. In the past two decades, at least 17 genetic linkages have been established and independently confirmed. For some of those linkages, the responsible gene within the specific chromosome interval has been also identified, for example, FcγRIIIA and FcγRIIA, PDCD1 and human leukocyte antigen-DR (HLA-DR). There are also at least 20 independent genetic effects (polymorphisms) identified and confirmed that are risk factors in lupus. Among those are HLA-DR2 (odds ratio [OR] 1.5–4), C2/C4 (OR 1.5–5), FcγRIIA (OR 1.3), PDCD1 (OR 2.6), PTPN22 (1.6), IRF5 (OR 1.3), TYK2 (1.6) and TNF-α (OR 4).

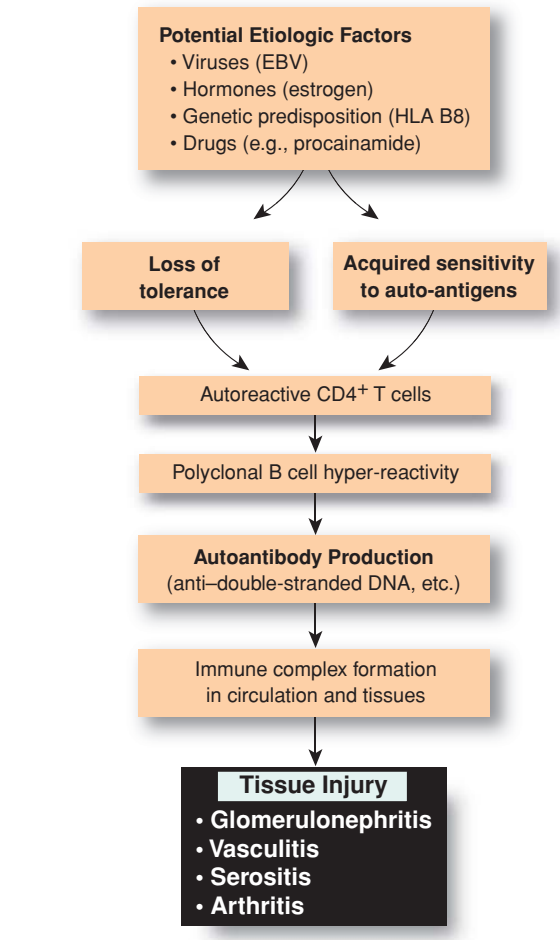

FIGURE 11-10. The pathogenesis of systemic lupus erythematosus is multifactorial. *EBV* = Epstein-Barr virus; *HLA* = human leukocyte antigen.

PATHOPHYSIOLOGY: Among the effector functions associated with these HLA haplotypes is a decrease in C3b receptors on cells that clear circulating immune complexes. A critical role for the D/DR region in the pathogenesis of SLE is supported by the observation that inherited deficiencies of certain complement components, particularly C2, C4 and C1q, are associated with an increased incidence of SLE and lupus-like disorders. The genes that encode C2 and C4 are within the MHC.

ENVIRONMENT. Lupus has an important genetic component as illustrated above and by the 20%–30% concordance of disease between monozygotic twins. In dizygotic twins, there is only 2% concordance. However, the observation that the second monozygotic twin does not develop lupus in three quarters of monozygotic twin

pairs also implies an important role for nongenetic factors, be they environmental, epigenetic or stochastic.

Ultraviolet irradiation and viral infections are two established environmental factors. For example, a typical lupus onset is a patient presenting to the clinic with malar rash and arthritis after prolonged exposure to the sun. Common viral infections also exacerbate or ignite lupus onset. Both factors are thought to operate by inducing a form of proinflammatory cell death. In the case of EBV exposure, molecular mimicry is considered of particular importance.

Other factors such as cigarette smoking, heavy metals, solvents, pesticides and exogenous estrogens have been implicated, but definitive proof is lacking. Finally, silica exposure significantly increases the risk of developing lupus with an OR of 4.0 if exposure lasts more than 1 year. It has been speculated that exposure to silica, which has been demonstrated to be toxic to macrophages, may impair clearance of apoptotic cells and thus favor self-immunization and SLE.

HORMONES. SLE is predominantly a female disease. Onset of SLE before puberty and after menopause is uncommon. The female predilection becomes less pronounced outside the reproductive age range. Finally, patients with Klinefelter syndrome, characterized by hypergonadotrophic hypogonadism, are prone to the development of SLE. These observations suggest a role for endogenous sex hormones in disease predisposition.

Indeed, hormones can impact the function of T cells and macrophages, and estrogens have been shown to increase B-cell differentiation and in vitro immunoglobulin (Ig) production including anti-dsDNA. Yet other explanations for the female predominance in SLE have been proposed, including incomplete inactivation of the X chromosome in females with SLE, leading to increased dosage of genes affecting the immune system.

Immunologic Factors in the Pathogenesis of SLE

B Cells

Pathogenic autoantibodies produced by B cells are an important cause of tissue damage in SLE. B cells are also relevant as antigen-presenting cells (APCs) and contribute to lupus autoantigen presentation. Recently, lupus has been associated with abnormal early B-cell tolerance, resulting in the escape of autoreactive B cells to the periphery.

Recent studies suggest roles for TLR-driven and interferon-α (IFN-α)-driven B-cell responses. Evidence for specific antigen-driven responses comes from the observation that, with time, the antibodies of SLE demonstrate gene rearrangements and mutations that are typical of antigen-driven responses. Moreover, patients with SLE often have antibodies to more than one epitope on a single antigen, further suggesting a primary role for an antigen-driven process. Although inciting antigens have not been identified, a number of factors render normal body constituents more immunogenic, including infection, ultraviolet light exposure and other environmental agents that damage cells.

T Cells

Two important observations in humans suggest a role for T cells in the pathogenesis of lupus: (1) the association of SLE with several MHC class II genes and (2) the autoantibodies found in lupus show features associated with T-cell–dependent responses such as isotype switching and somatic mutation.

$CD4^+$ T cells become autoreactive following DNA hypomethylation and they overexpress the LFA (CD11a) cell adhesion molecules, which stabilize the interaction between T cells and APCs. Autoreactive $CD4^+$ T cells have been best described in mouse models; no consistent defect in this regulatory T-cell population has been found in humans.

Dendritic Cells

The most potent APCs in our immune system have been shown to contribute to lupus autoimmunity by producing IFN-α, particularly plasmacytoid dendritic cells (DCs), and having a proinflammatory phenotype. Both characteristics predispose DCs to break tolerance, present autoantigens and sustain the ongoing autoimmunity.

Cytokines

The cytokine network is also abnormal in lupus and reflects (1) the systemic inflammatory status and (2) an ongoing antigen-driven autoimmune response. Some of the increased cytokines are IL-4, IL-6, IL-10 and IFN-α (Fig. 11-11).

Immune Complexes

A significant portion of injury in lupus is due to deposition of circulating immune complexes against self-antigens, particularly against DNA: the occurrence of circulating immune complexes that contain nuclear antigen; the presence of those

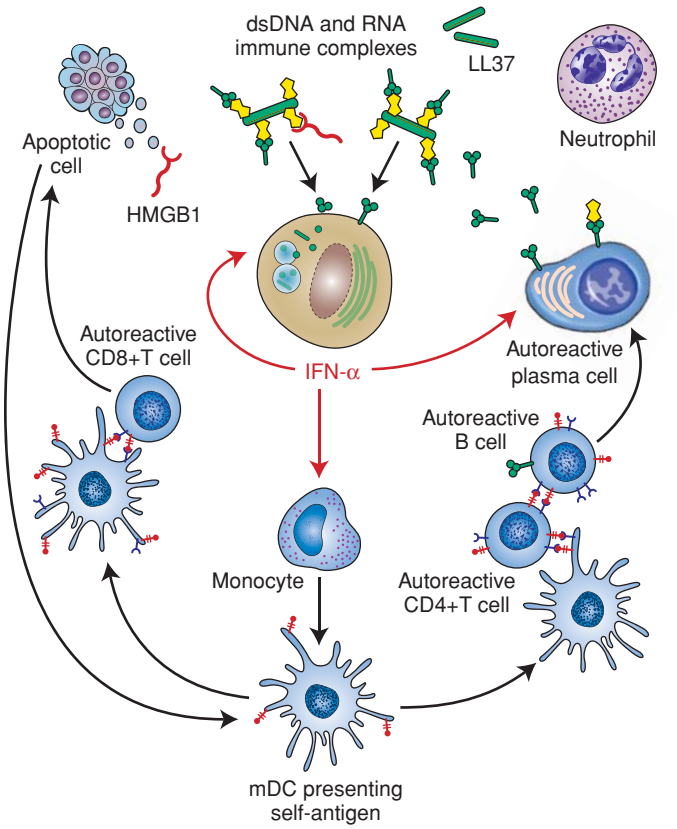

FIGURE 11-11. Immune pathogenesis of systemic lupus erythematosus (SLE). Nucleic acid complexes or Toll-like receptor (TLR) agonists elicit interferon-α (IFN-α) βψ dendritic cells (DCs). This, in turn, triggers autoantigen presentation and autoantibody production by plasma cells.

immune complexes in injured tissues, as identified by immunofluorescence; and the observation that immune complexes can be extracted from tissues that contain nuclear antigens. Additional evidence suggests that under certain conditions, immune complex formation also occurs in situ—that is, in tissues rather than in the circulation. Examples include antibodies against connective tissue components and perhaps the membranous form of lupus glomerulonephritis. Type II hypersensitivity reactions are also implicated in lupus, since cytotoxic antibodies against rbc and platelet membrane proteins can cause cytopenias (see Chapter 26).

Cell Death

Apoptosis (see Chapter 1) is characterized by nuclear condensation, membrane blebbing and subsequent cell shrinkage with preservation of an intact plasma membrane. The process culminates in the destruction of the nuclear components such as chromatin and snRNPs, incidentally the two major autoantigens in SLE.

Apoptosis avoids release of intracellular contents into the extracellular microenvironment, where they might have a powerful proinflammatory effect. Specifically, apoptosis would isolate intracellular autoantigens and render them inaccessible to the autoimmune system. Consequently, the body would be protected from developing responsiveness to such autoantigens. As mentioned above, impaired apoptotic mechanisms have led to development of experimental lupus-like disease, with production of lupus autoantibodies and glomerulonephritis. Such experimental lupus is greatly reduced in severity if release of intracellular material during cell death is prevented.

Along these lines, lupus patients have increased levels of circulating apoptotic debris and impaired capacity for uptake of dying cells. DNA/histones and RNA/proteins from apoptotic cells specifically bind to lupus autoantibodies and activate both DCs and autoreactive B cells via TLRs.

Toll-Like Receptors

TLRs recognize molecular microbial structures and constitute an important group of pattern recognition receptors of the innate immune system (see Chapter 2). Microbial TLR ligands include a wide range of molecules with strong adjuvant activity (such as lipopolysaccharide, lipopeptides, bacterial DNA and viral RNA and DNA). These ligands are powerful activators of DCs, macrophages and other APCs, and allow effective presentation of microbial antigens to cells of the adaptive immune system. However, endogenous ligands have also been identified for a substantial proportion of TLRs. In particular, in SLE, circulating DNA/histone and RNA/protein complexes from apoptotic debris (see above) become endogenous ligands, especially when complexed with autoantibodies. DNA/histone and RNA/protein, once taken up by DCs, engage TLR9 and TLR7 and stimulate DCs to produce large amounts of IFN-α. Indeed, studies from genetically modified mice show that the absence of TLR-9 or TLR-7 dramatically reduces the production of antichromatin or anti-snRNPs, respectively.

IFN-α

There are two major types of IFNs: type I (IFN-α, IFN-β) and type II (IFN-γ, which is secreted only by T cells). IFN-α is secreted by virally infected cells and by plasmacytoid DCs, whereas IFN-β is produced by many types of cells, such as myeloid DCs, following many—not necessarily infectious—stimuli. Type I IFNs share a ubiquitous heterodimeric receptor, mediate innate responses to viral infections and are also required for full DC response to TLRs and their stimulation of T and B cells.

IFN-α strongly stimulates both innate and adaptive immune responses. In lupus in particular, circulating DNA/histone and RNA/protein complexes from apoptotic debris chronically stimulate its production via engagement and activation of TLR7 and TLR9. Experimental manipulations confirm that IFN responsiveness correlates directly with severity of lupus: increased sensitivity to IFN magnifies the disease, while interventions that decrease IFN responses mitigate disease activity. Most lupus patients have increased circulating levels of IFN-α. Levels of expression of many genes that are upregulated by IFN-α are higher in patients with SLE than in normal patients.

CLINICAL FEATURES: Because circulating immune complexes deposit in many tissues, virtually every organ in the body may be involved (Fig. 11-12).

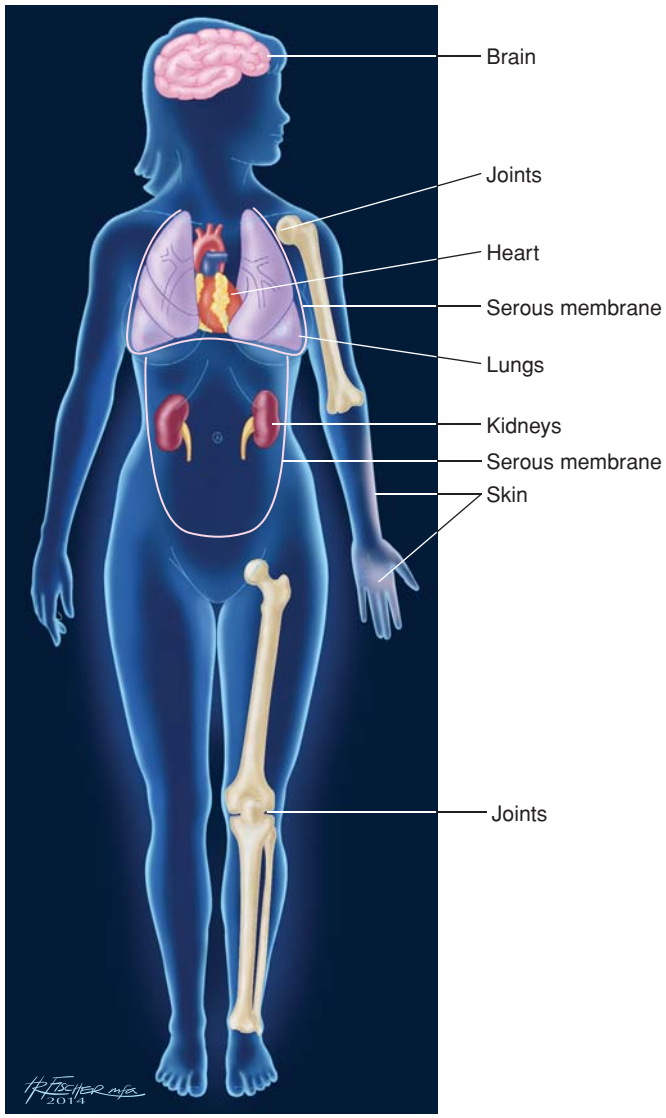

FIGURE 11-12. Organ involvement in systemic lupus erythematosus.

Joint disease is the most common manifestation of SLE; over 90% of patients have polyarthralgia. An inflammatory synovitis occurs, but unlike rheumatoid arthritis, joint destruction is unusual.

Skin involvement (see Chapter 28) is common. An erythematous rash in sun-exposed sites, a malar "butterfly" rash, is characteristic. Microscopically, perivascular lymphoid infiltrates and liquefactive degeneration of the basal cells are seen. Immunofluorescence studies reveal immunoglobulin and complement deposition along the dermal–epidermal junction ("lupus band").

Renal disease, especially glomerulonephritis, affects more than 50% of patients with SLE. Immune complexes that contain IgG antibodies to double-stranded DNA deposit in glomeruli and lead to various forms of glomerulonephritis including mesangial disease, focal proliferative nephritis, diffuse proliferative nephritis and membranous glomerulopathy (see Chapter 22). Although glomerulonephritis is the most common renal manifestation of SLE, interstitial nephritis or vasculitis (rarely) can also been seen. In many cases, immunoglobulins and complement are detectable in the interstitium and in renal blood vessels.

Serous membranes are commonly involved. More than one third of patients have pleuritis and pleural effusions. Pericarditis and peritonitis occur, but less frequently.

Disorders of the respiratory system occur frequently, with clinical manifestations ranging from pleural disease to upper airway and pulmonary parenchymal disease. Pneumonitis is thought to be caused by deposition of immune complexes in alveolar septa and is associated with patchy acute inflammation. Progressive interstitial fibrosis develops in some patients. An increased incidence of pulmonary hypertension has also been observed.

Cardiac involvement (see Chapter 17) is often seen in SLE, although congestive heart failure is rare and is usually associated with myocarditis. All layers of the heart may be involved, with pericarditis being the most common finding. **Libman-Sacks endocarditis,** which is usually not clinically significant, is characterized by small nonbacterial vegetations on valve leaflets. These lesions should be differentiated from the larger, bulkier vegetations of bacterial endocarditis.

Central nervous system (CNS) disease can manifest as psychiatric disease or vasculitis, the latter a life-threatening complication. Vasculitis can lead to hemorrhage and infarction of the brain, which may be fatal.

Antiphospholipid antibodies and antibodies directed against related protein–phospholipid complexes are identified in one third of SLE patients. These findings are associated with thromboembolic complications, including stroke, pulmonary embolism, deep venous thrombosis, portal vein thrombosis and spontaneous abortions.

Other organ involvement is less common and is often due to **vasculitis**. Lesions in the spleen are characterized by thickening and concentric fibrosis of the penicillary arteries, the so-called onion skin pattern.

The clinical course of SLE is extremely variable, typically with exacerbations and remissions. Because of immunosuppressive therapies, better recognition of mild forms of the disease and improved antihypertensive medication, overall 10-year survival approaches 90%. Patients with severe renal or CNS disease or with systolic hypertension have the worst prognosis.

PATHOLOGY: The renal lesions of SLE are largely due to deposition of immune complexes, leading to glomerular inflammation (Fig. 11-13). There is deposition of IgG and complement components in a "lumpy bumpy" pattern, and electron-dense complexes can be visualized using electron microscopy (see Chapter 22). There is T-lymphocyte infiltration of kidneys as well, with a variable amount of interstitial nephritis. Skin lesions are characterized by lymphocytic infiltration and by hydropic degeneration of keratinocytes (see Chapter 30).

There Are Several Variants of Lupus Erythematosus

Drug-Induced Lupus

A lupus-like syndrome may be precipitated in some people by the use of certain medications, notably procainamide (for arrhythmias), hydralazine (for hypertension) and isoniazid (for tuberculosis). Drug-induced lupus ranges from asymptomatic laboratory abnormalities (positive ANA test) to a syndrome clinically similar to SLE. Unlike SLE, drug-induced lupus shows no gender predominance and most patients are over 50 years old. Factors that predispose include large daily doses of the offending drug, slow drug-acetylator status and (in hydralazine-induced lupus) HLA-DR4 genotype. As in SLE, deposition of immune complexes

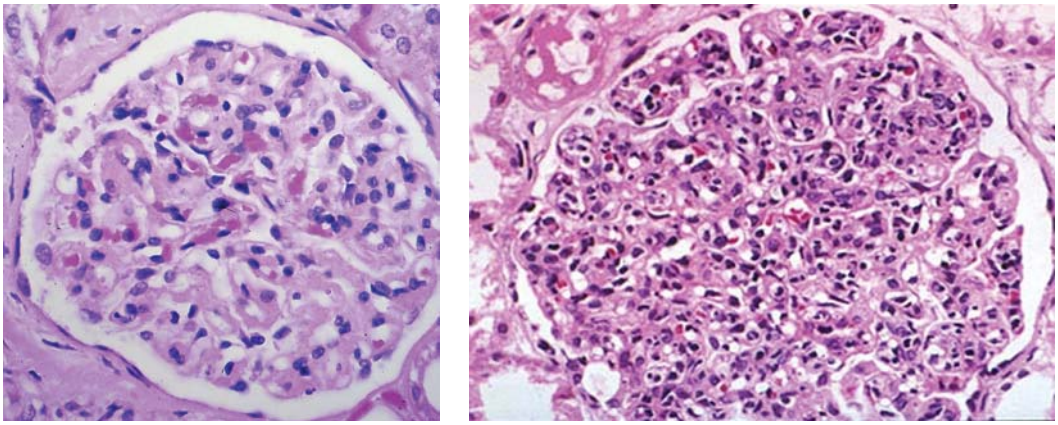

FIGURE 11-13. Glomerulonephritis in systemic lupus erythematosus (SLE). A normal glomerulus is shown at left, highlighting the inflammatory hypercellularity of the glomerulus from a patient with lupus, shown at right.

is a feature of drug-induced lupus. Patients typically exhibit constitutional signs, polyarthritis, pleuritis and antinuclear antibodies. Patients may develop rheumatoid factor, false-positive tests for syphilis and a positive direct antiglobulin (Coombs) test. Renal and CNS involvement rarely occur, and antibodies to double-stranded DNA and Sm antigen are distinctly uncommon. Autoantibodies to histones account for the positive ANA test result and are typical. As in idiopathic SLE, autoreactive $CD4^+$ T cells have been implicated in polyclonal B-cell activation. The syndrome usually resolves when the offending drug is discontinued.

Chronic Discoid Lupus

The most common variety of localized lupus erythematosus is a skin disorder, although identical lesions can occur in some cases of SLE. Erythematous, depigmented and telangiectatic plaques occur most commonly on the face and scalp. Lesional deposition of immunoglobulins and complement at the dermal–epidermal interface is similar to that in SLE. However, unlike SLE, uninvolved skin contains no immune deposits. Although ANAs develop in about one third of the patients, antibodies to double-stranded DNA and Sm antigen are not seen. Most patients with discoid lupus are not otherwise ill, but up to 10% eventually exhibit features of systemic disease.

Subacute Cutaneous Lupus

Subacute cutaneous lupus is characterized by papular and annular lesions, typically on the trunk. The disorder is aggravated by exposure to ultraviolet light, although lesions usually eventually resolve without scarring. Antibodies to SS-A (Ro antigen) (ribonucleoprotein complex) and an association with HLA-DR3 genotype are characteristic.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a systemic autoimmune disease, in which many organs are affected, in addition to the joints. As an inflammatory disorder of the joints, RA has a particular predilection for involvement of the hands and wrists. Patients are usually (3:1) women, with a peak incidence in early middle age. They usually complain of symmetric stiffness and pain in the joints, with swelling and warmth often noted by clinicians. Untreated, the disease can lead to destruction of cartilage and bone, with loss of joint function and considerable disability.

MOLECULAR PATHOGENESIS:

GENETIC FACTORS: A contribution of hereditary factors to RA susceptibility is suggested by the increased frequency of the disease in first-degree relatives of affected patients and by the concordance for the illness in monozygotic twins (15%). In addition, it is generally agreed that certain major histocompatibility genes are expressed in a nonrandom manner in patients with RA. An important genetic locus that predisposes to RA is present in HLA II genes, and a specific set of HLA-DR alleles (DR4, DR1, DR10, DR14) is consistently increased in these patients. These alleles share a pentapeptide sequence motif (shared epitope) in a hypervariable segment of the HLA-DRB1 gene, which forms the peptide-binding pocket on the HLA molecule. It is likely that the binding properties of this pocket influence the type of peptides that can be bound by RA-associated HLA-DR molecules and so affect the immune response to these peptides. Interestingly, seropositive RA (poor prognosis) is associated with a high frequency of an arginine in the shared epitope, whereas seronegative disease (good prognosis) commonly exhibits a lysine in the same position, further suggesting that the physical characteristics of the rheumatoid pocket influence the immune response in RA. Several non-HLA loci have been linked to RA, including a region of chromosome 18q21 that encodes the receptor activator of NFκB, or RANK.

HUMORAL IMMUNITY: Immunologic mechanisms are important in the pathogenesis of RA. Lymphocytes and plasma cells accumulate in the synovium, where they produce immunoglobulins, mainly of the IgG class. In addition, immune complex deposits are present in the articular cartilage and the synovium. Increased serum levels of IgM, IgA and IgG are also seen.

Some 80% of patients with classic RA are positive for rheumatoid factor (RF). RF represents multiple antibodies, mostly IgM, but sometimes IgG or IgA, directed against the Fc fragment of IgG. Significant titers of RF are also found in patients with related collagen vascular diseases, such as systemic lupus erythematosus, progressive systemic sclerosis and dermatomyositis. RF also occurs in many nonrheumatic disorders, including pulmonary fibrosis, cirrhosis, sarcoidosis, Waldenström macroglobulinemia, tuberculosis, kala-azar, lepromatous leprosy and viral hepatitis. Even healthy elderly individuals, particularly women, occasionally test positive for RF.

Although patients with classic RA may be seronegative, the presence of RF in high titer is frequently associated with severe and unremitting disease, many systemic complications and a serious prognosis. The presence of IgG-type RF is sometimes associated with the development of systemic complications, such as necrotizing vasculitis.

Immune complexes (IgG RF + IgG) and complement components are found in the synovium, synovial fluid and extra-articular lesions of patients with RA. Furthermore, patients with seropositive RA have lower levels of complement in their synovial fluid than do those who are seronegative.

Anticitrullinated protein antibody (ACPA) is a recently developed serologic test that, like RF, is positive in 2/3 of cases of RA. The test may be positive even before the onset of clinical disease.

CELLULAR IMMUNITY: It has also been postulated that cell-mediated immunity contributes to RA. Abundant T lymphocytes in rheumatoid synovium are frequently Ia positive ("activated") and of the helper type ($CD4^+$). They are often in close contact with HLA-DR–positive cells, which are either macrophages or dendritic Ia-positive cells.

T cells may directly or indirectly interact with macrophages through production of cytokines that inhibit migration and proliferation of the latter. Such substances have been found in rheumatoid synovial fluid and in supernatants from rheumatoid tissue explants. These studies provide strong evidence that joint destruction in RA reflects local production of cytokines, especially TNF-α and IL-1.

INFECTIOUS AGENTS: Infectious bacteria and viruses are not detected in joints of patients with RA, although structures resembling viruses have been reported early in the disease. Most patients with RA develop antibodies against a nuclear antigen in B cells infected with EBV. This antigen, RA-associated nuclear antigen (RANA), is closely related

to the nuclear antigen encoded by EBV (EBNA). Moreover, EBV is a polyclonal B-cell activator that stimulates production of RF. Interestingly, the blood of many patients with RA has increased numbers of EBV-infected B cells.

LOCAL FACTORS: Synovial cells cultured from rheumatic joints exhibit a decreased response to glucocorticoids and increased production of hyaluronate. These cells release a peptide (connective tissue–activating peptide) that may influence the function of other cells, producing increased amounts of prostaglandins, particularly PGE2.

A hypothetical scenario consistent with the evidence presented earlier might be constructed as follows:

1. In a genetically susceptible person, an unknown agent (possibly a virus, such as EBV) infects a joint or some other tissue and stimulates antibody formation.
2. These immunoglobulins act as new antigens, triggering production of anti IgG antibodies (RF).
3. Immune complexes containing RF are deposited in the synovium and activate complement. This increases vascular permeability and uptake of immune complexes by leukocytes, which in turn release lysosomal enzymes, activated oxygen species and other injurious products.
4. Activated macrophages in the synovium present unknown antigens to T cells, thus stimulating production of cytokines, which amplify inflammation, tissue injury and synovial cell proliferation.

CLINICAL FEATURES: RA patients suffer from joint pain and stiffness. As the disease progresses, inflammation is accompanied by loss of bone and cartilage and with progressive loss of motion and instability in the joints. Involvement of weightbearing joints like the hips and knees may lead to difficulty with gait and to increased immobility. RA inflammation outside the joints can present as subcutaneous nodules and occasionally nodules in the lungs; to pericarditis and pleurisy; to inflammation of the conjunctivae and sclera, sometimes accompanied by diffuse eye inflammation; to skin vasculitis with troublesome ulcerations; to anemia and decreased numbers of circulating neutrophils; and to secondary Sjögren syndrome, with infiltration of salivary and lacrimal glands with lymphocytes leading to dry mouth and eyes (see below for primary Sjögren syndrome) (Fig. 11-14).

PATHOLOGY: The synovium (see Chapter 30) is normally a delicate layer of just a few cells that lines the joints and secretes lubricating synovial fluid. In RA, dense infiltrates of inflammatory cells (lymphocytes, macrophages, DCs) cause dramatic enlargement of the synovium, and there is frequently production of large amounts of inflammatory joint fluid leading to joint effusions. Swelling and pain are noted by patients, together with stiffness, particularly upon arising. Along with activated immune cells, fibroblast-like synoviocytes contribute to the process through their secretion of proteolytic enzymes (matrix metalloproteinases, collagenases), which aid in cartilage destruction. Occasionally, leukocytoclastic vasculitis is seen in extra-articular sites, primarily skin.

VASCULITIDES

Vasculitis is a term for a broad category of diseases characterized by inflammation of blood vessels of different types (see Chapter 16), leading to pathology because of the impairment of blood flow to tissues. This group of diseases is generally subdivided depending on the caliber of blood vessel involved and on whether there is an associated rheumatic disease. Thus, both SLE and RA can be associated with vasculitis, which is also seen in dermatomyositis (see below), especially in children. Vasculitis is seen in conjunction with a number of infections, particularly viral infections, and as a consequence of taking certain drugs. Vasculitides that are not associated with systemic autoimmune diseases are discussed in Chapter 16. Vasculitic processes that are part of a constellation of particular diseases are addressed in sections that cover those specific diseases.

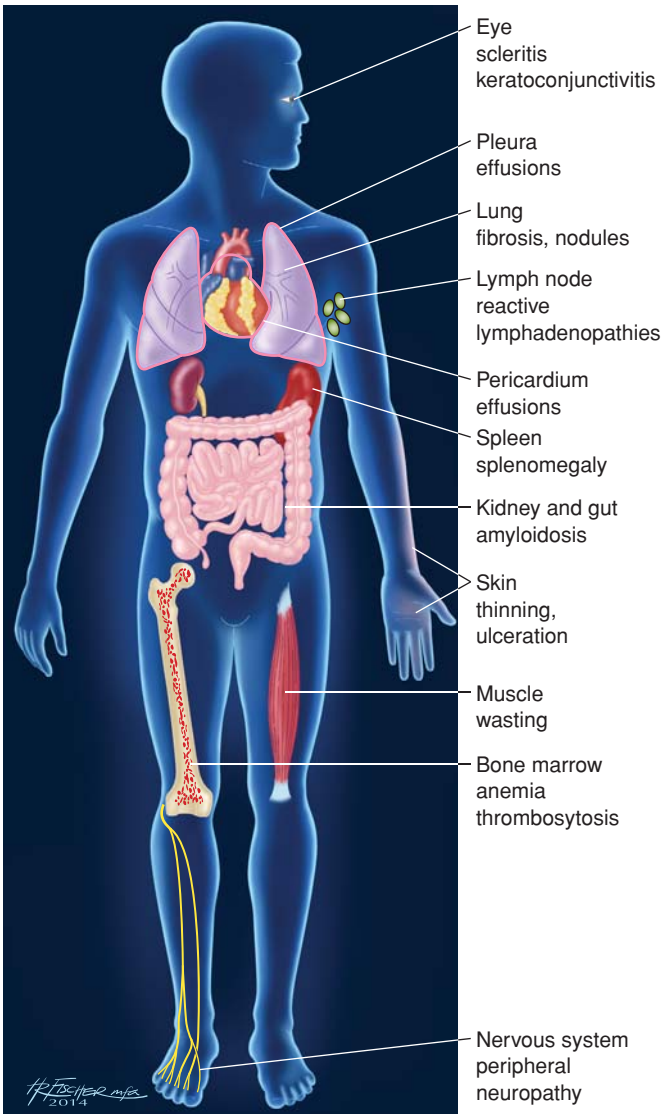

FIGURE 11-14. Organ involvement in rheumatoid arthritis.

SJÖGREN SYNDROME

This disease is marked by lymphocytic infiltration of exocrine glands, primarily salivary and lacrimal glands, leading to dry mouth **(xerostomia)** and dry eyes (**xerophthalmia** or **keratoconjunctivitis sicca**). It exists as a single entity (primary Sjögren syndrome [SS]) or together with other systemic

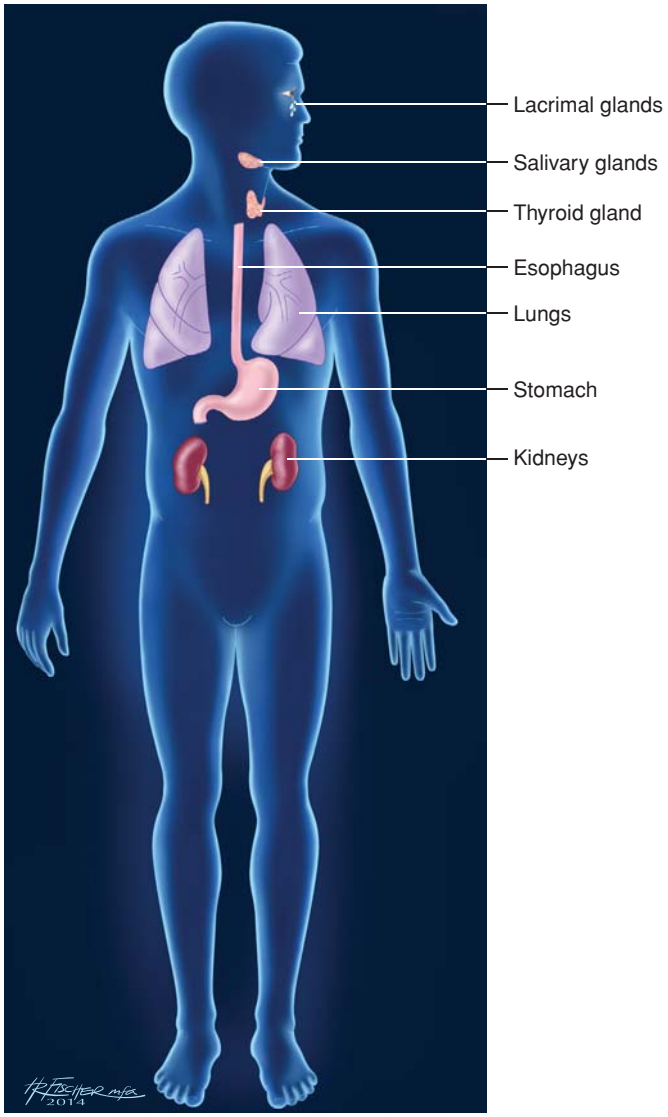

FIGURE 11-15. Organ involvement in Sjögren syndrome.

autoimmune diseases such as SLE and RA. Primary SS is also frequently associated with involvement of other organs, including the thyroid, lungs and kidneys (Fig. 11-15). The primary form of the disease most commonly begins in late middle age and patients are overwhelmingly female.

PATHOPHYSIOLOGY: The basis of lymphocyte accumulation in Sjögren disease is unknown. The majority of lymphocytes found in glands are $CD4^+$, with a significant $CD8^+$ minority. B cells are also present, with occasional germinal centers. It has been proposed that the primary abnormality is autoimmunity to salivary epithelial cells. Most patients with primary Sjögren disease produce antibodies to the cytoplasmic RNA-associated proteins SS-A (Ro) and SS-B (La). Antinuclear antibodies are frequently present, as is rheumatoid factor.

Autoantibodies to DNA or histones are rare; their presence suggests secondary SS associated with lupus. Organ-specific autoantibodies (e.g., against salivary gland antigens) are quite uncommon. As in SLE, it is controversial whether autoantibodies in SS mainly reflect polyclonal B-cell activation or are chiefly antigen driven, although these processes are not mutually exclusive.

SS has become the focus for investigation of possible viral etiology for autoimmune disease. Particular attention has been paid to possible roles of EBV and human T-cell leukemia virus-1 (HTLV-1). Although difficult to assign a role for EBV in the pathogenesis of SS, there is evidence that reactivation of this virus may be involved in perpetuating SS, polyclonal B-cell activation and development of lymphoma. In Japan, seropositivity for HTLV-1 among patients with SS is 23%, compared with 3.4% among unselected blood donors. Conversely, more than three quarters of HTLV-1–seropositive people have evidence of SS.

PATHOLOGY: Sjögren syndrome is characterized by intense lymphocytic infiltrates in salivary and lacrimal glands (see Chapter 29 and Fig. 11-16). Lymphocytic infiltrates are initially periductal. Most lobules are affected, especially the centers. Well-defined germinal centers are rare. The lymphoid infiltrates destroy acini and ducts; the latter often become dilated and filled with cellular debris. Preservation of glandular stroma helps distinguish SS from lymphoma. The lymphocytic infiltrates are predominantly $CD4^+$ T cells admixed with some B cells. Late in disease, affected glands atrophy and may be replaced by hyalinized fibrotic tissue. Owing to the absence of tears, corneas can become dry and fissured, and may ulcerate. Lack of saliva causes atrophy, inflammation and cracking of the oral mucosa. The pathology of the salivary and lacrimal glands is described in greater detail in Chapter 29.

Involvement of extraglandular sites is also common in SS. Pulmonary disease occurs in many patients, particularly

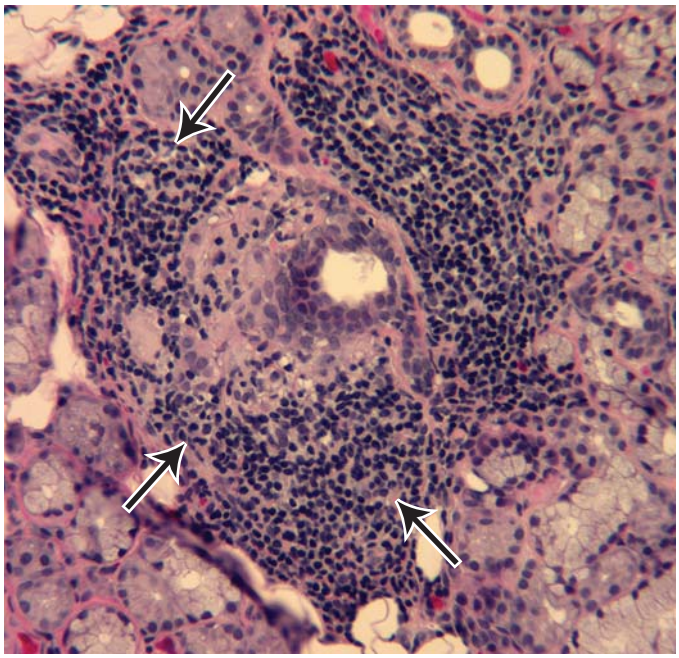

FIGURE 11-16. Histologic appearance of salivary glands in Sjögren syndrome. Note the infiltration of lymphocytes into the salivary gland tissue (*arrows*).

bronchial gland atrophy in association with lymphoid infiltration. Pulmonary SS is accompanied by thick tenacious secretions, focal atelectasis, bronchiectasis and recurrent infections. The gastrointestinal tract can be affected, and many patients have difficulty swallowing (dysphagia). Esophageal submucosal glands are infiltrated by lymphocytes. In addition, atrophic gastritis occurs secondary to lymphoid infiltration of the gastric mucosa. Liver disease, especially primary biliary cirrhosis, is present in 5%–10% of patients with SS and is associated with nodular lymphoid infiltrates and destruction of intrahepatic bile ducts (see Chapter 20). Interstitial nephritis and chronic thyroiditis occasionally accompany SS. SS is associated with a 40-fold increased risk of lymphoma, probably through B-cell clonal expansion.

CLINICAL FEATURES: Patients with Sjögren syndrome suffer the consequences of lack of tears and saliva. They complain of eye discomfort and can develop ulcerations and infections of the cornea and conjunctivae. Dry mouth symptoms are sometimes accompanied by increased dental caries and by thrush or other mouth infections. Lymphocytic infiltration of other glandular tissue can lead to dry skin and dryness in the female reproductive tract. Patients may develop extraglandular disease, with lymphocytic infiltration leading to impaired clearance of respiratory mucus and to interstitial lung and kidney disease. Hypergammaglobulinemia can lead to vasculitis, and some patients develop CNS involvement with transverse myelitis or cranial neuropathies. Patients are at a much greater risk of developing B-cell lymphomas.

SYSTEMIC SCLEROSIS (SCLERODERMA)

Systemic sclerosis is a systemic autoimmune disease of unknown origin characterized by excessive deposition of collagen and other connective tissue macromolecules in the skin and multiple internal organs (Fig. 11-17), prominent and often severe alterations in the microvasculature and humoral and cellular immunologic abnormalities. Systemic sclerosis is a complex and heterogeneous disease with clinical forms ranging from limited skin involvement with minimal systemic alterations (**limited cutaneous systemic sclerosis,** previously known as CREST syndrome; see below) to forms with diffuse skin sclerosis and severe and often progressive internal organ involvement **(diffuse cutaneous systemic sclerosis)**, and occasionally a fulminant course **(fulminant systemic sclerosis)**. Systemic sclerosis is the third most common systemic autoimmune disease (following rheumatoid arthritis and systemic lupus erythematosus) and is 3–8 times more frequent in women, with a peak occurrence from 40 to 50 years of age. Although systemic sclerosis is not inherited, it is accepted that genetic predisposition plays an important role in its development. Familial clusters have been reported, and there is an association between HLA-DQB1 and the characteristic autoantibodies.

Patients with Scleroderma Exhibit Abnormalities of Humoral and Cellular Immune Systems

There are normal numbers of circulating B lymphocytes, but hypergammaglobulinemia and cryoglobulinemia suggest

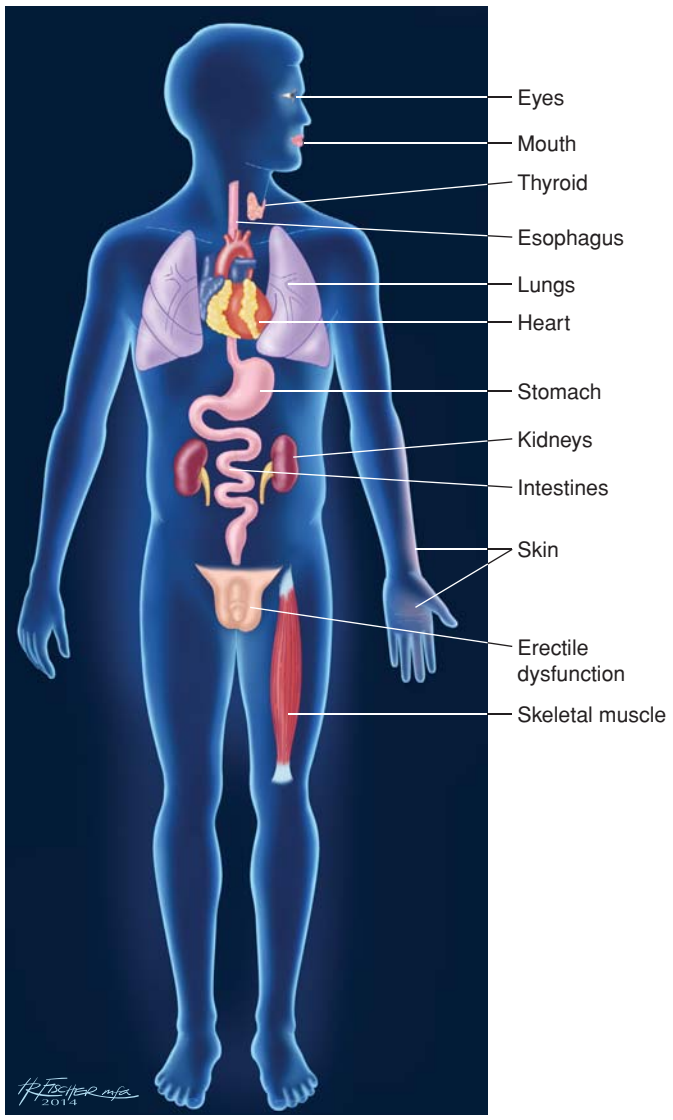

FIGURE 11-17. Organ involvement in systemic sclerosis.

that they may be hyperactive. The presence of specific antibodies is one of the most common manifestations of systemic sclerosis, and they are present in over 90% of patients. ANAs are common but usually at lower titers than in SLE. Commonly found antibodies include nucleolar autoantibodies (primarily against RNA polymerase). Antibodies to Scl-70, a nonhistone nuclear protein topoisomerase, are found in 30%–40% of patients with the diffuse form of systemic sclerosis. Anticentromere antibodies are associated with the CREST variant (see below). The Scl-70 autoantibody is the most common and specific for diffuse scleroderma, seen in 60% of patients. There is no correlation between ANA titer and disease severity. Rheumatoid factor is commonly present, as are autoantibodies against other tissues, such as smooth muscle, thyroid and salivary glands. Antibodies to collagen types I and IV have also been described.

Although autoantibodies are common in systemic sclerosis, they do not cause the clinical manifestations of the disease. However, owing to their high frequency and to their specificity for certain clinical subsets of the disease, their presence is very helpful to establish the diagnosis and to

predict a likely pattern of organ involvement, severity and progression of systemic sclerosis.

Cellular immune derangements are also seen in patients with progressive systemic sclerosis. Reduced circulating $CD8^+$ T suppressor cells, evidence of T-cell activation, alterations in functions mediated by IL-1 and elevated IL-2 and soluble IL-2 receptor occur in active disease. Increased levels of IL-4 and IL-6 have also been described. Tissues show active mononuclear inflammation, which precedes development of the vasculopathy and fibrosis characteristic of this disease. The infiltrates contain increased numbers of $CD4^+$ and γδ-T cells (which adhere to fibroblasts), as well as macrophages. Mast cells (degranulated) are also present in the skin of scleroderma patients. The incidence of other autoimmune disorders, such as thyroiditis and primary biliary cirrhosis, is increased.

PATHOPHYSIOLOGY: The pathogenesis of systemic sclerosis is extremely complex and the exact mechanisms involved are not well understood. The clinical and pathologic manifestations of systemic sclerosis result from three distinct processes: (1) fibroproliferative vascular lesions of small arteries and arterioles, (2) excessive and often progressive deposition of collagen and other extracellular matrix macromolecules in skin and various internal organs and (3) alterations of humoral and cellular immunity. The immunologic alterations include innate immunity abnormalities, tissue infiltration with macrophages and T and B lymphocytes, production of numerous disease-specific autoantibodies and dysregulation of cytokine, chemokine and growth factor production. It is not clear which of these processes is of primary importance or how they are temporally related during the development and progression of the disease.

Unknown etiologic factors trigger a sequence of pathogenetic events initiated by a genetically receptive host. These entail microvascular injury, characterized by structural and functional endothelial cell abnormalities. The endothelial cell abnormalities result either in increased production and release of many potent mediators including cytokines, chemokines, polypeptide growth factors and various other substances such as prostaglandins, reactive oxygen species (ROS) and thrombogenic and procoagulant activities, or in the reduction of important compounds such as prostacyclin and nitric oxide. The endothelial cell dysfunction allows chemokine- and cytokine-mediated attraction of inflammatory cells and fibroblast precursors from the bloodstream and bone marrow. These cells transmigrate into the surrounding tissues to establish a chronic inflammatory process with participation of macrophages and T and B lymphocytes.

These cells produce and secrete additional cytokines and growth factors. As a result, resident fibroblasts, epithelial cells, endothelial cells and pericytes become activated and undergo a phenotypic conversion into myofibroblasts (Fig. 11-18). This sequence of events causes a severe and often progressive fibroproliferative vasculopathy, vessel rarefaction and exaggerated and widespread accumulation of fibrotic tissue, the hallmark of the fibrotic process characteristic of the disease.

Vascular Dysfunction Is One of the Earliest Manifestations of Systemic Sclerosis

This is heralded by Raynaud phenomenon. This episodic circulatory compromise in the distal extremities, particularly the hands, often triggered by exposure to cold, is accompanied by nailfold capillary microvascular alterations that often precede any clinical evidence of tissue fibrosis.

The initial events responsible for the vascular and endothelial cell injury and subsequent activation are not known. Numerous putative etiologic factors have been suggested, including vasculotropic viral pathogens, antiendothelial cell antibodies, cellular products from inflammatory cells

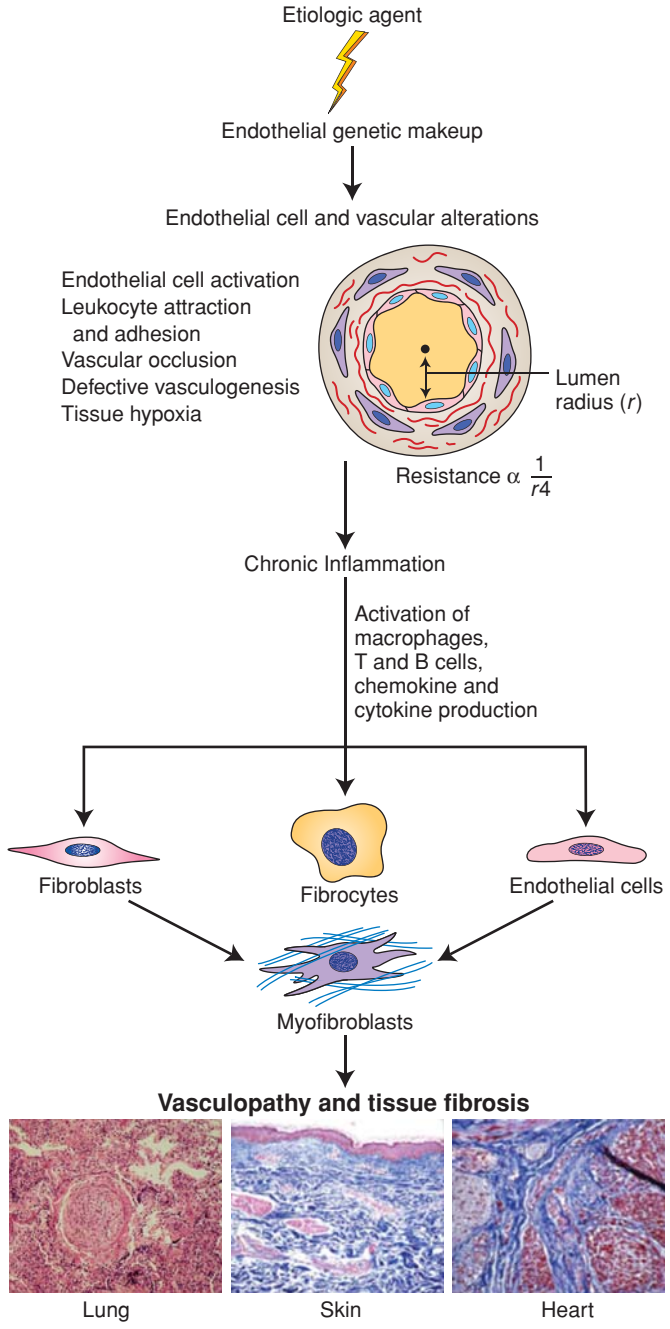

FIGURE 11-18. Involvement of endothelial cell and vascular alteration in the pathogenesis of systemic sclerosis.

or ROS generated during episodes of ischemia/reperfusion. Endothelial cell activation induces expression of chemokine and cell adhesion molecules, causes transendothelial cellular migration and leads to perivascular accumulation of immunologic/inflammatory cells. The latter include T and B lymphocytes and various macrophage populations. These produce and secrete diverse cytokines and/or growth factors, including transforming growth factor-β (TGF-β) and other profibrotic mediators such as endothelin-1, which stimulate smooth muscle cell proliferation and marked accumulation of subendothelial fibrotic tissue and initiation of platelet aggregation. They also trigger intravascular thrombosis, eventually leading to microvascular occlusion. The effects of vascular dysfunction in patients with systemic sclerosis are most dramatic when they involve the pulmonary and renal arterioles, causing renal crisis and pulmonary hypertension, respectively.

Myofibroblasts Are the Effector Cells in Systemic Sclerosis Tissue Fibrosis

The fibrotic process is the most notable characteristic of systemic sclerosis and causes most of its clinical manifestations (Fig. 11-17). This crucial component results from the accumulation in skin and other affected tissues of myofibroblasts derived from several sources: proliferation and activation of tissue fibroblasts or perivascular and vascular adventitial fibroblasts; chemokine-driven recruitment of fibroblast precursor cells from the bone marrow; transdifferentiation of epithelial cells to myofibroblasts via epithelial-to-mesenchymal transition (EMT; see Chapter 5); and other cellular transitions in which endothelial cells acquire mesenchymal phenotypes.

This increased population of myofibroblasts produces more fibrillar type I and type III collagens and expresses α-smooth muscle actin. They also produce less extracellular matrix (ECM)-degradative enzymes. Accumulation of myofibroblasts in affected tissues and the uncontrolled persistence of their elevated biosynthetic functions are crucial determinants of the extent and rate of progression of the fibrotic process in systemic sclerosis and of its clinical course, response to therapy, prognosis and mortality.

Role of TGF-β

A growth factor that plays a crucial role in the fibrosis that accompanies systemic sclerosis is TGF-β (Fig. 11-19). It also decreases production of collagen-degrading metalloproteinases while simultaneously upregulating production of protease inhibitors, which prevent ECM breakdown. The pathways involved in the activation of collagen genes following TGF-β binding to target cell surface receptors are schematically depicted in Fig. 11-19.

Connective tissue growth factor (CTGF) also plays a key role in systemic sclerosis–associated tissue fibrosis. TGF-β strongly stimulates CTGF synthesis in fibroblasts, vascular smooth muscle cells and endothelial cells. It magnifies the profibrotic phenotype and also enhances its own production via an autocrine loop. It thus maintains a continuous, prolonged cycle of excessive fibrosis.

PATHOLOGY: Sclerodermatous skin initially reveals edema, then induration. The thickened skin exhibits a striking increase in collagen fibers in the reticular dermis; thinning of the epidermis with loss of rete pegs; atrophy of dermal appendages (Fig. 11-20A); hyalinization and obliteration of arterioles; and variable mononuclear infiltrates, primarily of T cells. The stage of induration may progress to atrophy or revert to normal. Increased collagen deposition can also occur in the synovia, lungs, gastrointestinal tract, heart and kidneys.

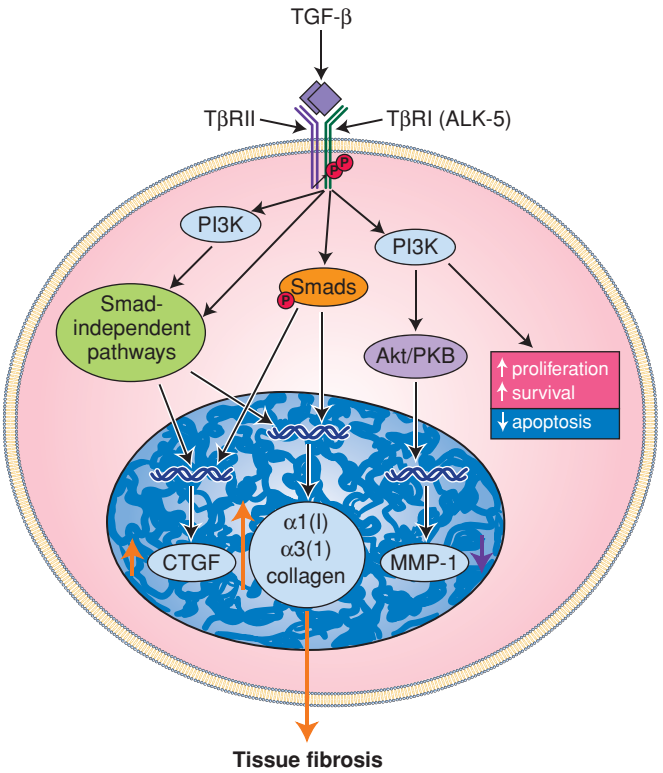

FIGURE 11-19. Involvement of transforming growth factor-β (TGF-β) in systemic sclerosis. Fibrogenic pathways are stimulated by TGF-β, and production of enzymes that degrade collagen is inhibited by TGF-β. Signaling pathways that are both independent of and that involve Smads may be involved in mediating these effects. *PI3K* = phosphoinositol-3-kinase; *CTGF* = connective tissue growth factor; *MMP-1* = matrix metalloproteinase-1.

Lesions in arteries, arterioles and capillaries are typical, and in some cases may be the first demonstrable pathology. Initial subintimal edema with fibrin deposition is followed by thickening and fibrosis of the vessel wall and reduplication or fraying of the internal elastic lamina. Involved vessels may become severely narrowed or occluded by thrombi.

The kidneys, involved in more than half of patients, show marked vascular changes, often with focal hemorrhage and cortical infarcts (see Chapter 22). The interlobular arteries and afferent arterioles tend to be the most severely affected vessels. Early fibromuscular thickening of the subintima causes luminal narrowing, followed by fibrosis (Fig. 11-20B). Fibrinoid necrosis is commonly seen in afferent arterioles. Glomerular alterations are nonspecific, and focal changes range from necrosis extending from the afferent arterioles to fibrosis. Early in disease, there is diffuse deposition of immunoglobulin, complement and fibrin in affected vessels, probably because of increased vascular permeability.

Heightened pulmonary vascular reactivity ("pulmonary Raynaud phenomenon") and, later, hypertension and

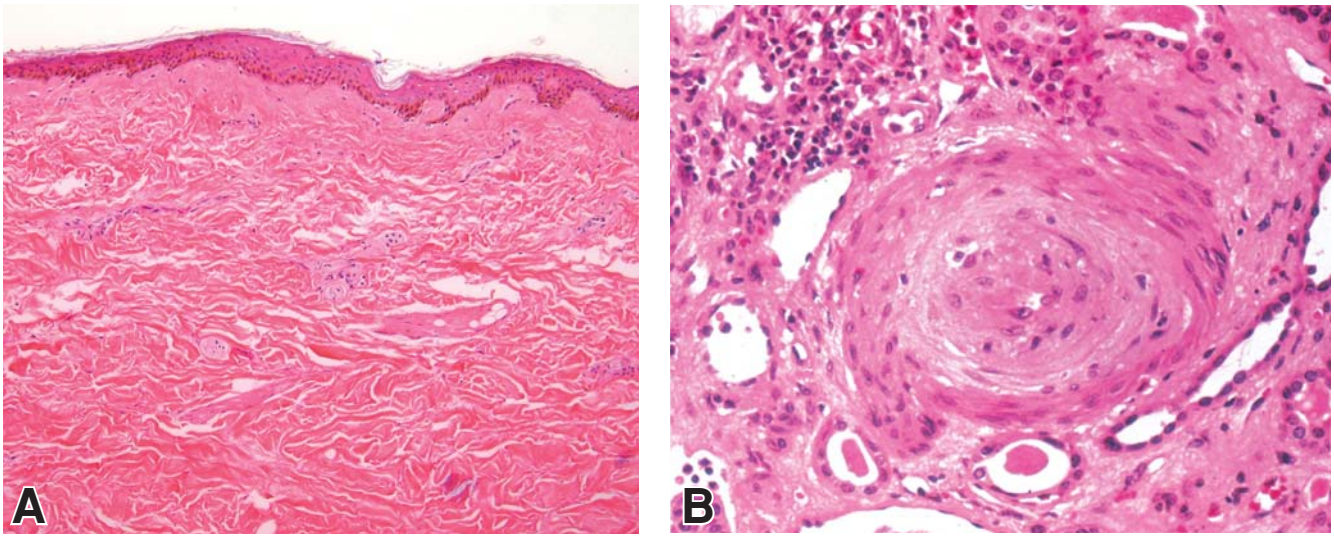

FIGURE 11-20. Histologic appearance of systemic sclerosis. A. Dermal fibrosis is characteristic of scleroderma. Dense collagen accumulation occurs beneath the epidermis. Note the absence of dermal appendages. **B.** Scleroderma that affects the kidney is manifested by vascular involvement. Here, the interlobular artery exhibits marked luminal narrowing due to pronounced intimal thickening.

diffuse interstitial fibrosis are the primary lung abnormalities. Pulmonary disease can progress to end-stage fibrosis, so-called honeycomb lung (see Chapter 18).

Most patients with scleroderma have patchy myocardial fibrosis, and in about one fourth of cases, more than 10% of the myocardium is involved. These lesions result from focal myocardial necrosis, which may reflect focal ischemia secondary to Raynaud-like reactivity of cardiac microvasculature.

Progressive systemic sclerosis can also involve any portion of the gastrointestinal tract. Esophageal dysfunction is the most common and troublesome gastrointestinal complication. Atrophy and fibrous replacement of smooth muscle are seen in the lower esophagus. The small bowel often exhibits patchy fibrosis of the muscular layers.

CLINICAL FEATURES: The most apparent and almost universal clinical features of systemic sclerosis are related to the progressive thickening and fibrosis of the skin. Scleroderma manifests as two distinct clinical syndromes, a generalized or diffuse **(progressive systemic)** form and a **limited variant**. Progressive systemic sclerosis (diffuse scleroderma) is characterized by severe and progressive disease of skin and early onset of all or most of the associated abnormalities of visceral organs. Symptoms usually begin with Raynaud phenomenon, namely, intermittent episodes of ischemia of the fingers, marked by triphasic color changes, paresthesias and pain. Raynaud phenomenon is accompanied or followed by edema of the fingers and hands, thickening and tightening of the skin, polyarthralgia and involvement of specific internal organs. The affected skin is tight, indurated and firmly bound to the subcutaneous tissue. The skin over the hands and face is most frequently involved, and as the disease progresses, the sclerotic changes extend and may affect the entire body.

The typical patient with generalized scleroderma exhibits "stone facies," owing to tightening of facial skin and restricted motion of the mouth. Progression of vascular lesions in the fingers leads to ischemic ulceration of the fingertips, with subsequent shortening and atrophy of the digits. Many patients suffer from painful tendonitis and joint pain.

OTHER ORGAN INVOLVEMENT. Musculoskeletal symptoms are often the first manifestations of the disease. Severity may vary from mild polyarthralgias to more severe arthralgias, but synovitis and frank arthritis are rare. In more advanced stages, thickening and fibrosis of periarticular tissues result in severe joint flexion contractures and distal phalangeal resorption also known as **acroosteolysis**. Muscle infiltration with fibrotic tissue may lead to an inflammatory myopathy or a more indolent noninflammatory form.

The gastrointestinal tract is the internal organ system most commonly involved. Esophageal involvement is almost universal, with symptoms of gastroesophageal reflux, heartburn and dysphagia due to dysfunctional esophageal sphincter motility. In severe cases, stricture may result. Impaired gastric emptying and small intestine peristalsis may cause distention, bloating, nausea and pain. Bacterial overgrowth may lead to secondary malabsorption and diarrhea.

Pulmonary involvement frequently leads to severe respiratory disability and is the most common cause of death. Patients develop progressively worsening tachypnea and exertional dyspnea, secondary to pulmonary fibrosis and/or pulmonary hypertension. The former usually develops early in the disease, but pulmonary hypertension is most commonly a late complication.

Cardiac involvement is not uncommon and may manifest as chest pain, arrhythmias and conduction defects. Infiltrative cardiomyopathy may cause left ventricular or biventricular failure. Cor pulmonale can develop in patients with pulmonary hypertension.

"Scleroderma renal crisis," as the renal disease may be known, typically begins abruptly, with malignant hypertension and rapidly progressive renal insufficiency. It is often heralded by severe headache, hypertensive retinopathy, seizures and other central nervous system symptoms, and/or myocardial ischemia, infarction or left ventricular failure. Prompt aggressive treatment can usually reverse this process, which otherwise is often fatal or may cause renal failure.

Functional thyroid abnormalities including elevated levels of antithyroid autoantibodies and clinical and subclinical hypothyroidism are common. Impotence caused by erectile failure may be an early feature of systemic sclerosis, and some degree of erectile dysfunction ultimately develops in many systemic sclerosis patients. Patients may develop the sicca syndrome (keratoconjunctivitis sicca and xerostomia) caused by fibrosis and lymphocytic infiltration of the salivary and lacrimal glands.

CREST. In many cases, the cutaneous involvement is confined to the digits and the dorsum of the hands and feet (acrosclerosis), and progression of the sclerotic process is relatively slow. This form of disease, previously known as the CREST syndrome (acronym for calcinosis, long-standing Raynaud phenomenon, esophageal dysmotility, sclerodactyly and telangiectases) is now known as limited systemic sclerosis to differentiate this clinical presentation from a more severe form with extensive cutaneous involvement. This latter form is known as diffuse systemic sclerosis. Other cutaneous manifestations include skin ulcerations, usually localized to fingertips or knuckles, and peculiar pigmentary changes with hyper- and hypopigmentation. Calcinosis is most commonly found in the fingertips and periarticular tissues. Many patients with CREST have circulating anticentromere antibodies.

MIXED CONNECTIVE TISSUE DISEASE

As suggested by the name, mixed connective tissue disease (MCTD) patients exhibit features of several different collagen vascular diseases including SLE, scleroderma and polymyositis. The exact incidence of MCTD is unclear. Between 80% and 90% of patients are female, and most are adults (mean age, 37 years). Findings characteristic of SLE include rash, Raynaud phenomenon, arthralgias and arthritis. Characteristics of scleroderma include swollen hands, esophageal hypomotility and pulmonary interstitial disease. Some patients also develop symptoms suggestive of rheumatoid arthritis. Patients with MCTD have been reported to respond well to corticosteroid therapy, although some studies have challenged this assertion.

The pathogenesis of MCTD is poorly understood. Patients often have evidence of B-cell activation with hypergammaglobulinemia and rheumatoid factor. ANAs are present but, differently from SLE, do not usually bind double-stranded DNA. The most distinctive ANA is directed against an extractable nuclear antigen. Specifically, patients with MCTD have high titers of antibody to uridine-rich ribonucleoprotein (anti-U1-RNP) in the absence of other extractable nuclear antigens, including PM-1 and Jo-1. Most diagnostic criteria for MCTD include high-titer anti-U1-RNP ANA as a sine qua non. Anti-RNP antibodies may be detected in SLE, but in much lower titers than in MCTD.

The cause of high titers of anti-U1-RNP antibody is unclear. However, there is an association with HLA-DR4 and HLA-DR2 genotypes, suggesting a role for T cells in autoantibody production. There is no direct evidence that these antibodies participate in the development of any of the characteristic lesions of MCTD.

There is controversy whether MCTD is a separate disease or a heterogeneous collection of patients with nonclassical presentations of SLE, scleroderma or polymyositis. For example, in some patients, MCTD seems to evolve into typical scleroderma; other patients develop renal disease similar to that seen in SLE; still others develop features of rheumatoid arthritis. Thus, MCTD may be an intermediate stage in the progression to another recognized autoimmune disease. Patients whose disease remains undifferentiated may constitute a distinct subset. Thus, it remains unclear whether MCTD is a distinct entity or simply an overlap of findings in patients with other types of collagen vascular disease.

Physiologic Responses to SIRS/Sepsis

DEFINITIONS

Systemic Inflammatory Response Syndrome Is a Bodily Reaction to a Broad Range of Insults

The insults that elicit systemic inflammatory response syndrome (SIRS) reactions include—but are not limited to—trauma, ischemia, inflammation and infection. Multiple insults may contribute simultaneously to the development of SIRS. Therefore, the triggering stimuli for the development of SIRS need not be specific and may represent combinations of multiple processes acting concurrently to initiate protective mechanisms for human self-defense. The American College of Chest Physicians and the Society of Critical Care Medicine Consensus Conference defined the terms "SIRS," "sepsis," "severe sepsis," "septic shock," and "multiple organ dysfunction syndrome (MODS)" in 1992 to standardize the classification of the human response to infection. The relationship between the conditions is represented in Fig. 12-1. The definition of SIRS requires that two or more of the abnormal findings described in Table 12-1 be present.

Should these criteria be met, and if an infection is documented in the patient, **sepsis** is the appropriate diagnosis. Sepsis represents the body's systemic inflammatory reaction to a documented or suspected infection. A patient's inability to eradicate pathogens can cause them to spread systemically and damage normal tissues and organ systems that are distant from the original insult.

Sepsis can progress to severe sepsis with clinical features of hypoperfusion including lactic acidosis, oliguria or acute change in mental status. If hypotension with perfusion abnormalities occurs despite adequate fluid replenishment, then septic shock develops along the continuum of worsening severity in sepsis. In a study of 3500 septic patients, mortality ranged from 25% in sepsis, to 40% in severe sepsis, to 60% in septic shock. MODS is defined as progressive organ dysfunction in critically ill patients with physiologic dysregulation leading to impaired homeostasis. Mortality strongly correlates with organ dysfunction, so that the more organs that fail, the greater the mortality. If five organs fail, mortality may exceed 80%.

EPIDEMIOLOGY: The incidence of sepsis is increasing despite advances in intensive care management and significant resource utilization allocated to caring for septic patients. Hospitalizations for sepsis in the United States have more than doubled, to over 725,000 in an 8-year period. There are now more than 200,000 deaths from sepsis per year. Sepsis is the leading cause of mortality in noncoronary intensive care units (ICUs) and the 11th most common cause of death in the United States. It affects nearly 20 million people globally, and its incidence is anticipated to rise owing to a constellation of factors. These include increasing antimicrobial resistance to available antimicrobial therapies, an aging population, the prevalence and frequency of use of immunosuppressive medications, infectious diseases like HIV/AIDS that compromise the

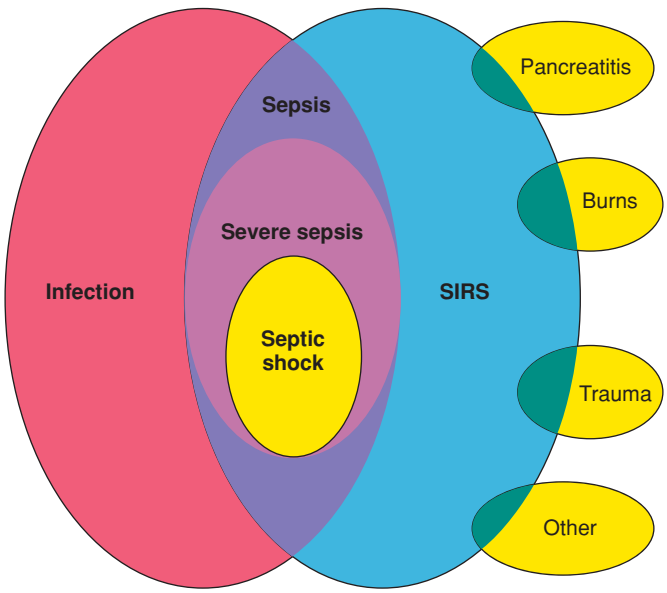

FIGURE 12-1. Venn diagram demonstrating the relationship between systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis and septic shock. After Bone, et al., *Chest,* 1992;101(6):1644–1655.

TABLE 12-1
DIAGNOSTIC CRITERIA FOR SIRS, SEPSIS, SEVERE SEPSIS AND SEPTIC SHOCK

Systemic Inflammatory Response Syndrome (SIRS) (two or more of the following abnormalities)
Temperature >38.5°C or <35°C
Heart rate >90 beats per minute
Respiratory rate >20 breaths per minute or $PaCO_2$ <32 mm Hg
White blood cell count >12,000 cells/mm^3 or <4,000 cells/mm^3 or >10% bands
Sepsis
SIRS with a documented or suspected infection
Severe Sepsis
Sepsis with organ dysfunction, hypoperfusion or hypotension
Septic Shock
Sepsis-induced hypotension (systolic blood pressure <90 mm Hg or drop of ≥40 mm Hg from baseline) despite adequate fluid resuscitation with inadequate perfusion
Multiple Organ Dysfunction Syndrome (MODS)
Physiologic dysregulation in a critically ill patient in which impaired homeostasis manifests as organ dysfunction

immune system and more widely available health care technologies and interventions.

Even though there has been an overall reduction in the proportional mortality from sepsis, the total number of deaths from sepsis is greater than in the past as more individuals are affected. Survival studies in sepsis usually monitor patients for 28 days. This contrasts with, for example, most cancer trials, which evaluate 5-year survival. Such a juxtaposition underscores the acutely damaging and life-threatening nature of sepsis. A hospitalized patient with severe sepsis has a greater risk of death than a patient admitted for acute myocardial infarction or stroke. Advancements in supportive care for sepsis continue to reduce early deaths, but initial sepsis survivors often suffer from functional deficits and reduced quality of life, as well as being at risk for higher long-term mortality.

Severe sepsis most frequently occurs in children younger than 1 year and elderly patients who are older than 65 years. In this context, the elderly represent only 12% of the U.S. population but account for over 65% of sepsis cases. Older age is an independent predictor of mortality in sepsis. Compared to younger people, elderly patients are more likely to have medical comorbidities and earlier mortality during hospitalization for sepsis. The most common comorbidities seen in septic patients overall are diabetes mellitus, chronic obstructive pulmonary disease, cancer, end-stage renal disease, HIV/AIDS and cirrhosis. Sepsis survivors older than 65 years more often need considerable nursing and/or rehabilitative care upon discharge. With the average age of the U.S. population rising, the incidence of sepsis is predicted to increase.

TRIGGERS OF SEPSIS

Infection in Any Part of the Body May Lead to Sepsis

The most common site of sepsis-related infection is the lungs. Over 40% of septic patients have a respiratory source of infection such as pneumonia. Fig. 12-2 shows the typical histopathology of bacterial pneumonia. Abdominal infections are the second most frequent cause of sepsis. These occur in many circumstances, including ruptured appendicitis, penetrating injuries to the bowel and postsurgical

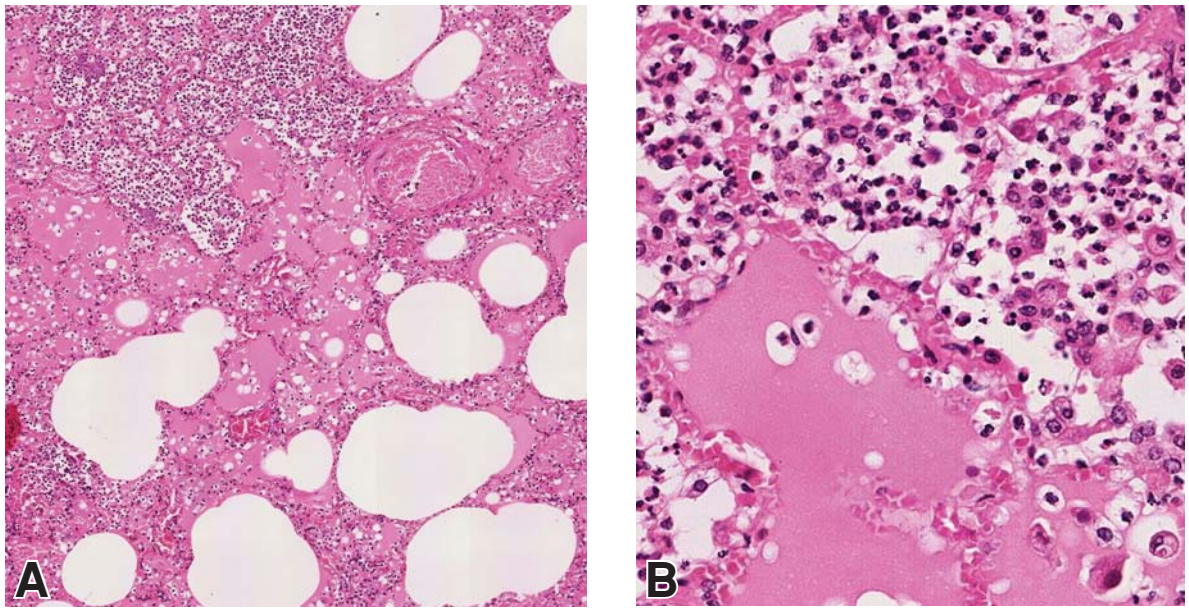

FIGURE 12-2. Histopathology of bacterial pneumonia. A. Some alveolar airspaces are filled with pink-stained protein-filled fluid. Numerous neutrophils have also infiltrated the alveolar space. The white spaces show alveoli where air was still exchanged through breathing. **B.** Higher power, showing intraalveolar fluid and many neutrophils.

anastomotic leaks. Urinary tract infections are the third most common starting point for sepsis. Additional causes of sepsis are attributable to soft tissue infections, primary bacteremia, meningitis, encephalitis, endocarditis and others. Infections that precipitate sepsis may be acquired in the community or during the course of hospitalization (i.e., nosocomial infections). Patients who develop sepsis as a result of nosocomial infections have higher mortality rates than those with community-acquired pathogens.

Age, Debility, Immune Status and Organ Function Help Determine the Risk of Sepsis

Sepsis occurs more often in those who are at the extremes of life: the aged and very young children. Males are more likely to develop sepsis than females, and blacks are more susceptible than whites. People with chronic illnesses, especially if their immune systems are compromised, are particularly at risk. AIDS, iatrogenic immunosuppression (e.g., postchemotherapy), long-standing respiratory or circulatory insufficiency and so forth predispose patients to sepsis.

Other, more poorly understood contributors relate to specific organ or organ system impairments and to the involvement of individual genetic, epigenetic and environmental factors. Many contributors participate in the pathophysiology of sepsis, including inflammatory mediators, clotting and complement systems and so forth (see below), and person-to-person variability in these systems undoubtedly affects susceptibility to development of sepsis in ways that are not yet quantified.

Infections with Many Different Organisms and Different Types of Organisms May Precipitate Sepsis

Infections with diverse types of pathogens may lead to sepsis, depending on the host response to the infectious insult. The nature of the infectious organisms that precipitate sepsis has shifted over time. Gram-positive bacteria are now responsible for more cases than are gram-negative organisms. A single bacterial species is responsible in over 85% of cases, with the remainder being due to polymicrobial bacterial infections or infections with fungi, anaerobes, viruses or parasites. The incidence of fungal sepsis has increased sharply in recent years, but fungi still provoke only about 5%–10% of cases overall.

Bacteremia (i.e., microbial infection of the bloodstream) may occur during sepsis, but it is not an essential component, because local infections can lead to distant tissue damage and organ dysfunction. Blood cultures are positive in only 20%–40% of patients with severe sepsis and 40%–70% of those with septic shock. Clinical suspicion for sepsis should remain high particularly if an infection is suspected but not detectable, and then empirical management should be initiated.

PATHOPHYSIOLOGY: Sepsis is part of a systemic overreaction that begins with inflammatory responses to infection (see Chapters 2 and 4). These responses reflect host recognition of pathogen-associated molecular patterns (PAMPs) that are present on invading microorganisms. PAMPs are perceived via pattern response receptors (PRRs), such as Toll-like receptors (TLRs) and C-type lectin receptors (CLRs) on dendritic cells (Fig. 12-3). For example, the cells of the innate immune system bind the peptidoglycan of gram-positive bacteria to TLR2 and the lipopolysaccharide of gram-negative bacteria to TLR4, as well as to other fungal, viral and parasitic components.

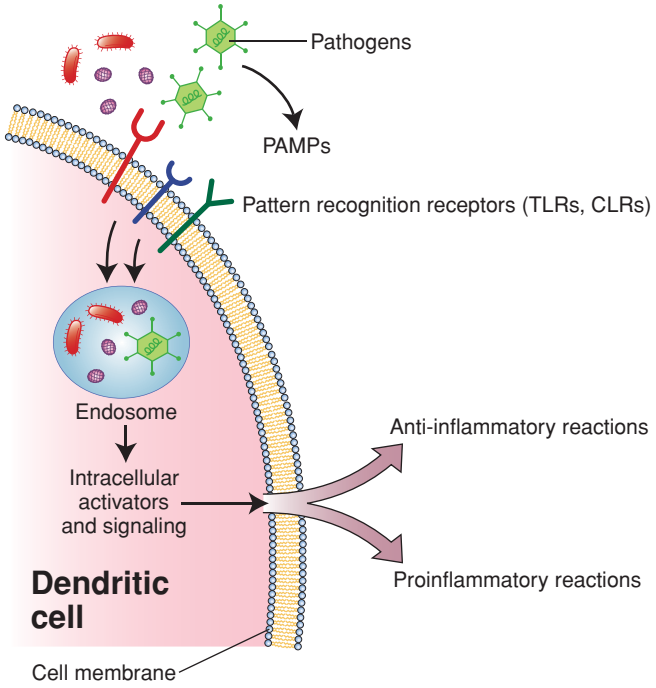

FIGURE 12-3. Mechanisms triggering soluble mediators in sepsis. Pathogen associated molecular pattern-containing molecules (PAMPs) are recognized by pattern recognition receptors (PRRs, mainly Toll-like receptors [TLRs] and C-type lectin receptors [CLRs]) on cells of the innate immune system, principally dendritic cells. Among other things, these interactions lead to endocytosis of the pathogens, which is in turn followed by activation of intracellular response systems. As a consequence, dendritic cells secrete a plethora of both proinflammatory and anti-inflammatory substances.

Endocytosis of these pathogens triggers major intracellular receptors of several types. Transmembrane TLR receptor binding to these mediators also activates nuclear factor-κB (NFκB) within monocytes and stimulates production of proinflammatory cytokines such as tumor necrosis factor-α (TNF-α) and interleukin-6 (IL-6), chemokines like IL-8 and intracellular adhesion molecule-1 (ICAM-1) and nitric oxide (NO; see Chapter 1).

Simultaneously, anti-inflammatory pathways are activated (see below), which are important as mediators of downstream or secondary effects of sepsis. The interplay of the triggering pathogen with the cells of the innate immune helps to determine whether pro- or anti-inflammatory forces predominate. Additional factors that participate in the decision as to the outcome include influences described above. The timing of the outcome, and the diverse intra- and extra-cellular pathways triggered, hang in the balance (Fig. 12-4). The opening act may favor a proinflammatory situation (Fig. 12-5).

The initial sequence is but the beginning, however. Tissue necrosis releases damage-associated molecular pattern molecules (DAMPs, or alarmins; see Chapters 2 and 4).

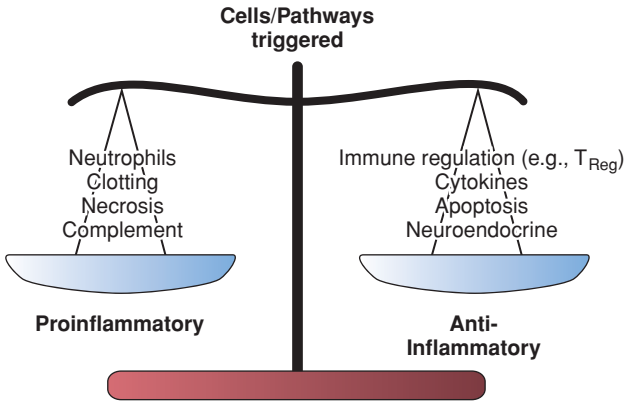

FIGURE 12-4. The balance of pro- and anti-inflammatory mediators that participate in sepsis.

DAMPs are recognized by pattern recognition receptors in cells of the innate immune system. Interaction between DAMPs and PRRs in turn drives those cells to produce more proinflammatory mediators. For reasons that are as yet unclear, and that probably reflect the interplay of host and environmental factors, this proinflammation stimulatory process spirals out of control and the body is flooded with inflammation-inducing, -potentiating and -sustaining factors that lead to uncontrolled inflammation.

Neutrophils are recruited to the site of injury and release mediators that lead to characteristic signs of local inflammation, such as protein-rich edema from microvascular leakage along with erythema and warmth from vasodilation (see below). A combination of proinflammatory and anti-inflammatory mediators is produced by macrophages in an effort to kill invading pathogens and to remove debris by phagocytosis of damaged tissue in a controlled approach. However, sepsis develops when the inflammatory response to infection cannot be contained in the local environment and becomes systemic.

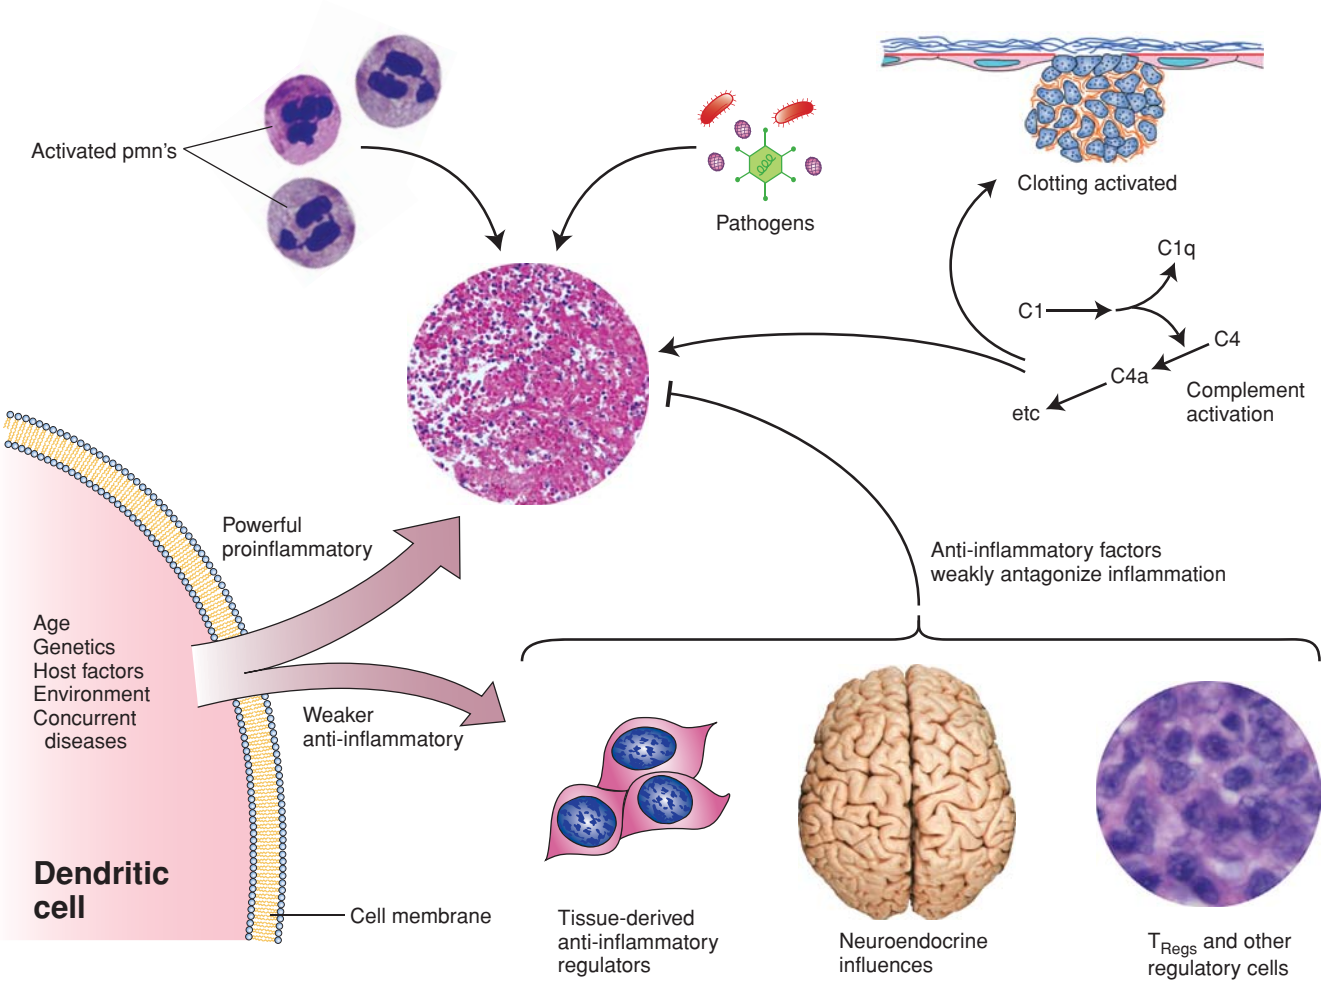

FIGURE 12-5. The elements of host responses favoring inflammatory activity during sepsis. Dendritic cell responses are determined, both quantitatively and qualitatively, by a combination of genetics, environment, age, other concurrent illnesses and other factors. When stimulated by an appropriate microbial trigger, whether bacterial, fungal or viral, pro- and anti-inflammatory substances are secreted by these dendritic cells. Here, the former (*upper*) predominate and are involved in a series of reactions. These include activation of neutrophils, blood-clotting elements and complement, all of which lead to tissue necrosis. This, in turn, magnifies the proinflammatory response. Anti-inflammatory elements (*lower*) include tissue-derived anti-inflammatory regulators, neuroendocrine influences and regulatory cells of different lineages, including T regulatory cells (T_{reg}s) and others.

Many Organ Systems Produce Anti-Inflammatory Mediators in Sepsis

Nervous System

Anti-inflammatory influences entail intricate regulatory pathways in which nervous system–derived mediators modulate inflammation. These mediators act in part via vagal stimulation, which triggers several intermediaries to stimulate acetylcholine (ACh) secretion by a subset of $CD4^+$ T cells. ACh directly downregulates macrophage production of proinflammatory cytokines. The neuroendocrine axis also acts through hypothalamic–pituitary intermediaries to increase corticosteroid production. The net effect of both ACh and cortisol secretion is to reduce inflammation.

Regulatory Cells

T-cell interactions with antigen-presenting cells (APCs; see Chapter 4) involve complex recognition processes, triggered by cell membrane molecules on each. In sepsis, these interactions are skewed, so that T regulatory cells (T_{reg}s, $CD4^+$/$CD25^+$) are activated. T_{reg}s act to dampen T-cell–mediated immune responses. Suppressor cells from other sources, such as bone marrow–derived suppressor cells (see Chapter 5), are also recruited and activated.

The Role of Apoptosis

An important feature of the pathogenesis of sepsis is the contribution of apoptosis to continued infection and the body's ongoing inability to handle it. This dysfunction of the programmed cell death (PCD) mechanism (see Chapter 1) has two features: excessive death among cell populations and insufficient elimination of others.

Excessive apoptosis occurs among lymphocytes and dendritic cells. Thus, in sepsis, both B lymphocytes and certain T-cell subsets are lost to PCD at a high rate. This is most pronounced among $CD4^+$ T lymphocytes, but $CD8^+$ T cells may also be affected. Certain populations of APCs, particularly interdigitating and follicular dendritic cells, undergo excessive PCD as well. Other types of macrophages are unaffected, or less dramatically impaired. Resulting decreases in total circulating lymphocyte counts (lymphopenia) impair immune responsiveness and are characteristic of people with sepsis. Lymphocyte apoptosis has been shown to be present in such patients. Apoptotic lymphocytes are found in the peripheral blood, bone marrow, spleen and even lymphoid aggregates such as the Peyer patches in the intestinal tract.

Circulating monocytes from patients with sepsis typically express less immune-stimulatory molecules on their cell membranes. However, monocytes expressing immunomodulatory molecules are not generally decreased. As a consequence of these diverse contributors, cells from patients with sepsis show impaired responsiveness to antigen stimulation.

Apoptosis of gastrointestinal epithelium also contributes to propagation of sepsis. Gut epithelial cells are lost to both PCD and ischemic necrosis as a result of circulatory impairment (see below). Intercellular tight junctions are loosened. Consequently, the epithelial barrier to gut flora becomes more porous. Bacteria from the gastrointestinal (GI) tract then enter the submucosal lymphoid tissue and then the general circulation, where they perpetuate the cycle of infection and inflammation.

Neutrophils are among the first line of antimicrobial defense (see Chapter 2). They are also programmed to undergo rapid PCD, the result being that the acute arm of the inflammatory response is, at least in part, self-limited by the cell death program of neutrophils. Altered apoptosis involving neutrophils also contributes to sepsis, but the alteration in cell death is in the opposite direction from that seen with lymphocytes and mononuclear phagocytes: PCD of polymorphonuclear leukocytes is markedly decreased. Impaired neutrophil apoptosis prolongs the acute inflammatory response, increases the release of degradative enzymes by these longer-lived neutrophils and so magnifies tissue injury.

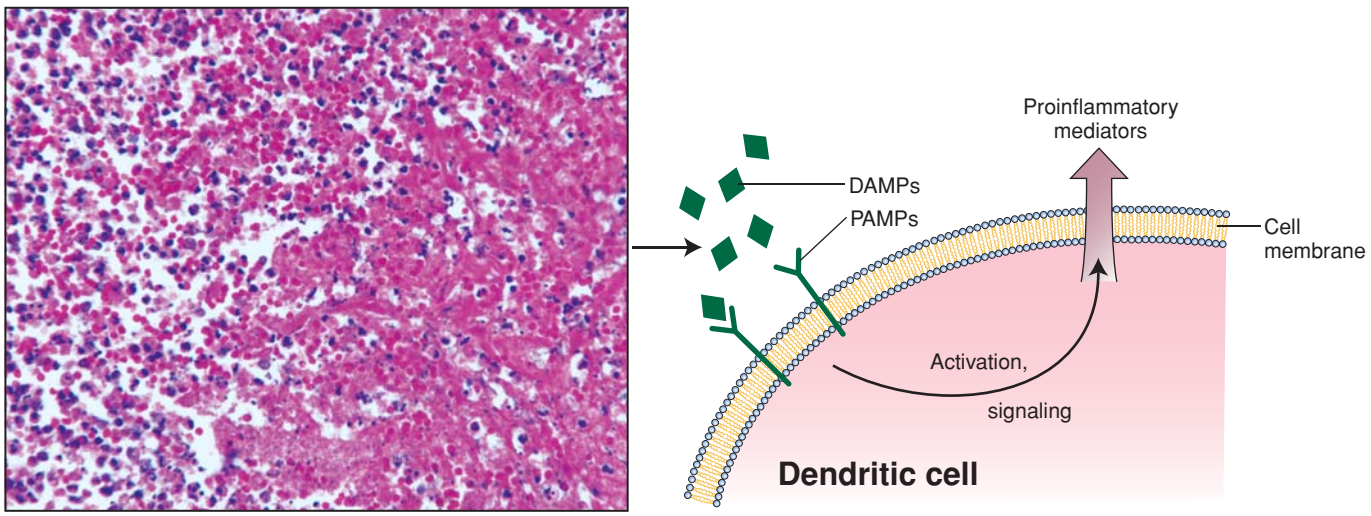

FIGURE 12-6. Tissue necrosis stimulates inflammation. Necrotic tissues, whether due to infections or other causes, release patterned molecules called damage-associated molecular patterns, or alarmins. These are similar to pathogen-associated molecular patterns (PAMPs) and bind to pattern recognition receptors (PRRs), in turn activating dendritic cells to release proinflammatory cytokines.

Alarmins and the Tissue Damage Response

Endogenous molecules released by damaged tissues also stimulate inflammatory responses. These molecules are DAMPs, also called alarmins. They are recognized by pattern recognition receptors similar to those that recognize PAMPs. Alarmins comprise nuclear, cytoplasmic and other cellular materials that are released by cells undergoing nonapoptotic cell death. Some types of cells may even produce and secrete alarmins despite the fact that they may not be dead or dying.

Alarmins bind specific receptors on innate immune system cells, such as dendritic cells, to activate innate immunity, inflammation (Fig. 12-6) and, subsequently, adoptive immunity. These pattern recognition receptors include TLRs as well as others. Alarmins may also engage and activate the IL-1 receptor.

As they are tissue derived, and not microbial in origin, alarmins signal tissue injury, not infection. They can trigger innate immune and inflammatory responses in settings of tissue death that occur in the absence of infectious agents, such as wounds or blunt trauma. They therefore represent the link between the pathogenesis of MODS in sepsis and MODS that occurs in settings that do not involve infection.

The Balance Between Pro- and Anti-Inflammatory Activities Helps to Determine the Course of Sepsis

Teleologically, proinflammatory influences protect the host against invading pathogens, and anti-inflammatory circuits should protect the host from potentially injurious overly exuberant inflammatory activity. In sepsis, however, it does not always work this way. Proinflammatory influences, for reasons that are still being studied, overwhelm counterregulatory braking mechanisms and engage in inflammatory excesses, which lead to tissue necrosis beyond what is elicited by pathogens or necessary to contain the infection.

Anti-inflammatory influences in sepsis may finally supervene, but when they do, they are too much and too late. That is, the net effect of anti-inflammatory activities is not so much to rein in inflammation that can damage tissues but rather to suppress immune responses and render the host susceptible to subsequent secondary or other infections (Fig. 12-7). In so doing, they magnify the impact of the initial infection and

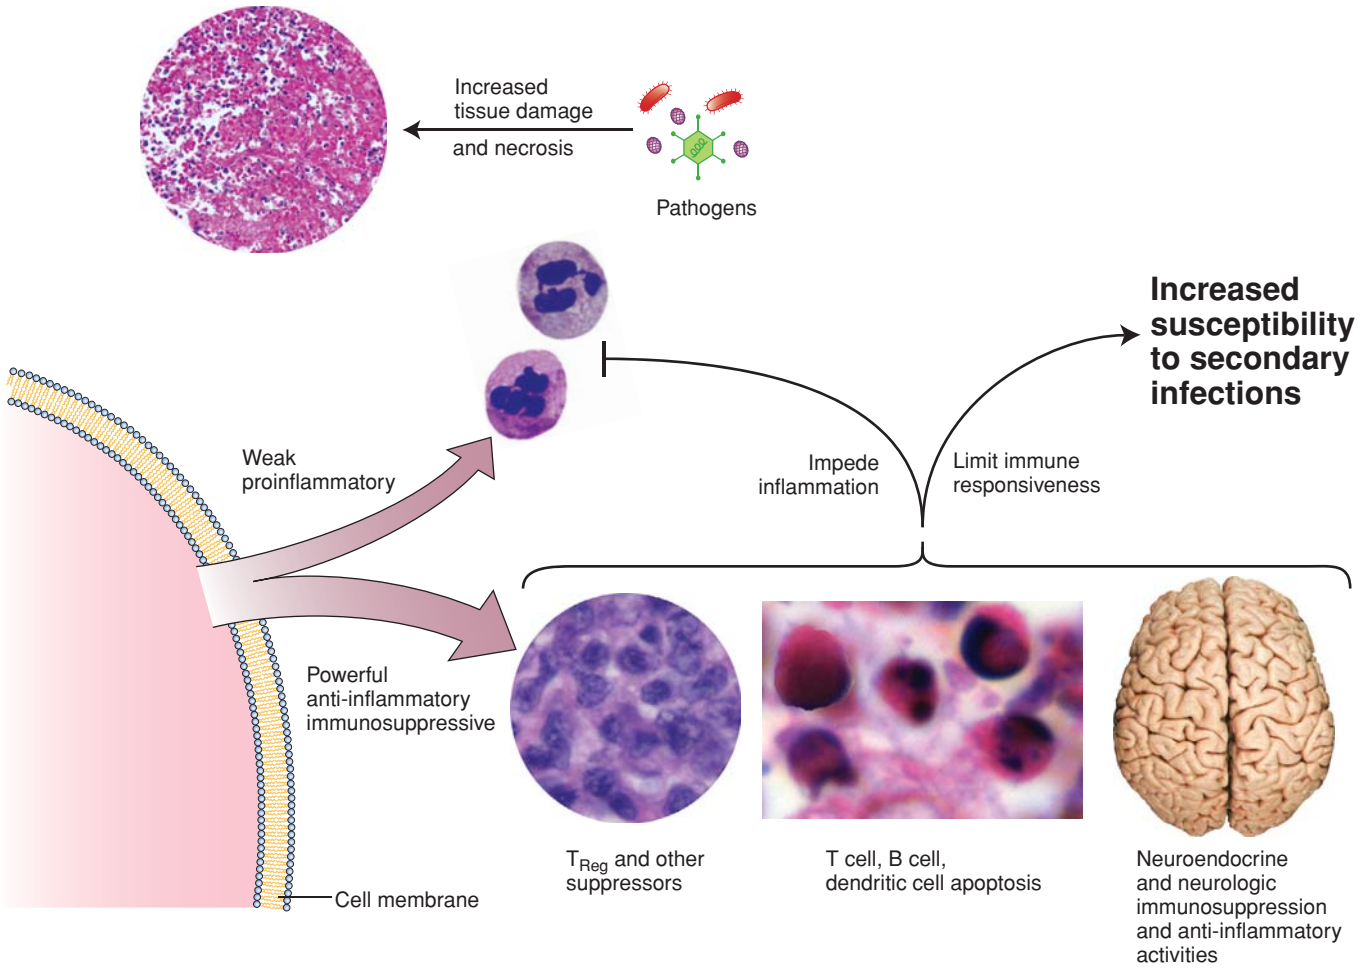

FIGURE 12-7. The elements of host responses impeding inflammation and immune responsiveness during sepsis. The same dendritic cell responses described in Fig. 12-5 may be balanced differently, either because of genetics, environment and so forth or as a function of timing following the initial infectious stimulus. In this setting, anti-inflammatory elements (*lower*) may predominate over proinflammatory agents (*upper*). Depending on when such anti-inflammatory responses predominate during sepsis, they may impair immune responsiveness and limit inflammatory responses to secondarily invading pathogens. This may magnify the tissue damage that was initially due to exaggerated proinflammatory responses.

simultaneously have the exact opposite of their seemingly intended purpose: they lead to more inflammation.

Circulation and Coagulation Are Abnormal in Sepsis

Disseminated intravascular coagulation (DIC) and dysfunctional patterns of circulation are characteristic of sepsis. PAMPs trigger expression of tissue factor (TF) by endothelial and other cells, particularly monocytes. TF activates the coagulation cascade (see Chapter 16) via factor VII. This leads to intravascular microthrombus formation. Pathogen-activated neutrophils release neutrophil extracellular traps (NETs; see Chapter 1), which also precipitate coagulation (Fig. 12-8).

Under normal circumstances, clot formation activates fibrinolytic pathways, which should limit the extent of clotting. However, in sepsis, mediators of fibrinolysis (tissue factor inhibitor, antithrombin, plasminogen activator and others) are impaired or inhibited. As a result, unimpeded formation of intravascular thrombi (DIC) limits blood flow and hence hampers adequate oxygen delivery to organs.

Simultaneously, additional factors magnify this vascular insufficiency. The ability of endothelial cells themselves to limit blood coagulation is impaired. Provoked by large amounts of thrombin (and freed of restraint normally exercised by protein C, which is decreased in sepsis), protease activated receptors (PARs) on endothelial cells downregulate endothelial anticoagulant activities.

At the same time, endothelial cells activate inducible nitric oxide synthase (iNOS). NO stimulates vasodilation, increases vascular permeability and causes leakage of plasma from the vascular system into tissue spaces. In the setting of DIC (see Chapters 7 and 16), sepsis-related impairments in erythrocyte deformability further limit oxygenation of organs and peripheral tissues.

Mechanistically, then, these diverse dysfunctions play into each other to increase the severity of the resulting pathophysiology. Invading pathogens, in the context of host and environmental factors that limit host modulatory activities, trigger excessively exuberant inflammatory responses and DIC, both of which lead to a cycle of tissue death, circulatory insufficiency and poor oxygen delivery to tissues. When anti-inflammatory activities start to participate in the process, they make matters worse because their net effect is to limit the ability of the adaptive immune system to respond to invading pathogens. Anti-inflammatory regulators therefore set the stage for subsequent secondary infection with additional pathogens (Fig. 12-9).

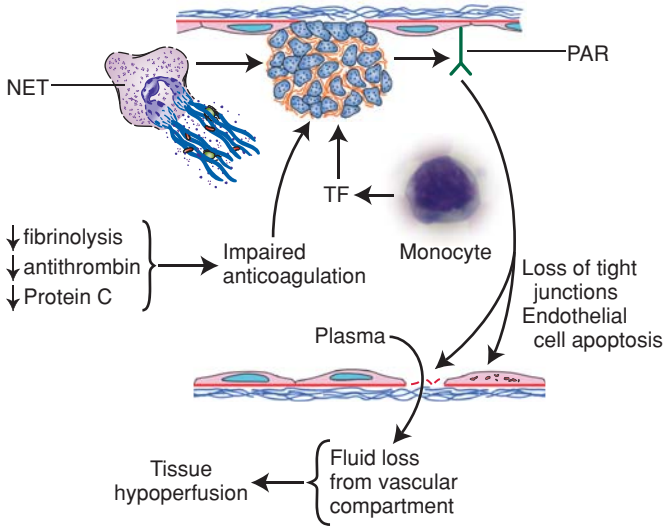

FIGURE 12-8. Pathogenesis of disseminated intravascular coagulation (DIC) and vascular insufficiency in sepsis. Several factors contribute to the development of DIC in patients with sepsis. These include the release of extracellular nets by neutrophils, trapping the microbial pathogens, and the production of tissue factor (TF) by activated monocytes and endothelial cells. TF both sets clotting in motion and inhibits fibrinolysis, the end result being excessive intravascular coagulation. At the same time, excessive thrombin activation in DIC triggers protease activated receptors (PARs) on endothelial cells. Endothelium undergoes apoptosis and intercellular tight junctions loosen, leading to vasodilation and fluid leakage from the circulation into extravascular spaces. Activated endothelial cells produce nitric oxide (NO), which causes vasodilation and vascular leakiness. Impaired red blood cell deformability adds to these factors to decrease the effectiveness of oxygen delivery to tissues.

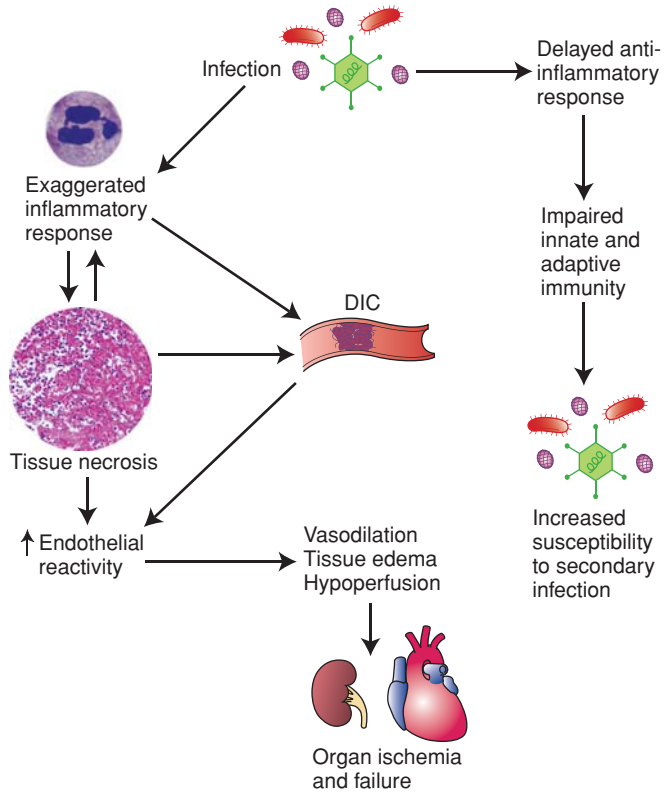

FIGURE 12-9. Sequence of events in many cases of sepsis. Following an infection as the initiating event, an exaggerated inflammatory response leads to excessive tissue necrosis (which, in turn, increases inflammation). Tissue necrosis and inflammation cause disseminated intravascular coagulation (DIC). Endothelial cell hyperreactivity results from all three of these stimuli and, together with DIC, provokes vasodilation and tissue edema and leads to hypoperfusion of tissues. This, in turn, causes organ dysfunction and failure. In parallel, delayed anti-inflammatory activities impair immune responses and render the patient more susceptible to secondary infection.

PHYSIOLOGIC RESPONSES TO SIRS/SEPSIS

The patient's response to inflammation and systemic infection depends on the severity of the condition, ranging from SIRS to sepsis to severe sepsis to septic shock to MODS.

Physiologic alterations vary, depending on where an individual falls in that spectrum. The SIRS response includes the clinical signs of tachycardia, tachypnea and hyperthermia or hypothermia.

Tachycardia is an important compensatory mechanism to maintain adequate perfusion in order to offset intravascular volume loss, vasodilation and diminished cardiac contractility. Tachypnea in sepsis may be due to increased stimulation of the respiratory center in the medulla by inflammatory mediators or be a response to counterbalance metabolic acidosis. Body temperature is controlled by the hypothalamus, which may readjust to a higher set point owing to an alteration in heat equilibrium, leading to hyperthermia in sepsis. Rigors may also be present with fever as skeletal muscle contractions generate additional heat. However, some individuals do not show any of the typical signs of sepsis. Development of hypothermia occurs more frequently in patients who die from sepsis than those who survive. It is associated with other adverse effects, such as surgical wound infections.

Severe sepsis arises in the presence of hypoperfusion or organ dysfunction, which may appear physiologically as an acute alteration in mental status or oliguria. In the course of development of septic shock, hypotension (systolic blood pressure [SBP] < 90 mm Hg or a decrease of more than 40 mm Hg in SBP) occurs despite adequate fluid resuscitation, resulting in perfusion abnormalities. These individual clinical signs are not specific for sepsis and may develop in other settings. In contrast, classic indicators of systemic inflammation may be absent in severe sepsis, particularly in higher-risk patient populations such as elderly and immunosuppressed patients.

Virtually every organ in the body is susceptible to impairment during septic responses, and MODS is a particularly life-threatening complication of sepsis. The renal, pulmonary, hepatic, endocrine, cardiovascular and central nervous systems frequently sustain injury in septic patients (Fig. 12-10). Primary organ damage is difficult to distinguish from injury that results from inadequate perfusion caused by cardiovascular insufficiency. Frequent physiologic and laboratory measurements are necessary to monitor end-organ function and direct supportive interventions.

PATHOLOGY: Laboratory pathology plays a central role in evaluating patients with possible sepsis and in following both their clinical course and the effectiveness of treatment (see below).

LABORATORY ABNORMALITIES IN SIRS/SEPSIS. One of the SIRS criteria is leukocytosis (white blood cell [WBC] count >12,000/mm^3), leukopenia (WBC count <4,000/mm^3) or greater than 10% bands. In a study of patients with gram-negative sepsis, leukopenia was more frequently seen among nonsurvivors of sepsis than among survivors, identifying it as a finding often related to more severe disease in sepsis. To facilitate the diagnosis and management of the septic patient, cultures should be obtained from all potentially infected sites including but not limited to blood, urine, sputum and indwelling catheters. Patients with positive cultures should receive appropriate antimicrobial therapy; however, a definitive site of infection may not be identified in a subset of patients and empiric broad-spectrum coverage is indicated for suspected infection.

Clinical measurements of poor perfusion in severe sepsis and septic shock include lactic acidosis, base deficit and decreased mixed central venous oxyhemoglobin saturation ($ScvO_2$). Significantly elevated lactate levels, greater than or equal to 4 mmol/L, increase the risk of mortality. Prompt normalization of lactate values within 6 hours of presentation through resuscitation and supportive care reflects resolution of global tissue hypoxia and diminishes organ

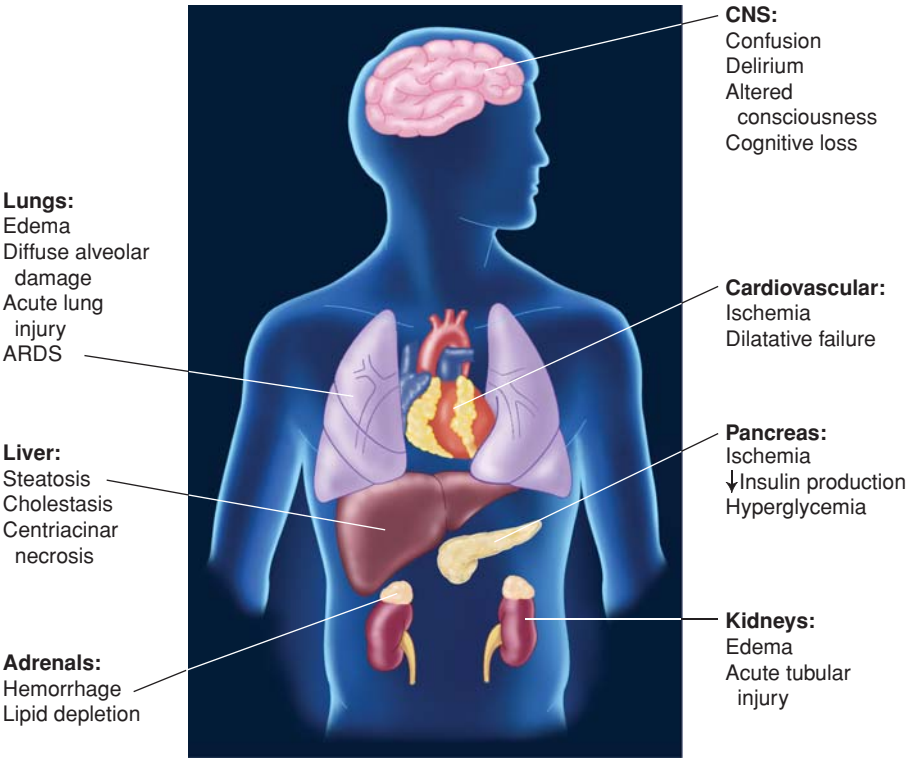

FIGURE 12-10. End-organ damage in septic patients. Individual organ or multisystem organ failure may occur during the human response to sepsis.

dysfunction and mortality in sepsis. Improved mortality is also associated with rapidly achieving $ScvO_2$ greater than 70% to enhance tissue oxygenation.

Septic patients develop a range of coagulation abnormalities, from mildly prolonged bleeding time and thrombocytopenia to life-threatening DIC. Proinflammatory cytokine production upregulates TF (see above), suppresses antithrombin, interferes with protein C anticoagulation activity and impedes fibrinolysis. Systemic intravascular microthrombi occur and may lead to tissue ischemia, necrosis or MODS. Platelets and coagulation factors are consumed while activation of fibrinolysis contributes, leading to failed hemostasis. Elevations in bleeding time and impaired clotting are common. The latter is measured by international normalized ratio (INR, which is a value calculated from the ratio of a patient's prothrombin time to a normal prothrombin time) and partial thromboplastin time (PTT). Platelet levels and fibrinogen may also be decreased.

End-organ damage in sepsis also leads to laboratory abnormalities depending on which organs are involved. Kidney injury increases serum creatinine and may also alter blood electrolyte levels. Hepatic damage may lead to elevated transaminases, severe hypoglycemia and reduced synthesis of coagulation factors. The latter may further impair hemostasis that may already be problematic as a result of DIC. Decreased partial pressure of oxygen in the arterial blood (PaO_2) results from lung dysfunction. Impaired adrenal function in sepsis can markedly decrease blood cortisol levels, which may lead to hypotension in septic shock.

BIOMARKERS. Biomarker identification in sepsis is helpful to diagnose the condition better, detect which patients may benefit from immunomodulatory therapies and predict outcomes. C-reactive protein (CRP) is a well-known marker of inflammation, but it is not sufficiently specific to discriminate septic patients from those with noninfectious SIRS. Multiple cytokines such as IL-6 and TNF-α lack adequate prognostic value to be useful markers in sepsis.

Other potential biomarkers, particularly procalcitonin (PCT), have potential utility in diagnosis. PCT is made in the lungs and intestines in the context of bacterial infection. Normally, it is not detectable in the circulation, but high circulating PCT levels in septic patients help to identify sepsis. It does not generally become elevated in nonbacterial infections, so PCT is a useful clinical adjunct to help determine if infection is present in a critically ill patient who develops a new fever. Its measurement also appears to have a role in antibiotic management. Implementing a PCT-based algorithm to guide antimicrobial therapy has reduced days of antibiotic exposure and costs in septic patients.

CLINICAL FEATURES:

ORGAN SYSTEM MANIFESTATIONS OF SEPSIS. Clearly, the clinical presentation of sepsis depends in part on the anatomic location(s) of the precipitating infection. However, some clinical features tend to be consistent regardless of the source of the infection. Respiratory compromise and cardiovascular dysfunction are most common. Pulmonary failure in the form of acute respiratory distress syndrome (ARDS; see Chapter 18), with impaired blood oxygenation and pulmonary infiltrates, is common. Circulatory insufficiency entails prolonged low blood pressure, which contributes to poor oxygen delivery to peripheral tissues, despite compensatory tachycardia.

Consequently, many other organ systems experience dysfunction relating to the effects of poor perfusion and inadequate oxygen delivery. Almost any organ system may be affected. Renal function often declines, as evidenced by oliguria (low urine output) and rising serum creatinine levels. Both central and peripheral nervous systems may evidence dysfunction: decreased cognition, impaired mental status and both myopathies and neuropathies. Sepsis has a substantial impact on endocrine homeostasis, as glycemic control and thyroid function are both compromised. Gut motility and liver function may decline.

CURRENT TREATMENT OF SEPSIS. Severe sepsis is a medical emergency and the first priority is to evaluate and maintain the "A, B, Cs:" airway, breathing and circulation. Mechanical ventilation may be needed to provide respiratory support for increased work of breathing or airway protection in septic patients. Blood pressure is assessed frequently to detect signs of hypoperfusion. Subsequent management continues after initial stabilization and evaluation of the septic patient.

Early goal-directed therapy (EGDT), antibiotics and source control of infection are effective in the management of human sepsis, but no targeted sepsis therapy exists; despite decades of intense research, treatment remains primarily supportive. EGDT is a valuable algorithm for initiating early, aggressive end-point–driven resuscitation, and it has been proven to improve survival in severe sepsis and septic shock. EGDT has been adapted into the Surviving Sepsis clinical practice guidelines, last revised in 2012. The international recommendations seek to minimize barotrauma from mechanical ventilation, maintain organ perfusion, control infection and reduce hyperglycemia. Additionally, corticosteroids may be useful if a patient's hemodynamic status does not stabilize with fluid resuscitation and vasopressors.

Hyperglycemia occurs with many nosocomial infections and correlates with decreased survival in sepsis. However, optimal blood glucose levels in sepsis remain controversial. Hypoglycemia is also detrimental and entails increased mortality. The Surviving Sepsis 2012 guidelines currently recommend maintaining glucose less than 180 mg/dL.

Multiple unsuccessful drug trials in sepsis underscore the difficulty in developing new therapies for patients. For many years, research efforts were focused on using anti-inflammatory agents to suppress hosts' robust inflammatory responses. These efforts have not borne fruit. The complex, simultaneous abnormalities of multiple pathways that likely drive sepsis present a significant challenge to developing efficacious therapeutics. Given the variability in the human response to sepsis, treatment targeted at specific patient populations or particular infectious sources may prove more successful than previous investigational therapies. Currently, no pharmacologic agent is approved in the United States for treatment of sepsis, and morbidity and mortality remain high.

Obesity

Only three decades ago, obesity was relatively uncommon, but its prevalence has been increasing rapidly. Astonishingly, on a global scale, 1 billion adults might be classified as overweight, and at least 400 million meet established criteria for obesity. One third of American adults are overweight and 1/3 are obese. Although overall prevalence of obesity in the United States may be leveling off, extreme obesity continues to increase. That is, individuals already in the obese category are growing heavier. In the developed world, obesity is more common among women and the poor, while in developing countries, it affects primarily the well-to-do. The explosion in obesity rates indicates that the fundamental problem is a recent change in environment, not genetics. It is especially worrisome that at least one in seven children in the United States is obese; a recent longitudinal study showed that childhood obesity more than doubles the risk of death from endogenous causes before the age of 55 years.

Chronic, Positive Caloric Imbalances Cause Obesity, but Underlying Factors Are Complex

Obesity is rooted in complex interactions of genetic, metabolic, physiologic, social, behavioral, technologic, governmental and commercial influences that lead to overnutrition and underexertion. The imbalance in energy intake and expenditure may be quite small: just 35 kcal/day—merely 1% of the typical flux of 3500 kcal/day in the developed world—becomes a weight gain of 14 kg (~30 lbs) of adiposity in a decade. For comparison, there are 300 kcal in two cans of regular soda or three 8-ounce servings of fruit juice. Thus, a child who consumes high-calorie snacks on the way to and from school substantially increases his risk for obesity, if there are no compensatory changes in intake or expenditure.

As another way to illustrate the precision of energy balance required to defend body weight and adiposity over the long run, consider that we consume and expend roughly 10^6 kcal per year. Proportionately small cumulative errors on this scale add up quickly. Severe clinical obesity may rarely entail monogenic causes that impair satiety (see below), but most cases result from the combined effects of lifestyle and other environmental factors, superimposed on several traits that are partially heritable.

In the past, eating was a highly social and cultural endeavor, and vigorous physical activity was necessary for typical daily life. Several factors associated with rising rates of obesity disrupt long-standing patterns of dining and movement. Altered eating habits include rising consumption of sugar, particularly sugary beverages; replacement of regular, social meals with unscheduled snacking; agricultural and other subsidies that lower the cost of carbohydrate calories; and the growth of a sophisticated industry for manufacturing processed foods that are savory and calorically dense. Simultaneously, physical activity has declined because of labor-saving devices, such as washing machines and private cars; television and other electronic entertainment; and jobs that have become more sedentary. These factors, alone and in moderation, may be highly desirable (e.g., the availability of enough food to sustain a world population of 7 billion people). Yet in combination and in excess, these factors help disrupt the normal physiologic mechanisms that balance body weight and adiposity. The result is chronic positive caloric imbalance and hence the global growth of obesity.

ENERGY INTAKE AND EXPENDITURE

Weight increases when energy intake exceeds expenditure; you are what you eat, minus what you burn. The normal

human gastrointestinal (GI) tract absorbs essentially all simple fuels that enter it. Many behaviors related to caloric intake and expenditure have a significant inherited component. For example, offspring of mothers with high prepregnancy body weights tend to eat in the absence of hunger (EAH) and to seek foods of high energy density (kcal/g).

Total daily energy expenditure (TDEE) consists of several regulated components:

1. **Basal metabolic rate (BMR):** BMR is the energy expended at complete rest, lying down, in the postabsorptive state. It includes maintenance levels of breathing, circulation of blood and essential metabolic functions. For people with sedentary occupations, BMR accounts for ~60% of TDEE. Over 75% of interindividual variation in BMR reflects differences in lean body mass.
2. **Calories spent to digest, absorb and store ingested calories** (6%–12% of TDEE).
3. **Energetic costs of emotion, medication and adaptive thermogenesis owing to the environment** (e.g., changes in temperature, exposure to infectious agents).
4. **Activity thermogenesis** generated by physical movement during purposeful exercise and nonexercise activity thermogenesis (NEAT). Purposeful exercise is a key element of successful weight loss programs. Except for high-level athletes, most people burn relatively few calories during purposeful exercise, but without compensatory increases in intake, even small shifts in overall energy balance add up. Levels of NEAT may vary substantially among apparently normal individuals, by up to 2000 calories/day, and lower NEAT correlates strongly with obesity. Obese people in sedentary occupations sit 2.5 hours more each day than their comparable lean counterparts. The cumulative impact of such inactivity on energy balance over the years can be substantial.

The Brain Is the Central Controller of Body Weight

The brain receives hormonal and neuronal signals about food deficits or surpluses and the rate of fuel utilization. To maintain homeostasis, it then coordinates responses, modulating behavior and the endocrine and autonomic nervous systems to adjust energy balance.

The **hypothalamus** is the main processor of signals from the periphery and is crucial to managing energy balance. Many hypothalamic nuclei regulate metabolism, but the arcuate nucleus plays a central role via two distinct populations of neurons, which generate opposing actions on food intake. One group makes **anorexigenic** (appetite-suppressing) peptides, including proopiomelanocortin (POMC) and cocaine- and amphetamine-regulated transcripts (CARTs). POMC is cleaved into α-melanocyte–stimulating hormone (α-MSH), which binds melanocortin receptors MC3R and MC4R to decrease appetite.

The other population of neurons produces two **orexigenic** (appetite-stimulating) neuropeptides: **neuropeptide Y** (NPY) and **agouti-related protein** (AgRP). NPY is among the most abundant neuropeptides in the mammalian brain and strongly stimulates feeding. It may bind any of six G-protein–coupled NPY receptor subtypes (Y1 through Y6), but Y1 and Y2 NPY receptors stimulate feeding most. AgRP antagonizes melanocortin receptors, thus blocking α-MSH anorexigenic effects and stimulating food intake.

The GI Tract, Adipocytes and Other Tissues Produce Hormones That Contribute to Regulation of Hunger and Satiety

Key systemic soluble mediators of these responses include:

- **Leptin:** The discovery of **leptin** revealed a key link between neural and nonneural systems in the control of appetite and energy expenditure. Leptin (from the Greek, "thin") is the protein product of the *LEP* gene, known historically as the *Ob* gene. It is produced mainly by adipocytes. Its serum concentration is proportional to body fat mass (i.e., it is lower in lean people and rises with obesity). Its chief physiologic role appears to be signaling to the brain that body adipose stores are sufficient. Low serum leptin levels increase appetite and decrease energy expenditure, in part by dampening the thyroidal axis. This effect impedes weight loss during caloric restriction. By contrast, normal leptin levels decrease appetite.

  In the brain, leptin interacts with leptin receptors on POMC/CART and NPY/AgRP neurons, regulating them in opposite ways. It directly activates anorexigenic POMC/CART neurons while blocking the activity of orexigenic NPY/AgRP neurons. The result is decreased food intake. Blood leptin levels are above normal in most obese people, but unfortunately, this increased leptin fails to suppress appetite and halt excessive fat accumulation. There is evidence to support several explanations, including an inability of leptin to reach its neuronal targets, a failure of intracellular signaling by the leptin receptor despite occupancy with leptin (desensitization) and psychological cues to overeat that overwhelm physiologic restraints. Leptin injections to treat obesity have to date not been successful.
- **Circadian rhythms** affect, and are affected by, caloric flux. Mice with genetic disruption of the circadian system develop obesity, hyperleptinemia, hyperlipidemia and hyperglycemia. In humans, shift workers, who must alter their sleep rhythms, exhibit increased prevalence of high body mass indices (BMIs), metabolic syndrome (see below) and cardiovascular events. Forced sleep restriction in humans disturbs appetite control and glucose tolerance. This effect is of particular concern, given the disturbances in sleep caused by obstructive apnea in people who are already obese.
- **Endocannabinoids** are endogenous lipids that bind to cannabinoid receptors 1 and 2 (CB1 and CB2). CB1 receptors are found in hypothalamic nuclei involved in control of energy balance and weight. They are also present in adipose tissue and the GI tract. Activated CB1 receptor stimulates food intake and may play a role in the development and maintenance of obesity. Rimonabant, a synthetic blocker of the CB1 receptor, suppresses appetite, decreases weight and improves metabolic parameters in obese subjects, but a major side effect of depression has stopped its use in the treatment of obesity.
- **The GI tract** contains a diverse group of mechanoreceptors and chemosensitive receptors that relay information via vagal afferent fibers that terminate in the nucleus tractus solitarii in the brainstem. For example, vagal activation due to gastric distension causes satiety and meal termination. Taste receptors for bitter, sweet and umami (savory flavor imparted by glutamate and nucleotides)

have been found in regions besides the tongue, particularly the stomach, small intestine and pancreas, where they may act as nutrient sensors and affect appetite and insulin release. As well, several hormones produced by the GI tract signal the central nervous system (CNS) to regulate energy intake. **Glucagon-like peptide 1** (GLP-1) is made by posttranslational processing of proglucagon by L cells located primarily in the mucosa of the distal ileum and colon. GLP-1 decreases food intake, slows gastric emptying, generates a feeling of satiety, augments postprandial glucose-stimulated insulin secretion and decreases secretion of glucagon, a hormone that opposes insulin action (see Chapter 27). These combined effects reduce the rate of caloric delivery to the intestines, and hence to the rest of the body, while enhancing insulin secretion and action. Long-acting GLP-1 analogs (exenatide and liraglutide) are used to treat type 2 diabetes mellitus and to induce weight reduction.

- **Ghrelin** is a hormone that stimulates hunger. It is produced primarily by endocrine cells in the stomach and, to a lesser extent, in the duodenum, ileum and colon. Ghrelin stimulates orexigenic NPY neurons in the arcuate nucleus of the hypothalamus. Circulating ghrelin levels increase during fasting, and its administration to normal subjects increases caloric intake. Patients with anorexia nervosa have high plasma concentrations of ghrelin; however, administration of exogenous ghrelin to treat this condition has not been successful. Plasma ghrelin declines after gastric bypass surgery, which may facilitate continued weight loss after the procedure. Patients with hyperphagia in Prader-Willi syndrome have very high plasma ghrelin levels. Moreover, serum ghrelin increases after diet-induced weight loss, which may contribute to poor long-term results of clinical weight loss programs.
- **Cholecystokinin (CCK)** is made mainly in duodenal and jejunal mucosa. It is released after fat and protein intake and acts on two distinct receptors. CCK stimulates release of enzymes from the pancreas and gallbladder to aid digestion, slows gastric emptying and reduces food intake. Regulation of food intake is mediated via vagal afferent signals to the brain.
- **Peptide YY** (PYY) is secreted along the entire GI tract, but mostly in the ileum and colon. Of its two forms, PYY(3-36) is the major circulating type. It is released in response to food intake, and its many actions include delaying pancreatic and gastric secretions, gallbladder emptying and gastric emptying. PYY(3-36) decreases appetite, duration of eating and total caloric intake.
- **Pancreatic polypeptide** (PP) is in the same peptide family as PYY. Although it is primarily produced in the pancreas, it is also found in the colon and rectum. The main stimulus to its release is food intake; PP reduces appetite and food intake.
- **Amylin** is a peptide mainly produced by pancreatic beta cells, but also found in gut endocrine cells, visceral sensory neurons and the hypothalamus. It is a potent inhibitor of gastric emptying and decreases food intake. An analog of amylin, pramlintide, is currently used to treat diabetes mellitus. It is associated with weight reduction in these patients and is in clinical trials for obesity.
- **Insulin** is best known for its role in peripheral glucose uptake, but it also affects appetite. Injection of insulin into the third cerebral ventricle of rats decreases food intake via insulin receptors in the arcuate nucleus of the hypothalamus, where it increases messenger RNA (mRNA) for POMC (anorexigenic) and suppresses mRNA for NPY (orexigenic). Clinically, however, insulin is administered peripherally and often increases appetite, which can cause already overweight patients to eat more. Part of the explanation may be hypoglycemia.
- **Other substances** regulate hunger, satiety, fat deposition and so forth in rodents, including galanin, adipocyte complement-related protein (ACRP), peroxisome proliferator-associated receptors (PPARs) and others.
- **Gut flora** affect body weight. Germ-free mice are protected from diet-induced obesity. Colonization of these mice with intestinal flora from conventionally raised mice enhances caloric uptake from complex dietary plant polysaccharides. These flora also modulate expression of specific host genes to increase caloric storage in adipose tissue. Distal gut flora from obese people contain different microbes from the flora of lean individuals. Gut bacteria from obese individuals may extract calories from complex components of the diet more efficiently than microbiota from their lean counterparts. Nevertheless, modern foods of high-caloric density contain mostly simple carbohydrates and oils, which are readily absorbed without microbial assistance. Regulatory effects on the host from variations in gut flora are still likely to be important, and gut flora "transplants" from lean to obese subjects have been proposed.

Known orexigenic and anorexigenic factors are illustrated in Fig. 13-1.

BODY MASS INDEX AND OBESITY

The standard most often used to define obesity is the BMI:

$$\text{BMI} = [\text{weight (kg)}] \div [\text{height (m)}]^2$$

Although BMI is an excellent indicator of obesity, it does not formally distinguish between fat mass and lean mass. A short, muscular person with little body fat may be misclassified as obese by BMI, while a person with excess adipose tissue and reduced muscle mass, such as an elderly or chronically ill individual, could have a normal BMI. There may also be ethnic variations in the amounts of adipose tissue, particularly visceral–abdominal adipose tissue, at a given BMI.

Obesity, Morbidity and Mortality in Multiethnic Populations

Most health organizations define overweight as a BMI between 25 and 29.9 kg/m^2. A BMI over 30 defines obesity, 30–35 class I obesity, 35–40 class II obesity and a BMI exceeding 40 extreme (class III) obesity. A high BMI correlates with excess morbidity, largely due to specific metabolic abnormalities like dyslipoproteinemia, hypertension, impaired regulation of plasma glucose concentrations, hypercoagulability and the risk of developing type 2 diabetes. A BMI above 35 (class II and class III obesity) is consistently associated with excess all-cause mortality, but BMIs of 25–30 (overweight) or 30–35 (class I obesity) are not. The correlation between obesity and mortality in Western countries has weakened over time, perhaps because of better treatments for cardiovascular risk factors and improved public health measures.

Various populations differ in susceptibility to metabolic abnormalities at similar BMIs. A multiethnic cross-sectional study in Canada found that the same degree of impaired glucose control seen on average in people of European descent with a BMI cutoff of 30—the barely obese—occurred at BMIs of only 21 in those with South Asian ancestry, 20.6 in Chinese people and 21.8 in Native Americans. Similar data were seen with respect to dyslipidemias. In this study, and in the experience of many clinicians, overweight South Asians face a particular burden of dysglycemia and dyslipidemia. Most importantly, appropriate BMI values to define obesity—and hence the need and intensity of intervention—differ substantially among populations. Thus, use of BMI based on data from people of European descent probably underestimates the cardiometabolic risks associated with weight gain in other ethnic groups.

Regional body fat distribution also determines health risks associated with obesity. Fat depots in various parts of the body play different roles, including energy metabolism, secretion of circulating proteins and metabolites into the bloodstream and physical cushioning and protection of internal organs. Visceral–abdominal obesity (also called central adiposity or "apple shaped") carries a greater risk of dyslipoproteinemia, hypertension, heart disease, diabetes and some forms of cancer than does gluteal–femoral obesity (lower-body obesity or "pear shaped"; Fig. 13-2).

BMI does not account for fat distribution, so abdominal obesity is better assessed by measuring waist circumference or the waist:hip ratio. Waist circumference above 102 cm (40 inches) and waist:hip ratio over 0.9 in men are associated with adverse outcomes. The same holds true for women with a waist circumference more than 88 cm (35 inches) or waist:hip ratio larger than 0.85. Thus, amounts of visceral fat and modifiable cardiovascular risk factors provide better guides to therapy than does BMI.

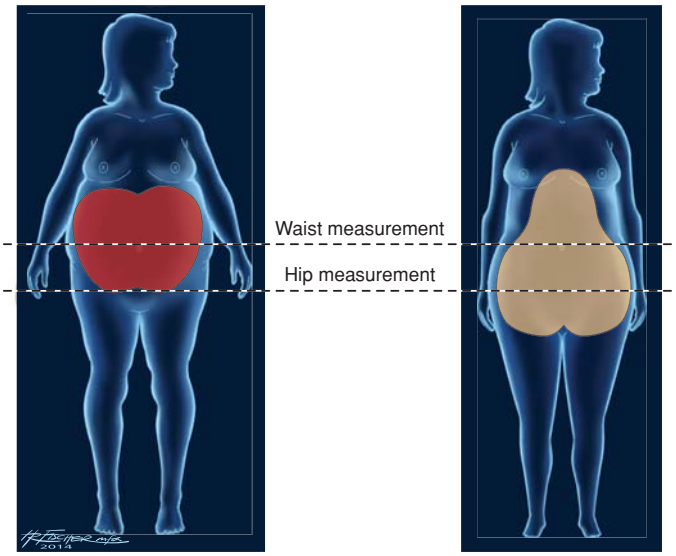

FIGURE 13-2. Regional adipose distribution and cardiometabolic risk. Individuals who accumulate adipose tissue in the abdomen ("apple shaped") exhibit increased risk of insulin resistance for glucose, type 2 diabetes mellitus and cardiovascular disease, compared to those with fat accumulations around the hips, buttocks and thighs ("pear shaped"). Standard methods to assess abdominal obesity include waist circumference and the waist:hip ratio.

Studies of Heritable Causes and Molecular Mediators of Obesity

Nearly everyone living in developed countries is exposed to a calorie-rich, sedentary environment; yet BMIs vary considerably, from extremely thin to morbidly obese. An inherited propensity toward obesity is clear, based on comparisons of BMIs (1) between monozygotic and dizygotic twins, (2) between genetically full or half-siblings raised apart after adoption in infancy and (3) in multigenerational kindreds. These reports yield estimates of heritability for obesity ranging from 20% to 80%. Most of these studies were done on people born before the recent increase in obesity. Notably, a study of twin children growing up during the obesity epidemic found that BMI and waist circumference each showed 77% heritability. Behaviors linked to obesity all have substantial inherited components: eating in the absence of hunger, impaired responses to internal signals of satiety, exaggerated responses to external food cues, rapid eating and low levels of physical activity, including NEAT.

MOLECULAR PATHOGENESIS: Many genetic studies have identified specific gene variants that, all together, contribute only slightly to the population-wide development of obesity:

- **Leptin gene mutations** have been linked to rare monogenic syndromes of severe obesity in humans. Homozygotes present with hyperphagia and severe, early-onset obesity. They die more readily after childhood infections and as adults develop hypothalamic hypogonadism,

insulin resistance and diabetes. Heterozygotes have reduced blood levels of leptin and increased body weight compared with unaffected siblings. Replacement therapy with injections of recombinant leptin is effective.

- **Leptin receptor gene mutations** have been found in rare families with severe early-onset obesity. The phenotype is similar to that in patients with mutations in the leptin gene, except that people with receptor mutations have more elevated serum leptin levels. They also have hypogonadotropic hypogonadism, failure of pubertal development, growth delay and secondary hypothyroidism. As expected, leptin supplementation is ineffective in these individuals.
- **Melanocortin-4 receptor gene (*MC4R*) mutations,** both dominant and recessive, are the leading cause of severe, monogenic, childhood-onset obesity, accounting for 5% of such cases. Because this syndrome is rare, *MC4R* mutations have only a minor effect on population-wide prevalence of obesity. Patients tend to have no phenotype other than overeating, obesity and the well-known cardiometabolic sequelae of obesity.
- **Mutations or deficiencies in POMC/α-MSH,** prohormone convertase 1 and the hypothalamic transcription factor SIM1 may cause isolated cases of obesity.
- Genome-wide association studies have identified several genes that encode brain/hypothalamic proteins and are associated with variations in BMI. However, all specific gene polymorphisms identified to date account for under 1% of the genetic basis for obesity.
- **Epigenetic programming** during fetal or immediate postnatal life may influence adult physiology. Children born to obese mothers show high rates of obesity, but—remarkably—those born to the same woman who undergoes biliopancreatic bypass surgery and loses considerable weight before subsequent pregnancies tend not to be obese. It is not known if maternal weight loss from more widely used bariatric surgical methods, such as vertical sleeve gastrectomy or Roux-en-Y bypass, provides similar protection to children born postsurgery.

Body weight control mechanisms are believed to have evolved to protect from weight loss in times of scarcity, not obesity in times of plenty. Striking examples of environmental influence on genetic predisposition include the Pima Native Americans in Arizona and the Aboriginal population of northern Australia. Pimas are now largely sedentary and eat a diet in which 50% of energy derives from fat, unlike their traditional low-fat diets. They have experienced huge increases in obesity and diabetes. By contrast, the genetically related Pimas in the Sierra Madre Mountains of Northern Mexico are more physically active, maintain more traditional low-fat diets and have much lower rates of obesity and type 2 diabetes.

Urbanized Aboriginal people in Australia have a high prevalence of diabetes and hypertriglyceridemia, compared with their nonurbanized counterparts. As little as a 7-week reexposure of urbanized Aboriginals with diabetes and hypertriglyceridemia to traditional lifestyle—eating less and moving more—led to weight loss and improved glucose tolerance, blood glucose, insulin and triglycerides.

Regarding heritable predisposition, diabetes risk among the Pima community varies inversely with the extent of European ancestry in each. This is consistent with the 3-fold difference in disease prevalence between the two parental populations (i.e., Pima and European).

Overnutrition, Insulin Resistance and Responsiveness Syndromes

Imbalanced Insulin Action Often Follows Overnutrition and Obesity and Causes Metabolic Complications Including Type 2 Diabetes Mellitus

The **insulin receptor** is a tetrameric glycoprotein with two extracellular α-subunits that bind insulin and two transmembrane β-subunits with insulin-stimulated tyrosine kinase activity. Activation of the receptor kinase leads to tyrosine phosphorylation of several docking proteins, including **insulin receptor substrate** (IRS)-1, IRS2 and Src homologous and collagen-like protein (SHC) (Fig. 13-3). The newly phosphorylated sites on IRS1, IRS2 and SHC recruit other signal transduction kinases or adaptor proteins. These, in turn, activate downstream kinases. As a result, lipid and protein substrates are phosphorylated, leading to translocation of glucose transport proteins from the interior of the cell to the plasma membrane. This effect facilitates glucose entry, particularly into skeletal muscle and, to a lesser extent, adipocytes.

Insulin has several additional functions unrelated to importing glucose:

- Suppression of hepatic glycogenolysis and gluconeogenesis, thus inhibiting hepatic glucose production in the postprandial state.
- Induction of hepatic fatty acid and triglyceride biosynthesis (de novo lipogenesis) to export and store calories in a compact, osmotically inactive form.
- Activation of endothelial nitric oxide synthase (eNOS) to produce nitric oxide (NO), a vasodilator that increases blood flow and hence glucose availability to skeletal muscle.
- Activation of extracellular signal-regulated kinase (ERK), a mitogen-activated protein (MAP) kinase. This kinase drives protein synthesis and cell division and increases endothelial production of endothelin-1, a vasoconstrictor that may modulate eNOS-mediated vasodilation.

All of these effects are healthy responses to handle the caloric content of a normal meal.

Obesity is usually associated with resistance to insulin's glucose-lowering effects, or more simply, insulin resistance for glucose [IRg] (Fig. 13-4). However, many other actions of insulin remain fully intact in obese subjects. Hence, such people develop an imbalance among the actions of insulin. For example, the ability of insulin to increase blood flow into muscle, drive glucose uptake into skeletal myocytes and block postprandial glucose production from the liver is impaired in overnutrition. Paradoxically, insulin still stimulates hepatic triglyceride biosynthesis, which contributes to development of fatty liver and hypertriglyceridemia. Moreover, insulin-induced activation of ERK continues unimpaired, driving vasoconstriction through endothelin-1

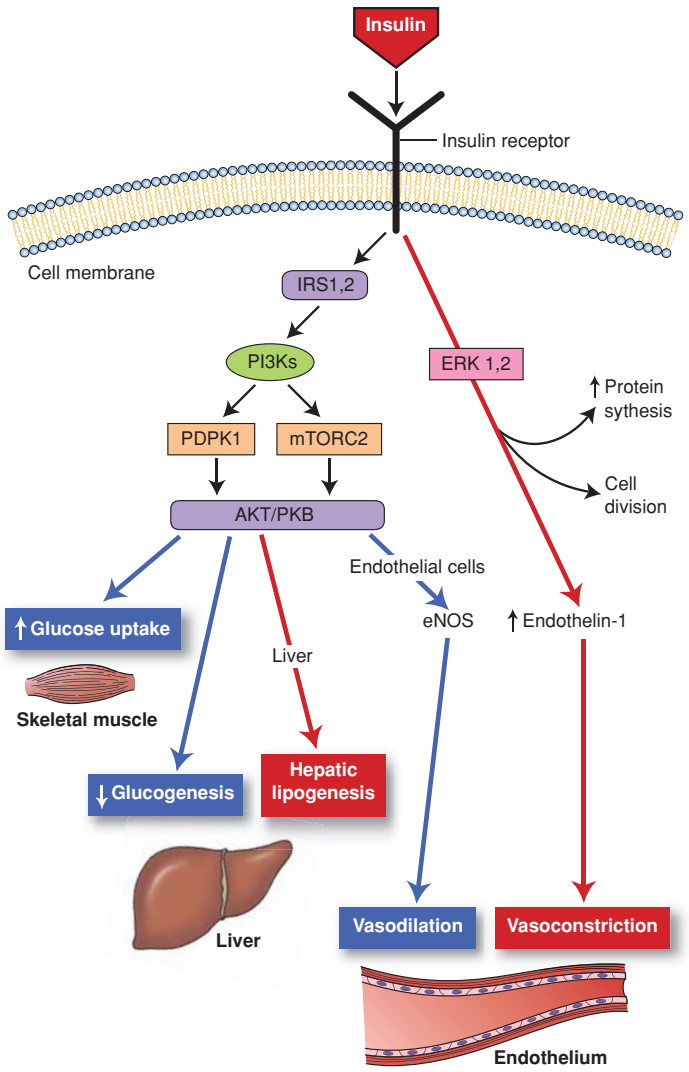

FIGURE 13-3. Key branches of insulin signaling and action. In normal physiology, insulin activates all pathways, but vasodilation produced by endothelial nitric oxide synthase (eNOS) dominates over vasoconstriction via ERK. Beneficial pathways when insulin is administered therapeutically are indicated in *blue* (glucose-lowering), while those that are potentially harmful are shown in *red* (hepatic lipogenesis and the ERK mitogen-activated protein [MAP] kinase). Strikingly, in obesity, type 2 diabetes and other conditions associated with pathway-selective insulin resistance and responsiveness (SEIRR), all pathways shown in blue become insulin resistant, while those in red remain insulin responsive. *From the standpoint of human health, it is the worst possible combination of effects.* Protein abbreviations: *AKT/PKB* = protein kinase B; *ERK* = extracellular signal-regulated kinase; *Gluc* = glucose; *IRS1,2* = insulin receptor substrates 1 and 2; *mTORC2* = mammalian target of rapamycin complex-2; *PDPK1* = 3′-phosphoinositide-dependent protein kinase-1; *PI3Ks* = isoforms of phosphatidylinositol 3′-kinases; *SHC* = Src homologous and collagen-like protein.

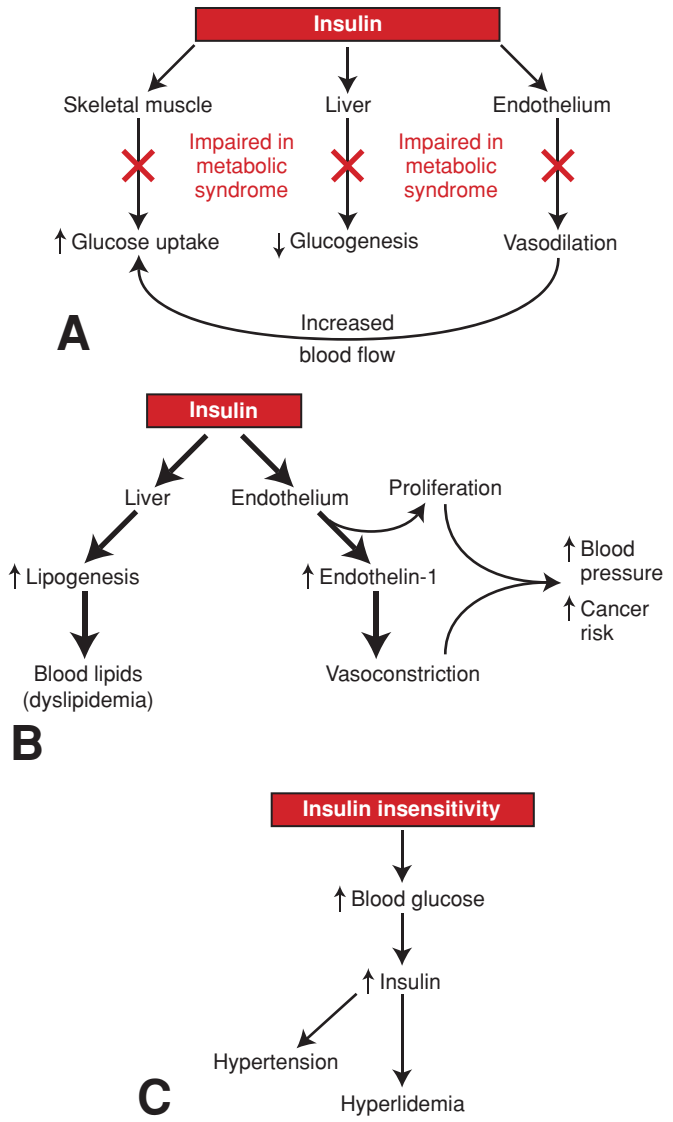

FIGURE 13-4. Mechanisms of insulin action that are impaired and that are intact in metabolic syndrome. A. Insulin activities that are impaired in metabolic syndrome. **B.** Insulin functions that remain intact in metabolic syndrome. **C.** Summary of insulin resistance for glucose and its consequences.

production and mitogenesis, possibly contributing to hypertension and cancer risk. This constellation of effects has been called pathway-selective insulin resistance and responsiveness (SEIRR). To control plasma concentrations of glucose, people with SEIRR become hyperinsulinemic, either from pancreatic overproduction of endogenous insulin or from therapeutic administration of exogenous insulin. Raising insulin levels cannot make these individuals metabolically normal, *even if they achieve normoglycemia,* because hyperinsulinemia drives lipid synthesis in the liver and the ERK MAP kinase to become overactive.

Insulin Resistance for Glucose and SEIRR Are Not Understood

There are currently several suggested mechanisms to explain IRg and SEIRR. Each potential pathway explains some facets of these phenomena but leaves others unclear.

- **Lipotoxicity:** In obese people, plasma concentrations of nonesterified fatty acids (NEFAs) tend to be high, in part because the normal postprandial suppression of lipolysis of triglycerides in adipose tissue becomes insulin resistant. An excess of plasma nonesterified fatty acids can lead to ectopic accumulation of triglycerides,

diacylglycerol and ceramide in liver and muscle cells. These molecules activate protein kinase C to induce insulin resistance for glucose by blocking the insulin receptor tyrosine kinase signal cascade (see above). Plasma levels of nonesterified fatty acids are preferentially increased in visceral–abdominal adiposity (Fig. 13-2). However, this hypothesis appears inconsistent with some newer information. For example, protein kinase C activation produces proximal blocks in insulin signaling, but such inhibition cannot explain ongoing insulin-dependent lipogenesis in the liver pathway–selective activation of ERK. Also, fatty liver in people with certain genetic defects in triglyceride disposal (and fatty liver in animals with analogous molecular manipulations) does not cause insulin resistance for glucose, even when the liver also shows remarkably high levels of diacylglycerol and ceramide.

- **Inflammation:** Adipose tissue in obesity often contains an inflammatory infiltrate, particularly of macrophages. Circulating levels of cytokines, particularly tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β), are increased in visceral–abdominal obesity. These cytokines can also induce insulin resistance for glucose in experimental animals and cultured cells. However, in early stages of human overnutrition syndromes, TNF-α and other cytokines are not elevated; yet these people are already insulin resistant for glucose. A recent prospective clinical trial of high-dose salicylate as an anti-inflammatory agent produced only minor improvements in glycemic control. As well, TNF-α–induced blocks in insulin signaling may be too proximal to explain downstream pathway-selectivity.
- **Endoplasmic reticulum (ER) stress:** In animal models of obesity and insulin resistance for glucose, ER stress pathways are activated, as part of the unfolded protein response (see Chapter 1). Chemical induction of ER stress in cultured cells impairs insulin signaling, and relief of ER stress in obese animals improves their glucose handling. Evidence for this pathway in obese humans, however, has been mixed.
- **NAD(P)H oxidase-4 (NOX4):** NOX4, a molecule activated by insulin, affects the balance among other downstream limbs of the insulin signaling cascade. However, any role for NOX4 in SEIRR in people remains conjectural.

Imbalanced insulin action in target tissues and compensatory hyperinsulinemia are closely tied to a diverse set of cardiovascular risk factors that are prevalent in obese, sedentary people and patients with diabetes. These risk factors, together called the **metabolic syndrome,** include (1) abdominal adiposity with increased waist circumference, (2) mild hypertension (perhaps related to failure of endothelium-dependent vascular relaxation), (3) impaired fasting plasma glucose levels and (4) dyslipoproteinemia with elevated plasma triglycerides and low plasma high-density lipoprotein (HDL) cholesterol (Table 13-1).

The Complications of Overnutrition and Obesity Affect Most Organ Systems

Obesity and central adiposity are associated with increased morbidity and, for class II and III obesity, increased mortality as well (Fig. 13-5). Fat cells undergo both hyperplasia and hypertrophy. The excess from the imbalance between energy intake and energy expenditure is stored in adipocytes, which enlarge, increase in number or both. An extremely obese adult can have four times as many adipocytes as a lean one, each cell containing twice as much lipid.

TABLE 13-1
FREQUENTLY OBSERVED CONCOMITANTS OF THE METABOLIC SYNDROME

Clinical Signs
Central (upper body) obesity with increased waist circumference
Acanthosis nigricans (hypertrophic, hyperpigmented skin changes)
Laboratory Abnormalities
Elevated fasting and/or postprandial glucose
Insulin resistance for glucose, with hyperinsulinemia, but continued responsiveness—and hence overactivity—of other pathways downstream of the insulin receptor
Dyslipidemia characterized by increased triglycerides and low high-density lipoprotein cholesterol
Hypercoagulability and abnormal thrombolysis
Hyperuricemia
Endothelial and vascular smooth muscle dysfunction
Albuminuria
Comorbid Illnesses
Hypertension
Atherosclerosis
Hyperandrogenism with polycystic ovary syndrome

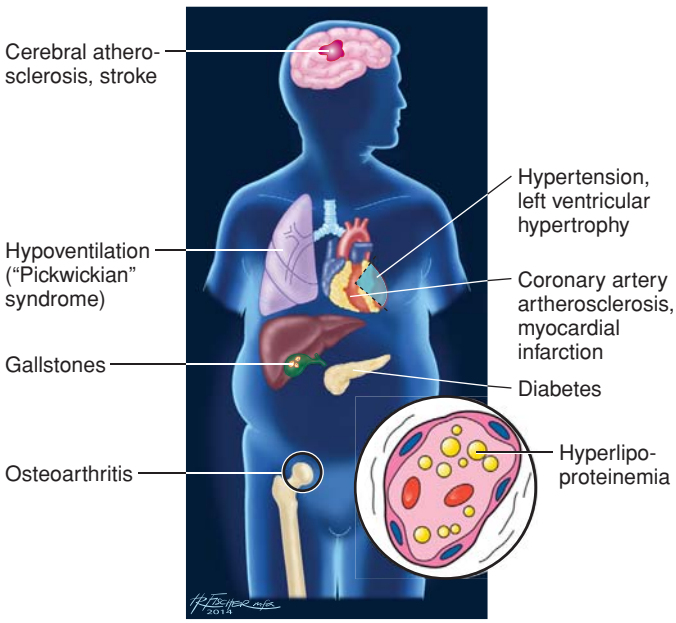

FIGURE 13-5. Medical complications of obesity.

Endocrine Complications

- **Type 2 diabetes mellitus (T2DM):** T2DM is strongly associated with obesity, and more than 80% of cases are attributed to obesity. The risk of diabetes increases linearly with BMI and with increments in abdominal fat, waist circumference or waist:hip ratio. Conversely, weight loss and exercise decrease risk of T2DM and can prevent progression of insulin resistance to diabetes. In a large American population with impaired glucose tolerance, simply engaging in brisk walking for 150 minutes per week and loss of 7% of body weight reduced the rate of progression of blood glucose levels to overt T2DM in 60% of subjects. More drastic measures for morbid obesity (e.g., weight loss after gastric bypass surgery) resulted in complete resolution of diabetes in almost 80% of patients. Thus, these harmful effects appear reversible.
- **Dyslipidemia and dyslipoproteinemia:** By far, the major killer in obesity and diabetes is atherosclerotic cardiovascular disease. Several deleterious plasma lipid and lipoprotein abnormalities often occur in obesity, including elevated fasting levels of triglyceride- and cholesterol-rich lipoproteins and nonesterified fatty acids and reduced HDLs. These abnormalities are strongly associated with an increased risk of cardiovascular disease, particularly in people with central adiposity. In addition, nonfasting plasma triglyceride concentrations independently predict subsequent heart attacks and strokes. They reflect the persistence of a particular class of harmful lipoproteins, called remnants, that appear in the circulation after each meal or snack. Like low-density lipoproteins (LDLs), these particles contain apolipoprotein B and cholesterol, and can be trapped within arterial walls, initiating and accelerating atherosclerotic vascular disease (see Chapter 16). As the prevalence of obesity rises, dyslipoproteinemias beyond simple elevations in plasma LDL cholesterol have contributed increasingly to cardiovascular risk.
- **Other endocrine complications:** Obesity is also associated with polycystic ovary syndrome, irregular menses, amenorrhea, infertility and hypogonadism.

Cardiovascular Complications

- **Hypertension:** Obesity entails a high risk of hypertension and is associated with heightened sympathetic activity. High insulin levels in obese patients with insulin resistance act on pathways unrelated to glucose importation. These include enhancing renal reabsorption of sodium, which contributes to hypertension, and stimulating endothelial production of the vasoconstrictor endothelin-1. In addition, obese adipose tissue also secretes substances including angiotensin II and its precursors that directly cause vasoconstriction and increase blood pressure. By interfering with the action of antihypertensive agents, obesity makes hypertension more difficult to control. Even a small reduction in weight may decrease blood pressure in this population.
- **Coronary heart disease:** BMI has a modest and graded association with myocardial infarction, but body fat distribution, especially the waist:hip ratio, is a stronger indicator of risk. Dyslipoproteinemia and hypertension are the best predictors of atherosclerotic cardiovascular disease linked to obesity.
- **Congestive heart failure:** Obesity is associated with increased risk of heart failure due to eccentric cardiac dilatation. Also, the combination of obesity and hypertension leads to ventricular wall thickening and larger heart volume. Obese patients are also at increased risk of atrial fibrillation and atrial flutter.
- **Thromboembolic disease:** Deep venous thromboses and pulmonary embolism are more common in obese patients. Thromboembolic disease of the lower extremities may be related to increased abdominal pressure, impaired fibrinolysis and increased circulating cytokines, particularly with abdominal obesity.

Additional Complications of Obesity

- **Neurologic:** Obesity increases risk of ischemic stroke as BMI increases.
- **Pulmonary:** Obesity may interfere mechanically with lung function. Increased weight, particularly excess abdominal obesity, decreases ventilatory drive, respiratory compliance and ventilation, particularly ventilation of lung bases. It thus adds to ventilation–perfusion mismatch. Obesity is a major risk factor for **obstructive sleep apnea,** which renders patients prone to breathing disorders during sleep. **Obesity-hypoventilation syndrome** refers to decreased ventilatory responsiveness to hypercapnia or hypoxia. This condition impairs responses to the increased ventilatory demands that are imposed by the mechanical effects of obesity. The severe form of this syndrome is **Pickwickian syndrome,** in which extreme obesity, irregular breathing, cyanosis, secondary polycythemia and right ventricular dysfunction all lead to fixed pulmonary hypertension.
- **Hepatobiliary:** Obese people, particularly women, suffer from an increased incidence of gallstones. Interestingly, weight loss may also precipitate gallstones, owing to increased cholesterol supersaturation in bile, enhanced cholesterol crystal nucleation and decreased gallbladder contractility. Many liver abnormalities, manifested by increased serum liver enzymes, hepatomegaly and altered liver histology, may also complicate obesity. These represent a spectrum of disease, **nonalcoholic fatty liver disease** (NAFLD), characterized by accumulation of fat within hepatocytes (see pathway-selective insulin resistance and responsiveness, above, and Chapter 20). A subset of patients with simple steatosis progress to nonalcoholic steatohepatitis (NASH), and inflammatory changes within the liver can cause fibrosis, cirrhosis and portal hypertension. NASH is the leading cause of so-called "idiopathic" cirrhosis.
- **Gastrointestinal:** Gastroesophageal reflux is more common in obese people.
- **Cancer:** Certain cancers occur with greater frequency in those who are obese. Specifically, risks for esophageal, gallbladder, pancreatic, breast, renal, uterine, cervical and prostate cancers are all increased. Once cancer is diagnosed, obesity is associated with a worse prognosis. Activation of ERK (see above) may provide a mitogenic stimulus that predisposes obese people to certain tumors. Obesity has also been associated with overexpression of aromatase in adipose tissue within the breast, local production of estrogen and increased breast cancer risk.
- **Musculoskeletal:** Hyperuricemia and gout are more common in obese people. Obesity increases the risk of osteoarthritis, particularly of weight-bearing joints such as the knees. However, non–weight-bearing joints can also be affected, suggesting mechanisms other than increased mechanical load. Weight loss decreases the risk of osteoarthritis.

- **Skin:** Obesity causes **striae,** stretching and thinning of the epidermis in a ribbon-like pattern**. Acanthosis nigricans** is a velvety, hypertrophic, hyperpigmented lesion, especially at skinfold areas (axillae, nape of the neck). It may be a response to high circulating insulin levels in patients with insulin resistance. Excessive hair growth **(hirsutism)** can result from increases in circulating androgens in susceptible women.
- **Psychological and social:** Obesity has also been associated with impaired quality of life, increased sick leave absences and disability claims and depression.

Diabetes Mellitus

Almost a century ago, Sir William Osler defined diabetes mellitus as "a syndrome due to a disturbance in carbohydrate metabolism from various causes, in which sugar appears in the urine, associated with thirst, polyuria, wasting and imperfect oxidation of fats." With the advent of insulin and other therapies, however, such extreme features are unusual in properly managed patients with diabetes.

Yet long-term consequences persist. Hence, diabetes mellitus in the modern setting is redefined as "a state of premature cardiovascular death that is associated with chronic hyperglycemia and may also be associated with blindness and renal failure." This emphasis reflects the fact that in industrialized countries, cardiovascular disease kills 70% of patients with diabetes, compared to 50% of the general population. It also affects them earlier in life, with greater morbidity. Adults with diabetes are two to four times more likely to have heart disease or stroke than those without diabetes.

Diabetes is a major health problem that affects increasing numbers of people throughout the world. Two major forms are recognized, distinguished by different underlying pathophysiologies. **Type 1 diabetes mellitus (T1DM),** formerly known as **insulin-dependent diabetes mellitus (IDDM)** or **juvenile-onset diabetes,** is caused by autoimmune destruction of insulin-producing beta cells in the pancreatic islets of Langerhans. It affects fewer than 10% of all patients with diabetes. By contrast, **T2DM,** formerly known as **non–insulin-dependent diabetes mellitus (NIDDM)** or **maturity-onset diabetes,** is usually associated with obesity. It results from a complex interrelationship between insulin resistance of target tissues and an oversecretion of insulin by the pancreas (see above). This balance may, or may not, be sufficient to control plasma glucose concentrations. Table 13-2 compares the key features of type 1 and type 2 diabetes.

Gestational diabetes develops in some pregnant women owing to resistance to the glucose-lowering actions of insulin in pregnancy, combined with a beta cell defect in the pancreas.

TABLE 13-2
COMPARISON OF TYPE 1 AND TYPE 2 DIABETES MELLITUS

	Type 1 Diabetes	Type 2 Diabetes
Age at onset	Usually before 20	Usually after 30
Type of onset	Abrupt; symptomatic (polyuria, polydipsia, dehydration); often severe with ketoacidosis	Gradual; usually subtle; often asymptomatic
Usual body weight	Normal; recent weight loss is common	Overweight
Family history	<20%	>60%
Monozygotic twins	50% concordant	90% concordant
HLA associations	+	No
Antibodies to islet cell antigens (insulin, glutamic acid decarboxylase [GAD-65], IA-2)	+	No
Islet lesions	Early—inflammation Late—atrophy and fibrosis	Late—fibrosis, amyloid
Beta cell mass	Markedly reduced	Normal or slightly reduced
Circulating insulin levels	Markedly reduced or absent	Elevated (early)
Insulin resistance for glucose (i.e., selective resistance to the glucose-lowering actions of insulin)	Normal sensitivity to glucose-lowering actions of insulin	Significant insulin resistance for glucose, but with continued insulin responsiveness of other pathways
Clinical management	Administration of exogenous insulin absolutely required	Exogenous insulin usually not needed initially; insulin supplementation may be needed at later stages; weight loss typically improves the condition

HLA = human leukocyte antigen; IA-2 = islet cell antigen-512.

TABLE 13-3
ETIOLOGIC CLASSIFICATION OF DIABETES MELLITUS

I. Type 1 diabetes (beta cell destruction, absolute insulin deficiency) – A. Immune mediated – B. Idiopathic
II. Type 2 diabetes (insulin resistance for glucose, with relative insulin deficiency)
III. Other specific types – Genetic defects of beta cell function (e.g., maturity-onset diabetes of the young) – Genetic defects in insulin action (e.g., type A insulin resistance, which can be caused by mutations in the insulin receptor) – Diseases of the exocrine pancreas – Endocrinopathies (e.g., Cushing disease, acromegaly, etc.) – Drug or chemical induced (e.g., glucocorticoids) – Infections (e.g., cytomegalovirus, rubella) – Uncommon forms of immune-mediated diabetes (e.g., "stiff-man syndrome") – Other genetic syndromes (e.g., Turner syndrome, Down syndrome)
IV. Gestational diabetes mellitus

Copyright 2013 American Diabetes Association. From *Diabetes Care,* Vol. 36, 2013. Modified with permission from the American Diabetes Association.

It almost always abates after delivery. Diabetes can also occur in other endocrine conditions or drug therapy, especially in Cushing syndrome or during treatment with glucocorticoids. Other rare clinical syndromes entail abnormal glucose metabolism or overt **hyperglycemia**. As these conditions are uncommon and have well-defined genetic etiologies that differ from the more common forms of diabetes, they will not be considered in detail. Table 13-3 shows the classification of diabetes as recommended by the American Diabetes Association (ADA).

Current criteria for the diagnosis of diabetes mellitus are based on abnormal threshold levels for glucose or hemoglobin A_{1c} that are closely associated with the chronic complications of this disorder. In particular, hyperglycemia causes the microvascular changes of diabetic retinopathy and renal glomerular damage. In a younger patient with abrupt onset of hyperglycemia and elevated plasma ketones or frank ketoacidosis, T1DM arises from absolute insulin deficiency. By contrast, T2DM typically develops gradually over years before it is recognized, most often in an overweight, middle-aged person with a genetic predisposition.

TABLE 13-4
CRITERIA FOR THE DIAGNOSIS OF DIABETES

1. HbA_{1c}[a] ≥6.5%
OR
2. FPG ≥126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 h
OR
3. 2-h plasma glucose ≥200 mg/dL (11.1 mmol/L) during an OGTT
OR
4. In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose ≥200 mg/dL (11.1 mmol/L)

FPG = fasting plasma glucose; HbA_{1c} = hemoglobin A_{1c}; OGTT = oral glucose tolerance test.
[a]In the absence of unequivocal hyperglycemia, criteria 1–3 should be confirmed by repeat testing.
Copyright 2013 American Diabetes Association. From *Diabetes Care,* Vol. 36, 2013. Modified with permission from the American Diabetes Association.

TABLE 13-5
CATEGORIES OF INCREASED RISK FOR DIABETES (PREDIABETES)[a]

FPG 100 mg/dL (5.6 mmol/L) to 125 mg/dL (6.9 mmol/L) (IFG)
2-h PG in the 75-g OGTT 140 mg/dL (7.8 mmol/L) to 199 mg/dL (11.0 mmol/L) (IGT)
HbA_{1c} 5.7%–6.4%

FPG = fasting plasma glucose; HbA_{1c} = hemoglobin A_{1c}; IFG = impaired fasting glucose; IGT = impaired glucose tolerance; OGTT = oral glucose tolerance test; PG = plasma glucose.
[a]For all three tests, risk is continuous, extending below the lower limit of the range and becoming disproportionately greater at the higher ends of the range.
Copyright 2013 American Diabetes Association. From *Diabetes Care,* Vol. 36, 2013. Modified with permission from the American Diabetes Association.

The ADA suggests any of four criteria to diagnose diabetes (Table 13-4). One of the four criteria has to be present for the diagnosis, but some criteria require repeat testing for confirmation. In addition, the ADA recognizes three categories of increased risk for diabetes (Table 13-5). Some of those are commonly referred to as "prediabetes," but the term should be used with caution, because only half of those patients will ultimately develop diabetes.

TYPE 2 DIABETES MELLITUS

T2DM is characterized by a combination of reduced tissue sensitivity to the glucose-lowering effects of insulin and oversecretion of insulin from the pancreas, which eventuates in an inadequate control of plasma glucose concentrations.

T2DM usually develops in adults, mostly in obese people and in the elderly. Recently, it has been appearing increasingly in younger adults and adolescents, as severe obesity and lack of exercise become more severe and common in this age group. Patients with T2DM exhibit hyperinsulinemia in terms of absolute concentrations, but these excessive insulin concentrations fail to control their blood sugar levels. When T2DM patients require administration of exogenous insulin, their total daily doses are much higher than in lean T1DM (insulin-deficient) patients. Because a number of insulin actions in obesity, prediabetes and T2DM still remain responsive, such as hepatic lipogenesis and ERK activation, some investigators attribute metabolic harm to hyperinsulinemia.

EPIDEMIOLOGY: In 2010, about 8% of the American population and/or 11% of those older than 20 years had T2DM. More than a quarter were undiagnosed. Over 25% of people over 60 have diabetes, and 35% of adults are felt to have prediabetes. T2DM is most prevalent in women, especially of lower socioeconomic

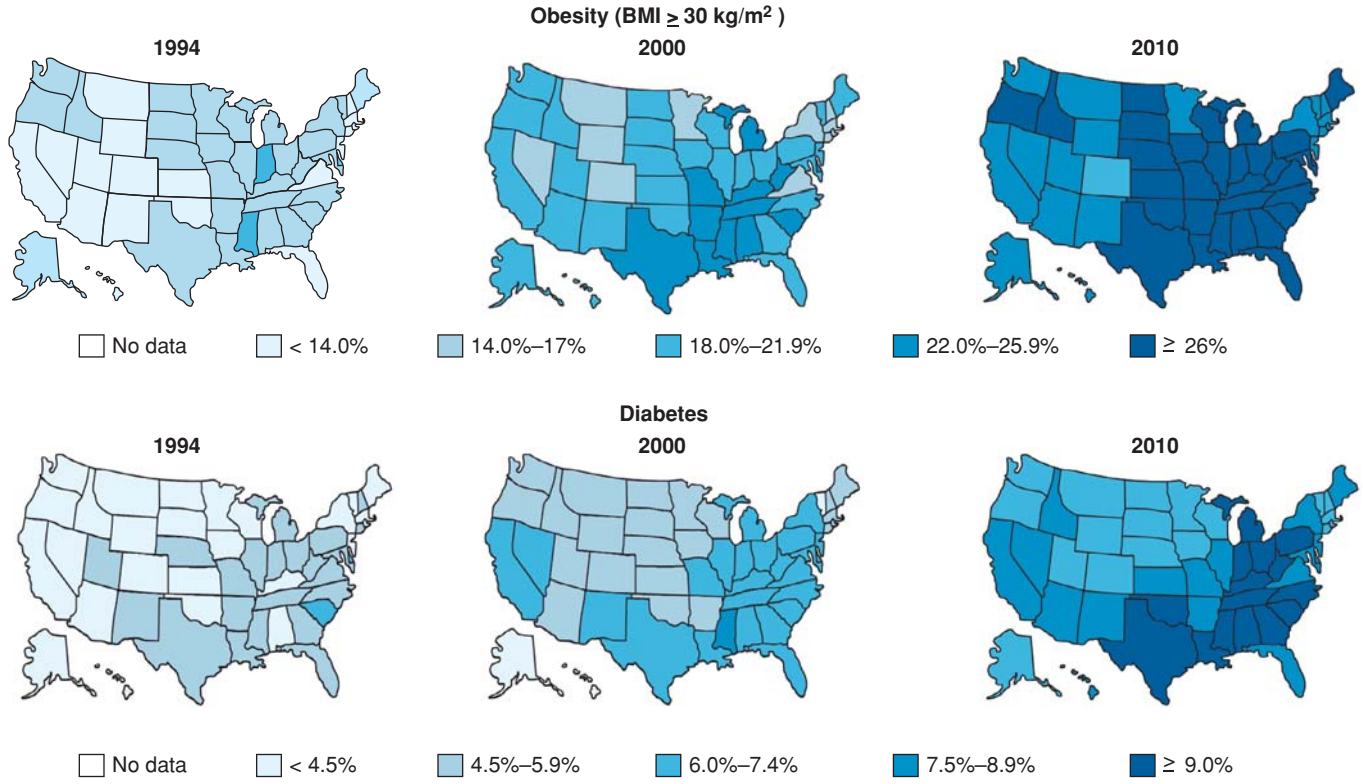

FIGURE 13-6. The increasing prevalence of obesity and diabetes in the United States.

strata. All nonwhite ethnic groups are more affected than white Americans. Diabetes is also increasing worldwide: in China, for example, it affects about 10% of adults.

Diabetes is the leading cause of kidney failure, nontraumatic lower limb amputations and new cases of blindness among American adults. It is also a major factor in heart disease and stroke, and is the 7th leading cause of death. Fig. 13-6 shows the dramatic increase in prevalence of diabetes in the United States from 1994 to 2010.

Type 2 Diabetes Mellitus Results from Insulin Resistance and Inability to Hypersecrete Insulin

T2DM is a two-hit disease. The first "hit" is resistance to the glucose-lowering actions of insulin in its target tissues (liver, skeletal muscle, adipose tissue). This defect alone provokes increased total pancreatic output of insulin and may later be followed by moderate defects in glucose handling, indicative of prediabetes. The second "hit" occurs when increased pancreatic insulin output can no longer compensate for the highly increased demand for insulin to control blood sugar levels. Pancreatic islets often show degenerative changes in these patients. Progression to overt diabetes occurs most commonly in patients with both of these hits (Fig. 13-7).

ETIOLOGIC FACTORS: Several risk factors are clearly associated with T2DM. The most important ones are **obesity, overnutrition and low levels of physical activity**. As noted above, the risk of T2DM increases linearly with BMI. More than 80% of cases of T2DM can be attributed to obesity. As noted above, visceral–abdominal obesity ("apple shaped") is more associated with insulin resistance for glucose and T2DM compared to gluteal–femoral obesity ("pear shaped"). Accordingly, weight loss lowers the risk of T2DM and can prevent progression of high-risk individuals to frank diabetes.

MOLECULAR PATHOGENESIS: ***Multifactorial and multigenic inheritance is a key contributor to the development of T2DM.*** Several observations demonstrate genetic influences in the development of T2DM:

- More than 1/3 of patients with T2DM have at least one parent with the disease.
- Among monozygotic twins, concordance for T2DM approaches 100%.
- The prevalence of T2DM among different ethnic groups who are living in similar environments varies tremendously.
- First-degree relatives of patients with T2DM have a significantly higher lifetime risk of T2DM compared with matched subjects without a family history.

Despite the high familial prevalence of the disease, inheritance is complex and involves multiple interacting susceptibility genes. As with obesity, monogenic causes of T2DM represent only a small fraction of cases, and commonly inherited polymorphisms contribute only small degrees of risk for, or protection from, T2DM. Factors such as obesity (which itself has strong genetic determinants; see above), hypertension and exercise influence phenotypic expression of T2DM and complicate genetic analysis.

A rare autosomal dominant form of inherited diabetes, known as **maturity-onset diabetes of the young (MODY),** is associated with gene defects that affect beta cell function, including the gene for glucokinase, a key sensor for glucose

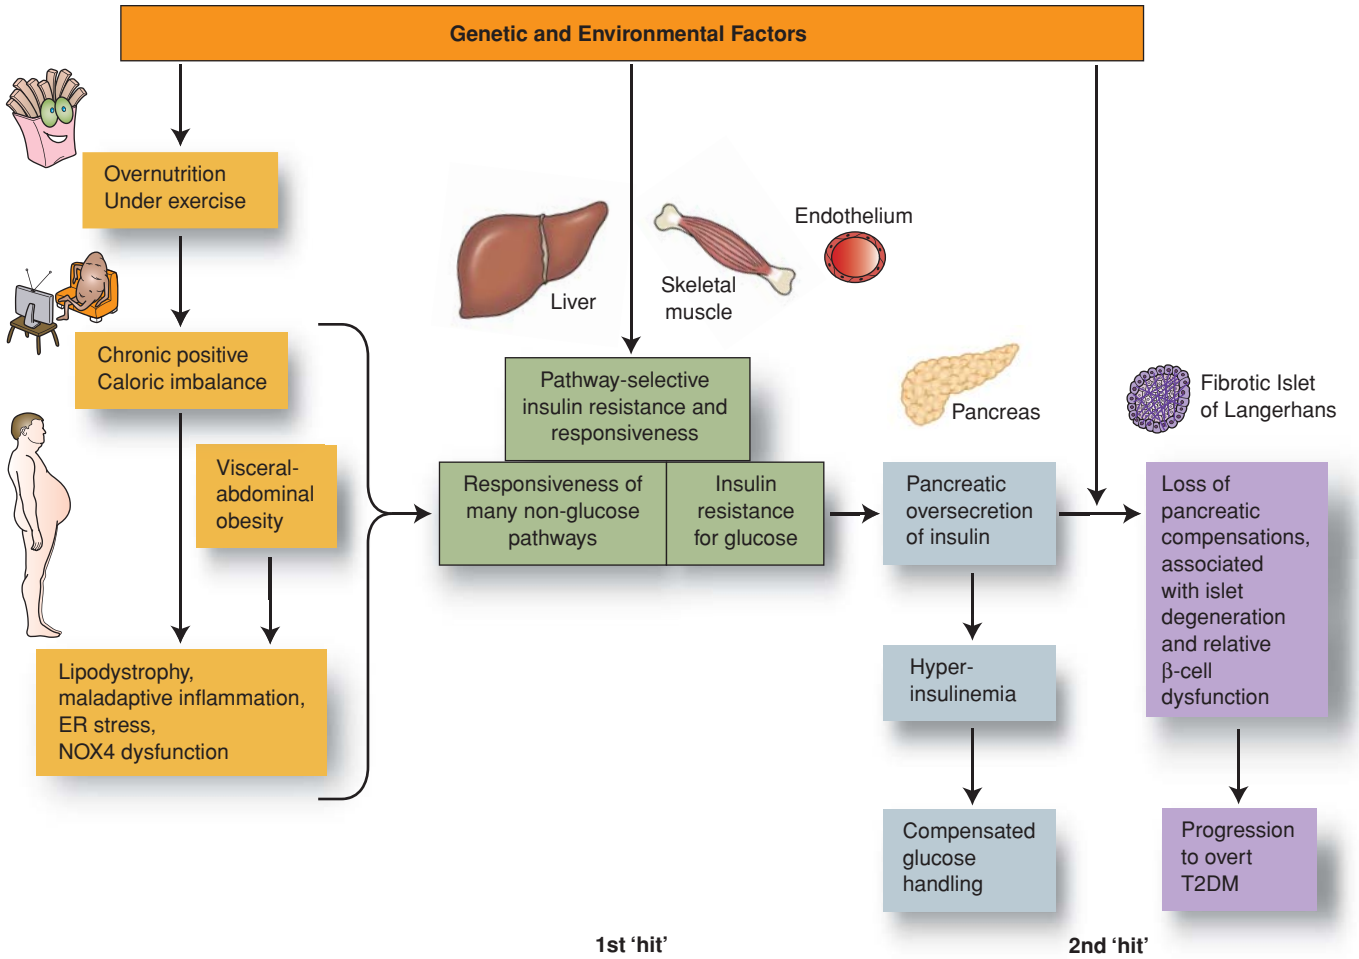

FIGURE 13-7. Pathogenesis of obesity-related type 2 diabetes mellitus (T2DM). The expanded visceral fat mass in upper body obesity elaborates several factors that may contribute to insulin resistance for glucose. These include an increase in circulating free (nonesterified) fatty acids (FFAs) and other cytokines and proteins that inhibit insulin action, as well as a decrease in factors that enhance insulin signaling, such as adiponectin. These changes result in impairments to insulin action in liver and skeletal muscle at the level of the insulin receptor and at postreceptor signaling sites, resulting in a failure of insulin to suppress hepatic glucose production and to promote glucose uptake into muscle. The resulting hyperglycemia is normally countered by increased insulin secretion by pancreatic beta cells. Continuing responsiveness of pathways downstream of the insulin receptor that are unrelated to glucose control, such as lipogenesis in the liver and activation of the extracellular signal-regulated kinase (ERK) mitogen-activated protein (MAP) kinase, may contribute to fatty liver, dyslipoproteinemia and hypertension. In many individuals, the combination of resistance to the glucose-lowering actions of insulin and a genetically determined impairment of the beta cell response to hyperglycemia eventually results in hyperglycemia, and T2DM ensues.

metabolism within the beta cell. Several mutations in genes that control beta cell development and function have been described. Mutations in these genes, however, do not account for typical T2DM.

Insulin Resistance for Glucose

After a carbohydrate-rich meal, the gut absorbs glucose. This increases blood glucose, which stimulates insulin secretion by pancreatic beta cells. In turn, insulin increases glucose uptake by skeletal muscle and adipose tissue (Fig. 13-4). At the same time, insulin suppresses hepatic glucose production by (1) inhibiting glycogenolysis and gluconeogenesis, (2) enhancing glycogen synthesis, (3) blocking the effects of glucagon on the liver and (4) antagonizing glucagon release from the pancreas.

All of these effects of insulin are impaired in IRg. Initially, compromised insulin action is subclinical. As the condition progresses, fasting glucose rises or impaired glucose tolerance develops. Eventually, the patient develops frank hyperglycemia and overt T2DM (Fig. 13-8). IRg increases hepatic glucose output and reduces glucose uptake by peripheral tissues, primarily muscles and adipose tissue.

By itself, insulin resistance rarely causes T2DM: increased insulin secretion (hyperinsulinism) by beta cells compensates for these defects and prevents blood glucose levels from rising. Only when the pancreas can no longer keep up with this high demand do blood glucose levels start to increase (Fig. 13-8). In many obese and prediabetic patients, subclinical beta cell dysfunction exists before overt diabetes.

Beta Cell Dysfunction

At first, an impairment in the first phase of insulin secretion following glucose stimulation precedes glucose intolerance in T2DM (Fig. 13-9). Later in the second phase of the disease, release of newly synthesized insulin is faulty. This effect can be reversed, at least in some patients, by restoring good control of glycemia. This partially reversible reduction in

insulin secretion results from a paradoxical inhibitory effect of glucose upon insulin release that may be seen at high blood glucose levels ("glucose toxicity").

Impaired first-phase insulin secretion can serve as a marker of risk for T2DM in family members of subjects with T2DM, and may be seen in patients with prior gestational diabetes. Over a long time, insulin secretion in T2DM gradually declines, together with beta cell mass.

The Role of Incretins

In the 1960s, it was discovered that the ability of an oral glucose load to stimulate insulin secretion was significantly greater than that evoked from a comparable intravenous infusion of glucose. This discrepancy was named the **incretin effect** (Fig. 13-10A). Incretins are peptides secreted by the gut in response to meals that increase insulin secretion and decrease glucagon secretion. Most of this effect is now thought to be due to glucose-dependent insulinotropic peptide (GIP) and GLP-1. Incretins are rapidly inactivated by dipeptidyl peptidase 4 (DPP-4) in the circulation. Effects of incretins include (1) enhanced glucose-dependent stimulation of insulin secretion by beta cells, (2) inhibition of glucagon secretion by alpha cells, (3) inhibition of appetite and (4) slowed gastric emptying.

In patients with T2DM, the incretin effect is markedly reduced (Fig. 13-10B), an effect that has been attributed to defects in secretion of GLP-1 and GIP. The role, if any, of these changes in incretins in the pathogenesis of T2DM is unknown.

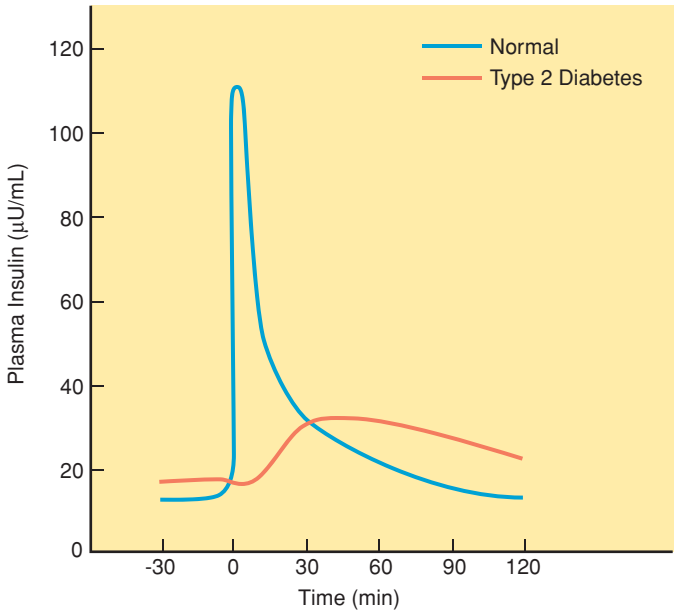

FIGURE 13-9. Insulin response in diabetes. Typical patterns of insulin production in response to glucose challenge in normal (*blue*) and type 2 diabetic (*red*) patients.

Therapeutic Implications

Early in T2DM, insulin resistance for glucose and hyperinsulinemia predominate. Both can improve dramatically with even modest weight loss and exercise, and lifestyle interventions are at the center of clinical management. In addition, insulin sensitizers are useful in those patients. Metformin is considered an "insulin sensitizer," because it improves glucose uptake by muscle and inhibits hepatic glucose production, although its mechanism of action at a molecular level remains in dispute. Thiazolidinediones, a class of PPAR-γ agonists, are also classified as insulin sensitizers because they lower insulin requirements and improve fatty liver. Some of their side effects, such as water retention, increased appetite and others, have limited their use.

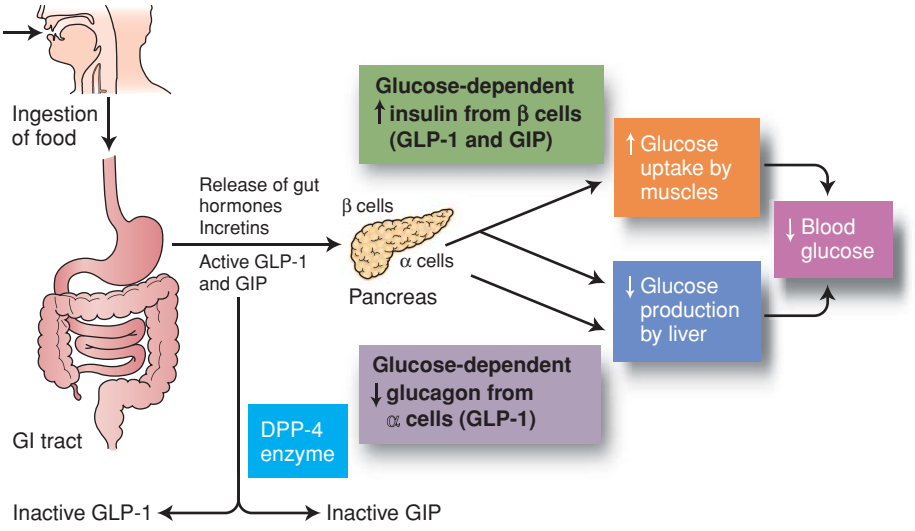
Later in the course of diabetes, as beta cell dysfunction sets in, insulin sensitizers alone cannot control T2DM. Other agents (e.g., secretagogues such as sulfonylureas, incretin-based agents [GLP-1 analogs and DPP4 inhibitors] and, ultimately, exogenous insulin) are needed. Bariatric surgery has also become a therapeutic option, reducing caloric intake, BMI and the need for medications. Remarkably, some patients with T2DM before bariatric surgery require no medications after surgery.

PATHOLOGY: Lesions may be found in the islets of Langerhans of many, but not all, patients with T2DM. Unlike T1DM (see below), the number of beta cells is not consistently reduced in T2DM, and no morphologic lesions of these cells have been found by light or electron microscopy.

In some islets, fibrous tissue accumulates, sometimes so much that islets are obliterated. Islet amyloid is often present (Fig. 13-11), particularly in patients older than 60 years. This type of amyloid is composed of a polypeptide molecule known as **amylin,** which is secreted with insulin by the beta cell. Importantly, as many as 20% of aged nondiabetics also have amyloid in their pancreatic islets, a finding that has been attributed to the aging process itself.

TYPE 1 DIABETES MELLITUS

T1DM is a lifelong disorder of glucose homeostasis that results from autoimmune destruction of beta cells in the islets of Langerhans. In contrast to T2DM, T1DM is a one-hit



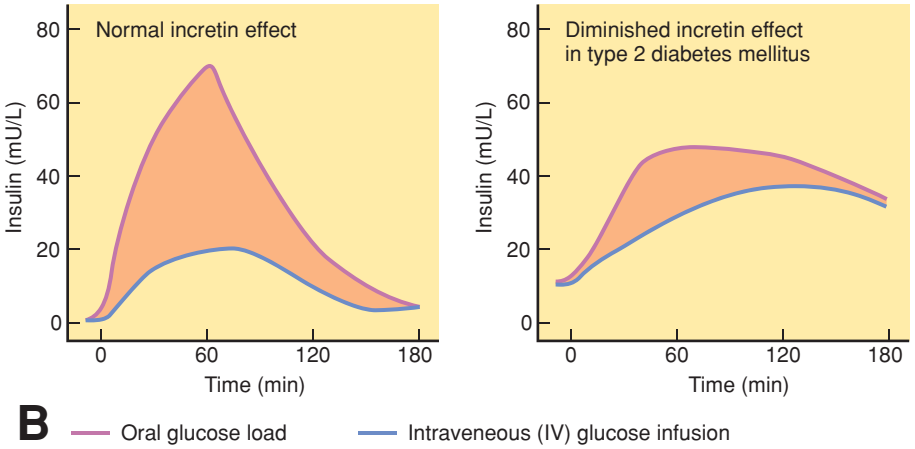


FIGURE 13-10. Incretins. A. Physiologic roles of incretins in glucose metabolism. Involvement of incretins in regulating the responses of the body to a caloric load. *GIP* = glucose-dependent insulinotropic peptide; *GLP-1* = glucagon-like peptide-1. **B.** Diminished incretin responsiveness in type 2 diabetes mellitus.

disease that is caused by autoimmune destruction of pancreatic beta cells. Triggers for this autoimmune reaction remain unknown (see below). Because T1DM reflects absolute insulin deficiency, rather than complex defects in insulin action, these patients can be made almost metabolically normal by closely controlling the amounts, timing and preparations of exogenous insulin. Considerable research is being devoted to two independent approaches to supply insulin in a highly regulated fashion to T1DM patients—namely, islet cell transplantation and "closed loop" machines that simultaneously monitor glucose concentrations and administer exogenous insulin. Management of T1DM can be complicated if patients become obese; historically, T1DM patients were uniformly lean.

T1DM is characterized by few, if any, functional beta cells and extremely limited or nonexistent insulin secretion. Without insulin, the body switches energy use to a pattern that resembles starvation, regardless of the availability of food. Thus, adipose stores, rather than exogenous glucose, are preferentially metabolized for energy. Oxidation of fat overproduces **ketone bodies** (acetoacetic acid and β-hydroxybutyric acid), which are released into the blood from the liver and lead to metabolic ketoacidosis. Hyperglycemia results from unsuppressed hepatic glucose output and reduced glucose uptake into skeletal muscle and adipose tissue. Blood glucose levels exceed the kidneys' ability to resorb it, leading to glycosuria. This, in turn, causes osmotic diuresis, which can lead to dehydration from accompanying loss of body water. If uncorrected, progressive acidosis and dehydration cause coma and death (Fig. 13-12).

EPIDEMIOLOGY: It is estimated that more than 1 million Americans suffer from T1DM. Most develop this disease within the first two decades of life, but more and more cases are being recognized in older people. In some older patients, autoimmune beta cell destruction may develop slowly over many years. The name latent autoimmune diabetes in adults (LADA) is commonly applied to those patients.

T1DM is most common among northern Europeans and their descendants and occurs less often in other ethnic groups. For example, T1DM develops in Finland 20–40 times more than in Japan. Although it can develop at any age, the peak age of onset coincides with puberty. In many geographical areas, an increased incidence in late fall and early winter suggests seasonal infections as autoimmune triggers (see below).

MOLECULAR PATHOGENESIS:
AUTOIMMUNITY: The concept of an autoimmune pathogenesis for T1DM is suggested by the

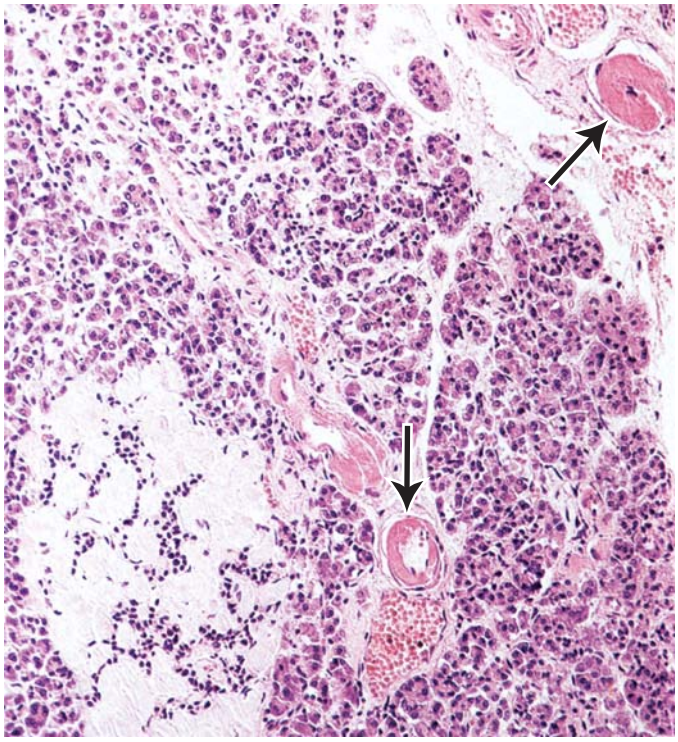

FIGURE 13-11. Amyloid deposition (hyalinization) of an islet in the pancreas of a patient with type 2 diabetes mellitus (*lower left*). Blood vessels adjacent to the islet show the advanced hyaline arteriolosclerosis (*arrows*) characteristic of diabetes.

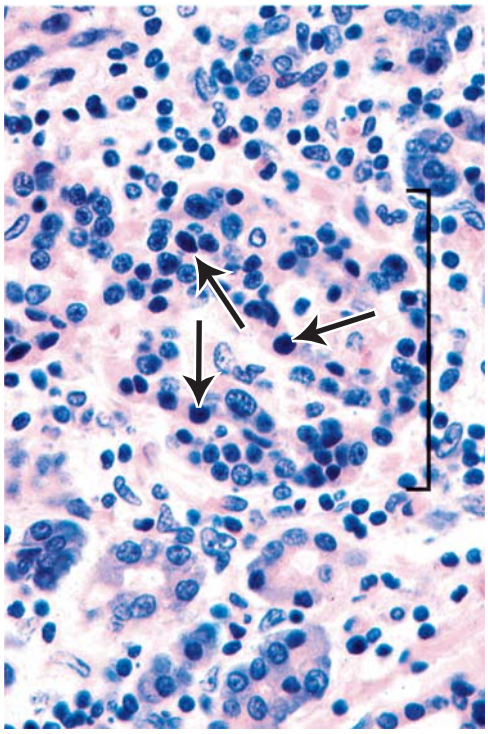

FIGURE 13-13. Insulitis in type 1 diabetes mellitus. A lymphocytic inflammatory infiltrate (*arrows*) is seen in and around the islet (*left of bracket*).

observation that pancreatic islets from patients who die shortly after the onset of the disease show mononuclear infiltrates, or **insulitis,** in their pancreatic islets (Fig. 13-13). $CD8^+$ T lymphocytes predominate among these inflammatory cells. The infiltrating cells also elaborate proinflammatory cytokines, for example, IL-1, IL-6, interferon-α and nitric oxide, which may further contribute to beta cell injury.

Most newly diagnosed children with this disease have circulating antibodies against components of the beta cells. Major target antigens include insulin, glutamic acid decarboxylase (GAD) and insulinoma-associated protein 2 (IA-2), also known as islet cell antigen 512 (ICA-512). Many patients develop anti-islet cell antibodies months or years before insulin production decreases and clinical symptoms appear, a clinical state known as "pre-T1DM" (Fig. 13-14). However, these antibodies are now regarded as responses to beta cell antigens released during destruction of beta cells by cell-mediated immune mechanisms, rather than the cause of beta cell depletion. Nevertheless, detection of serum antibodies to islet cells and target islet antigens is a useful clinical tool for differentiating T1DM.

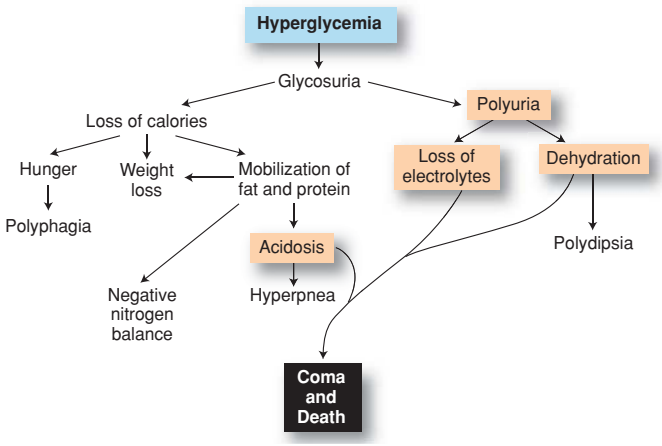

FIGURE 13-12. Symptoms and signs of uncontrolled hyperglycemia in diabetes mellitus.

Cell-mediated immune mechanisms are fundamental to the pathogenesis of T1DM. Cytotoxic T lymphocytes sensitized to beta cells in T1DM persist indefinitely, possibly for a lifetime. Patients transplanted with a donor pancreas or a preparation of purified islets must be treated with immunosuppressive drugs. Ten percent of patients with T1DM develop at least one other organ-specific autoimmune disease, including Hashimoto thyroiditis, Graves disease, myasthenia gravis, Addison disease and pernicious anemia. Interestingly, most patients with polyendocrine immune syndromes (see Chapter 27) also exhibit human leukocyte antigen (HLA)-DR3 and -DR4.

Studies in first-degree relatives of subjects with T1DM have shown that antibodies against islet cells are present several years before the onset of the disease. Thus, beta cell destruction in T1DM generally develops slowly over years. Specific stages of the disease have been described (Fig. 13-14). Only when 80% or more of insulin-secreting cells are eliminated and insulin deprivation is severe is T1DM with hyperglycemia or ketoacidosis clinically evident.

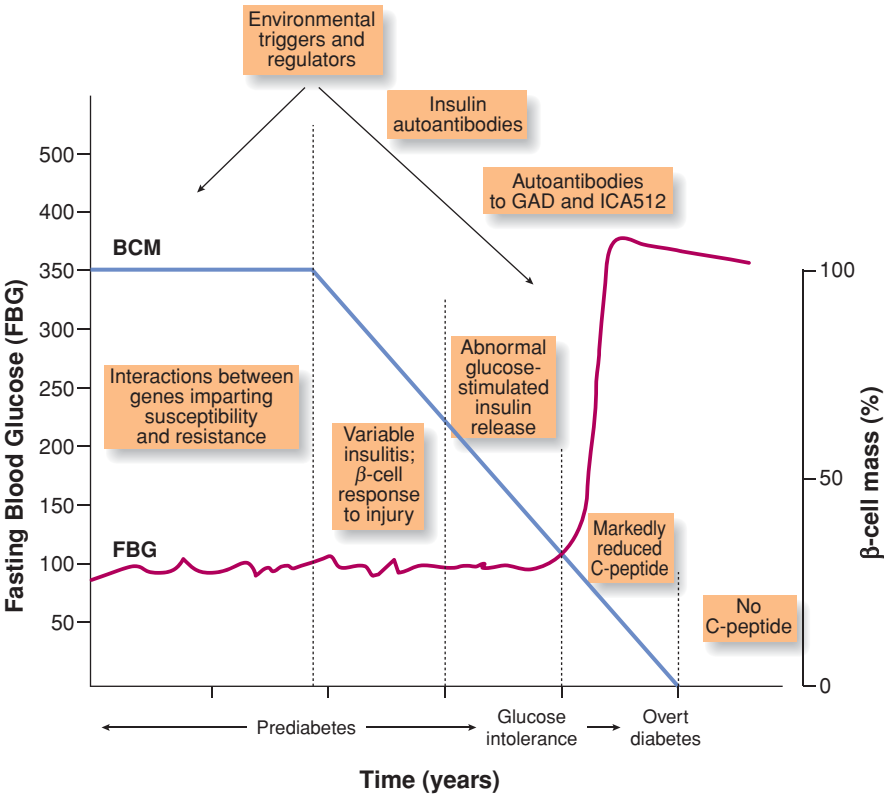

FIGURE 13-14. Pathogenetic stages in the development of type 1 diabetes (T1DM). The disease develops from an initial genetic susceptibility to defective recognition of beta cell epitopes and ends with essentially complete beta cell destruction in most patients. An environmental event is believed to trigger the immune attack, and people with certain genetic markers (human leukocyte antigen [HLA]-DR3 and -DR4) are particularly susceptible to the autoimmune disease. Patients with islet cell antibodies and normal blood glucose levels are considered to have a state of "pre–type 1 diabetes." The rate of decline in beta cell mass (*blue line*) determines the length of time between onset of beta cell destruction and eventual hyperglycemia (*red line,* fasting blood glucose) owing to loss of greater than 90% of functioning beta cells. In the serum, autoantibodies to insulin appear early, followed by antibodies to the beta cell antigen glutamic acid decarboxylase (GAD-65) and the islet cell antigen (ICA-512). *BCM* = beta cell mass.

GENETIC FACTORS: Evidence for the role of genetic factors in the pathogenesis of T1DM include the following:

1. Relatives of people with T1DM have an increased risk for development of T1DM. The lifetime risk of T1DM in the U.S. general population is 0.4%, but it is 3%–8% for first-degree relatives of people with T1DM. An identical twin of a T1DM patient has a 30%–50% risk of developing T1DM. Interestingly, children of fathers with T1DM are three times more likely to develop the disease than are children of mothers with T1DM. This suggests genetic imprinting involving paternal susceptibility genes or protective intrauterine or other maternal influences.
2. There are differences in risk among different ethnic groups who live in similar environments.
3. T1DM is strongly linked to the highly polymorphic HLA class II immune recognition molecules—DR and DQ—on chromosome 6. While only 45% of the population in the United States express DR3 or DR4, 95% of those who develop T1DM express these haplotypes. Because of the known role of HLA molecules in antigen presentation, the T1DM–HLA association is consistent with other evidence that T1DM has an autoimmune component.
4. Many other independent chromosomal regions (several of them non-HLA) are also associated with susceptibility to T1DM, but their contributions to the overall incidence of T1DM are small.

ETIOLOGIC FACTORS:

ENVIRONMENTAL FACTORS: Evidence for the role of environmental factors in the pathogenesis of T1DM includes the following:

- Only 1/3 to 1/2 of monozygotic twins of T1DM patients develop T1DM.
- Recent increases in T1DM incidence in some populations suggest a possible environmental role.
- About 80% to 90% of patients with T1DM have no family history of the disease.
- There are seasonal differences in the incidence of T1DM.

Viruses have been implicated in at least some cases. Thus, T1DM occasionally develops after infection with coxsackie B virus and, less often, mumps virus. Certain proteins may share antigenic determinants with human cell surface proteins and trigger autoreactivity by molecular mimicry. For example, a coxsackie B virus protein has close similarity to the human GAD-65 islet protein.

Dietary factors have been suggested as playing a role in the pathogenesis of T1DM. However, there is little to support this possibility.

PATHOLOGY: As noted above, the most characteristic early lesion in the pancreas of T1DM is a chiefly lymphocytic infiltrate in the islets (insulitis), sometimes with scattered macrophages and neutrophils (Fig. 13-13). As the disease becomes chronic, islet beta cells become progressively depleted; eventually insulin-producing cells are no longer discernible. Loss of beta cells results in variably sized islets, many of which appear as ribbon-like cords that may be difficult to distinguish from surrounding acinar tissue. Islet fibrosis is uncommon. Unlike T2DM, amyloid is not seen in pancreatic islets in T1DM. The exocrine pancreas in chronic T1DM often shows diffuse interlobular and interacinar fibrosis, accompanied by atrophy of the acinar cells.

CLINICAL FEATURES: The clinical picture of T1DM reflects lack of insulin, and insulin's unique role in energy metabolism in the body. The disease

classically presents with acute metabolic decompensation, with hyperglycemia and ketoacidosis. Depending on the degree of absolute insulin deficiency, severe ketoacidosis may be preceded by weeks to months of increased urine output **(polyuria)** and increased thirst **(polydipsia).** Excessive diuresis results from the osmotic load from glucose in the urine. Weight loss in spite of increased appetite **(polyphagia)** results from unregulated catabolism of body stores of fat, protein and carbohydrate. Often the clinical onset of T1DM coincides with another acute illness, such as a febrile viral or bacterial infection (Fig. 13-12).

COMPLICATIONS OF DIABETES

The discovery of insulin in the early 20th century promised to cure diabetes, but as patients with diabetes lived longer, they began to develop complications. ***The severity and chronicity of hyperglycemia in both T2DM and T1DM are the major pathogenetic factors leading to the "microvascular" complications of diabetes, including retinopathy, nephropathy and neuropathy. Thus, control of blood glucose remains the major means by which the development of microvascular diabetic complications can be minimized.*** It has been more difficult to demonstrate that glucose control can prevent "macrovascular" (large-vessel) complications, meaning atherosclerosis and its sequelae (coronary artery disease, peripheral vascular disease and cerebrovascular disease). These macrovascular complications are especially common in patients with T2DM, in part since the patients tend to be older and frequently harbor additional cardiovascular risk factors, particularly dyslipoproteinemia, hypertension and hypercoagulability.

PATHOPHYSIOLOGY: Several biochemical mechanisms have been proposed to account for the development of pathologic changes in diabetes.

ADVERSE EFFECTS ON KNOWN ATHEROSCLEROTIC CARDIOVASCULAR RISK FACTORS: In T2DM, the harmful pattern of pathway-selective insulin resistance and responsiveness promotes (1) fatty liver, (2) overproduction of triglyceride-rich apoB-lipoproteins, (3) impaired hepatic removal of atherogenic postprandial lipoproteins from the circulation, (4) vasoconstriction, (5) overexpression of tissue factor and (6) possibly salt retention. Enhanced production or action of angiotensin II may also play a role. Benefits have been shown from lipid-lowering agents (statins); treatment of hypertension, particularly with angiotensin-converting enzyme (ACE) inhibitors; and low daily doses of aspirin to inhibit platelet function. In T1DM, significant hypertriglyceridemia can develop in the context of poor glycemic control but usually corrects quickly once insulin doses and diet are properly managed.

EXCESSIVE REACTIVE OXYGEN SPECIES: In various cell types in culture, high concentrations of glucose increase production of reactive oxygen species (ROS) as byproducts of mitochondrial oxidative phosphorylation. Proposed mediators of glucose-induced oxidative damage include nitric oxide, superoxide anions and aldose reductase (see Chapter 1). Nevertheless, antioxidant supplementation does not affect the course of diabetes and atherosclerosis in people. Thus, there is no clinical evidence that ROS contribute to diabetes or its complications.

PROTEIN GLYCATION: Glucose covalently attaches to an assortment of proteins nonenzymatically, a process termed **glycation** (also termed **nonenzymatic glycosylation**). Glycation occurs roughly in proportion to the severity of hyperglycemia. Numerous cellular proteins are modified in this manner, including hemoglobin, components of the crystalline lens and cellular basement membrane proteins. A specific fraction of glycated hemoglobin in circulating red blood cells, hemoglobin A_{1c}, is used routinely to monitor the overall degree of hyperglycemia during the preceding 6–8 weeks. Because glycation of hemoglobin is irreversible, hemoglobin A_{1c} levels serve as a marker for glycemic control.

The initial glycation products (known chemically as Schiff bases) are labile and can dissociate rapidly. With time, these labile products undergo complex chemical rearrangements to form stable **advanced glycosylation end-products (AGEs),** which consist of glucose derivatives bound covalently to protein amino groups. AGE formation permanently alters protein structure and, possibly, function. For example, albumin and immunoglobulin G (IgG) do not normally bind to collagen, but they adhere to glycated collagen. Unstable chemical bonds in proteins containing AGEs can lead to physical cross-linking of nearby proteins, which may contribute to the characteristic thickening of vascular basement membranes in diabetes. Importantly, unlike the initial labile glycation products, AGEs can continue to cross-link proteins even if blood glucose returns to normal. Patients with diabetic retinopathy have higher levels of AGEs than do diabetics without retinopathy. Nevertheless, the role of AGEs in diabetic microvascular disease is uncertain. Compounds that inhibit AGE formation (e.g., aminoguanidine) do not protect people from diabetic complications, unlike experimental animals.

THE ALDOSE REDUCTASE PATHWAY: By mass action, hyperglycemia also increases glucose uptake by tissues that do not depend on insulin. Some of the increased flux of glucose is metabolized by aldose reductase, via the reaction:

$$\text{Glucose} + \text{NADPH} \rightarrow \text{Sorbitol} + \text{NADP}$$

This reaction depletes cellular reducing equivalents, which alters redox status and allows sorbitol to accumulate. Sorbitol's role, if any, in the complications of diabetes is undefined. Aldose reductase has a low affinity for glucose, but it generates considerable amounts of sorbitol in tissues when blood glucose is elevated. In the ocular lens, excess sorbitol may simply create an osmotic gradient that causes influx of fluid and consequent swelling. Increased intracellular sorbitol has been linked to decreased myo-inositol (a precursor of phosphoinositides), lower protein kinase C activity and inhibition of the plasma membrane sodium pump. However, inhibition of aldose reductase shows no benefit in human clinical trials, so the roles of aldose reductase and sorbitol in the complications of diabetes is unclear.

Atherosclerosis Is a Deadly Complication of Diabetes

Atherosclerotic heart disease and ischemic strokes account for over half of all deaths among adults with diabetes. The extent and severity of atherosclerotic lesions in medium-sized and large arteries are increased in patients with long-standing diabetes. Diabetes eliminates the usual protective effect of being female, and coronary artery disease develops at a younger age than in nondiabetic people. Moreover, mortality from myocardial infarction is higher in diabetics than in nondiabetics. As indicated above, patients with T2DM often have multiple risk factors of the metabolic syndrome that contribute to atherogenesis.

Atherosclerotic peripheral vascular disease, particularly of the lower extremities, commonly complicates diabetes. Vascular insufficiency may cause ulcers and gangrene of the toes and feet, ultimately necessitating amputation. ***Diabetes accounts for more than 60% of nontraumatic limb amputations in the United States.***

Even though epidemiologic analyses suggest a correlation between chronic hyperglycemia and higher rates of cardiovascular disease, glucose levels per se are probably not the culprits. Most randomized clinical trials have failed to show that lower hemoglobin A_{1c} levels correlate with improved macrovascular outcomes in T2DM.

PATHOPHYSIOLOGY: How diabetes promotes atherosclerosis is uncertain. There are at least three general schools of thought:

1. **Direct effects of diabetes or hyperglycemia on the arterial wall.** As noted above, however, none of the clinical therapies based on this idea (intensive glycemic control, aldose reductase inhibitors, antioxidants) reduces this type of complication of T2DM.
2. **Side effects of diabetic therapy,** such as high insulin concentrations associated with certain forms of treatment.
3. **Exacerbation of general risk factors for atherosclerosis** (e.g., hypertension, dyslipoproteinemia, hypercoagulability). Dyslipoproteinemia in T2DM is partly due to

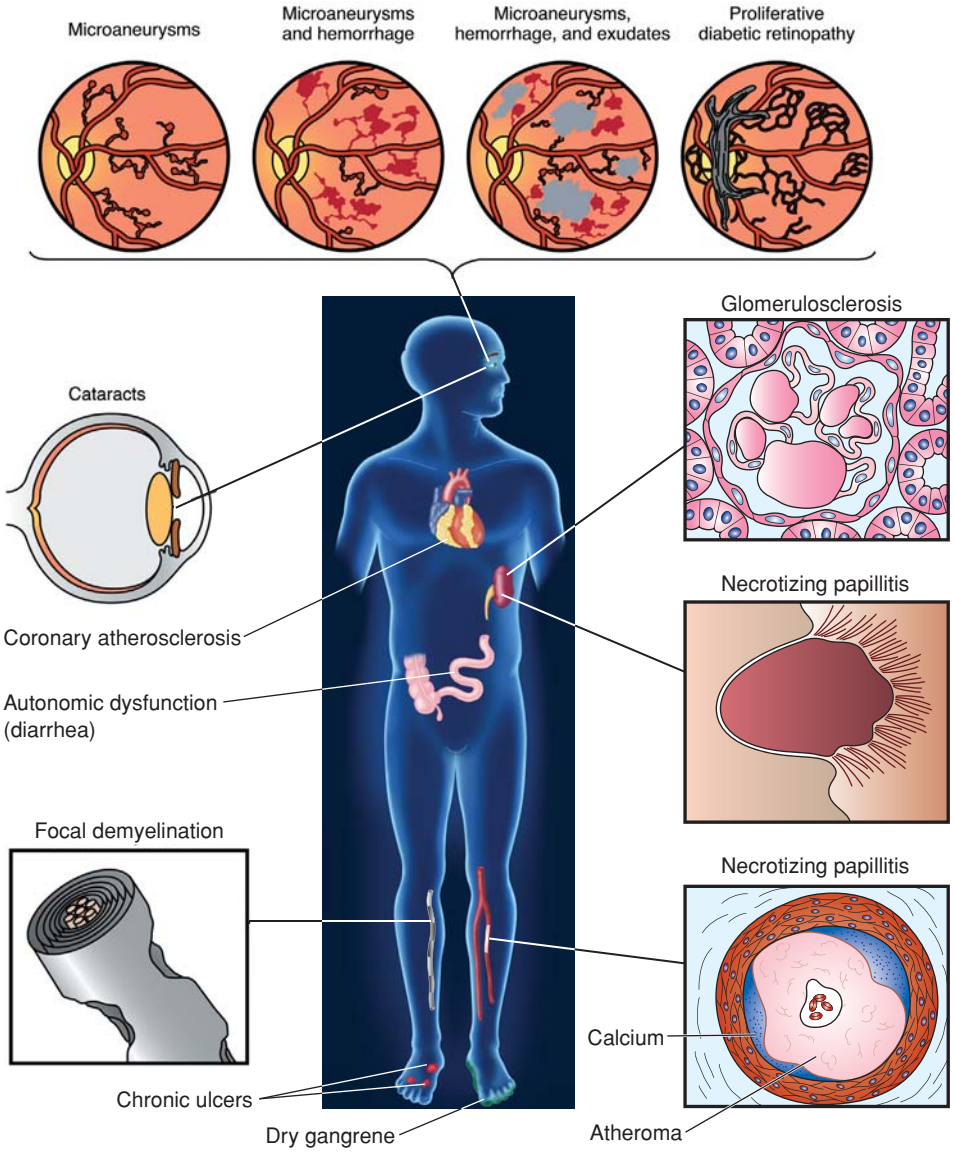

FIGURE 13-15. Secondary complications of diabetes. The effects of diabetes on a number of vital organs result in complications that may be incapacitating (cerebral and peripheral vascular disease), painful (neuropathy) or life-threatening (coronary artery disease, pyelonephritis with necrotizing papillitis).

hepatic and intestinal overproduction of triglyceride-rich apoB-lipoproteins. A defect in lipoprotein lipase impairs clearance of chylomicrons and causes postprandial hypertriglyceridemia. In addition, the liver's uptake of atherogenic postprandial remnant lipoprotein particles is impaired. At this point, the most successful strategies to reduce cardiovascular events in T2DM involve management of these risk factors (e.g., administration of statins, antihypertensive agents and low-dose aspirin). Gastric bypass surgery for weight loss has been associated with substantial decreases in cardiovascular deaths.

Diabetic Microvascular Disease Is Responsible for Many of the Complications of Diabetes

Arteriolosclerosis and capillary basement membrane thickening are characteristic vascular changes in diabetes (see Chapter 16). The frequent occurrence of hypertension contributes to the development of the arteriolar lesions. Deposition of basement membrane proteins, which may also become glycated, increases in diabetes. Platelet aggregation in smaller blood vessels and impaired fibrinolysis may also contribute to diabetic microvascular disease.

However it develops, the effects of microvascular disease on tissue perfusion and wound healing are profound. Blood flow to the heart, already compromised by large-vessel disease (coronary atherosclerosis), is reduced. Chronic ulcers due to trauma and infection of the feet heal poorly in diabetic patients, in part because of microvascular disease. The major complications of diabetic microvascular disease involve the kidney and the retina (Fig. 13-15).

Diabetic Nephropathy

Diabetes is the leading cause of renal failure in the United States, accounting for almost half of new cases. One third of patients with T1DM ultimately develop renal failure, as do up to 20% of patients with T2DM. Some patients with T1DM may die from uremia, but most of those who develop nephropathy die of cardiovascular disease, which is 40 times more common in T1DM patients who have end-stage renal disease. The prevalence of diabetic nephropathy increases with the severity and duration of hyperglycemia. ***Kidney disease due to diabetes is the most common reason for renal transplantation in adults.***

Initially, hyperglycemia leads to glomerular hypertension and renal hyperperfusion (Fig. 13-16). Increased glomerular pressure favors deposition of protein in the mesangium, resulting in glomerulosclerosis and, eventually, renal failure. AGEs and lipoprotein abnormalities may contribute to chemical changes in the glomerular basement membrane. The diabetic kidney produces growth factors, particularly transforming growth factor-β (TGF-β), that have been implicated in some of the cellular abnormalities. In animal models, inhibiting TGF-β attenuates renal disease. Whatever the underlying mechanism, strict control of blood glucose and blood pressure retards development of diabetic nephropathy. ACE inhibitors or angiotensin receptor blockers reduce systemic blood pressure, glomerular hypertension and renal perfusion, and thus retard progression of diabetic nephropathy.

Eventually, a unique lesion, **Kimmelstiel-Wilson disease** or **nodular glomerulosclerosis** (see Chapter 22), develops. It

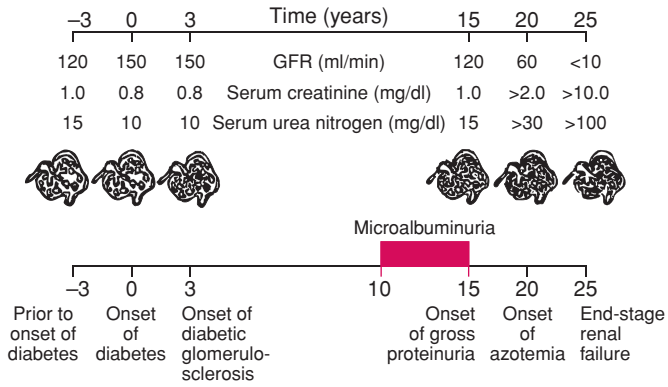

FIGURE 13-16. Natural history of diabetic nephropathy. Initially, renal hypertrophy and hyperfiltration lead to an increase in the glomerular filtration rate (GFR). Once the decline in renal function begins, on average at least 10 years after the onset of diabetes, leakage of a small amount of serum albumin into the urine (microalbuminuria) is the first abnormality that is easily and reliably measured. The elevation in serum creatinine and gross proteinuria occur much later.

assumes two microscopic patterns. Most commonly, spherical masses of basement membrane–like material accumulate in glomerular lobules (Fig. 13-17). Less often, this material deposits more diffusely and somewhat irregularly throughout the glomerulus. Clinically, the onset of glomerular disease is heralded by the appearance in the urine of small amounts of serum albumin, **microalbuminuria**. Proteinuria increases with time and with progressive decline in renal function.

Diabetic Retinopathy

Diabetic retinopathy is the leading cause of blindness in the Unites States in adults under 74. The risk is higher in T1DM than in T2DM. In fact, 10% of patients with T1DM of 30 years' duration become legally blind. Nevertheless, as there are many more patients with T2DM, they are the most

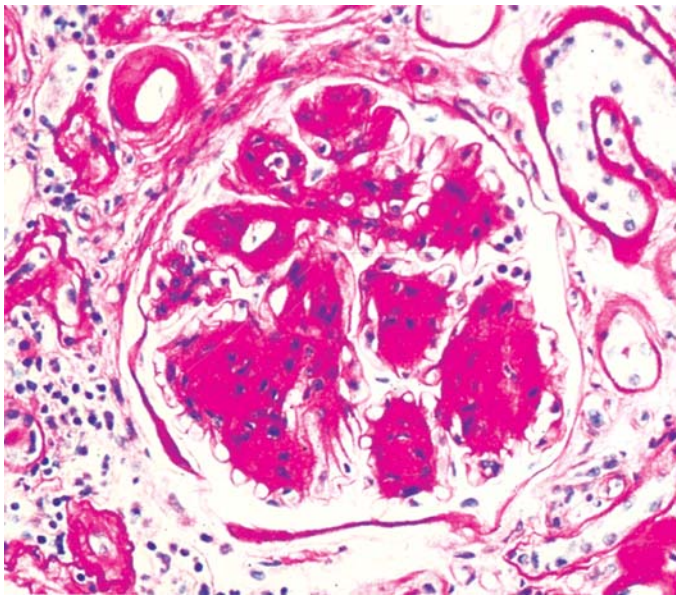

FIGURE 13-17. Diabetic glomerulosclerosis. A periodic acid–Schiff stain demonstrates nodular accumulations of basement membrane–like material in the glomerulus.

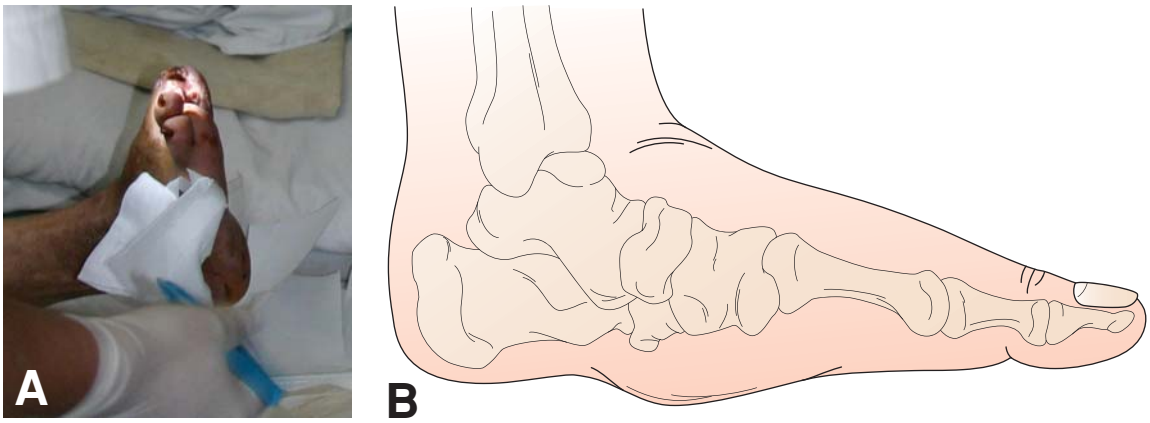

FIGURE 13-18. Foot complications of diabetes mellitus. A. Foot ulcer. **B.** Charcot foot.

numerous patients with diabetic retinopathy. Retinopathy is the most devastating ophthalmic complication of diabetes, although glaucoma, cataracts and corneal disease are also increased. Like nephropathy, the prevalence of diabetic retinopathy reflects the duration and degree of glycemic control (also see Chapter 33).

Diabetic Neuropathy Affects Sensory and Autonomic Innervation

Peripheral sensory impairment and autonomic nerve dysfunction are among the most common and distressing complications of diabetes. Changes in the nerves are complex, with abnormalities in axons, the myelin sheath and Schwann cells. Microvasculopathy involving the small blood vessels of nerves contributes to diabetic neuropathy. Hyperglycemia increases the perception of pain, independently of any structural lesions in the nerves.

Peripheral neuropathy is initially characterized by pain and abnormal sensations in the extremities. However, fine touch, pain detection and proprioception are ultimately lost. As a result, patients with diabetes tend to ignore irritation and minor trauma to the feet, joints and legs, and they develop foot ulcers (Fig. 13-18), which are common in patients with severe diabetes. Peripheral neuropathy also contributes to Charcot joint, a painless destructive joint disease that occasionally occurs (Fig. 13-18).

Abnormalities in autonomic regulation of cardiovascular and GI functions frequently lead to postural hypotension and altered gut motility (e.g., gastroparesis and diarrhea). Erectile dysfunction and retrograde ejaculation are other complications of autonomic dysfunction, although vascular disease also contributes. Hypotonic urinary bladder may develop, leading to urinary retention and predisposing to infection.

Bacterial and Fungal Infections Complicate Hyperglycemia

Host responses to microbial pathogens are abnormal in patients with poorly controlled diabetes. Leukocyte function is compromised and immune responses are blunted. Before the use of insulin, tuberculosis and purulent infections were often life-threatening. Now, patients with well-controlled diabetes are much less susceptible to infections. However, **urinary tract infections** continue to be problematic because glucose makes the urine an enriched culture medium. Urinary retention from autonomic neuropathy may exacerbate this tendency. Infection ascending from the bladder to the kidney (i.e., **pyelonephritis**) is thus a constant concern. **Renal papillary necrosis** may be a devastating complication of urinary tract infection.

A dreaded infectious complication of poorly controlled diabetes is **mucormycosis**. This often fatal fungal infection tends to originate in the nasopharynx or paranasal sinuses and spreads rapidly to the orbit and brain (see Chapter 9).

Gestational Diabetes Puts Mother and Fetus at Risk

Gestational diabetes develops in only a few percent of seemingly healthy women during pregnancy. It may continue after parturition in a small proportion of these patients. Pregnancy is a state of IRg, but only pregnant women with impaired beta cell secretion of insulin become diabetic. Abnormalities in the amount and timing of pancreatic insulin secretion predispose these women to overt T2DM later in life.

Poor control of diabetes in pregnancy (either gestational diabetes or preexisting diabetes) may lead to the birth of large infants, complicate labor and delivery and necessitate a cesarean section. The fetal pancreas tries to compensate for poor maternal control of diabetes during gestation. Such fetuses develop beta cell hyperplasia, which may lead to hypoglycemia at birth and in the early postnatal period.

Infants of diabetic mothers have a 5% to 10% incidence of major developmental abnormalities, including anomalies of the heart and great vessels and neural tube defects, such as anencephaly and spina bifida. The frequency of these lesions is a function of the control of maternal diabetes during early gestation.

OBSTETRIC PATHOLOGY AND THE PATHOLOGY OF PREGNANCY

Normal pregnancy is characterized by profound changes in almost every maternal organ system in order to accommodate the demands of the fetoplacental unit. An important component of obstetric pathology is the study of the placenta, which has two separate vascular supplies from two genetically distinct individuals. It invades its host under normal circumstances, but can also result in potentially fatal cancer.

PLACENTA

Anatomy

The placenta includes the **placental disc, umbilical cord** and **extraplacental membranes** (Fig. 14-1). It is a flattened discoid organ with two surfaces. The fetus faces one aspect **(fetal** or **chorionic surface),** which is covered by membranes, the **amnion** and **chorion**. These contain the **amniotic fluid** that surrounds the fetus. The opposite surface is the **maternal surface** (or the **decidual surface,** since the endometrium becomes decidualized during pregnancy).

Fetal blood enters the placenta through two umbilical arteries that spiral around an umbilical vein. Each artery supplies half of the placenta. The umbilical cord inserts into the chorionic surface on the placenta. The major branches of the umbilical arteries and vein (chorionic plate blood vessels) then branch along the surface of the disc and penetrate into the placental disc to form the chorionic villous tree. Primary stem villi originate at the chorionic plate and contain the major branches of the umbilical arteries and veins. These villous trunks progressively subdivide into smaller branches, ending in the terminal (or, tertiary) villi, where oxygen and nutrient transport occurs. At term, the terminal villi constitute 40% of the villous volume and 60% of villous cross-sections.

The **decidua** forms the border between fetal tissue composing the villous trees and the underlying uterus. The decidua contains 80–100 small uterine arteries (**spiral**

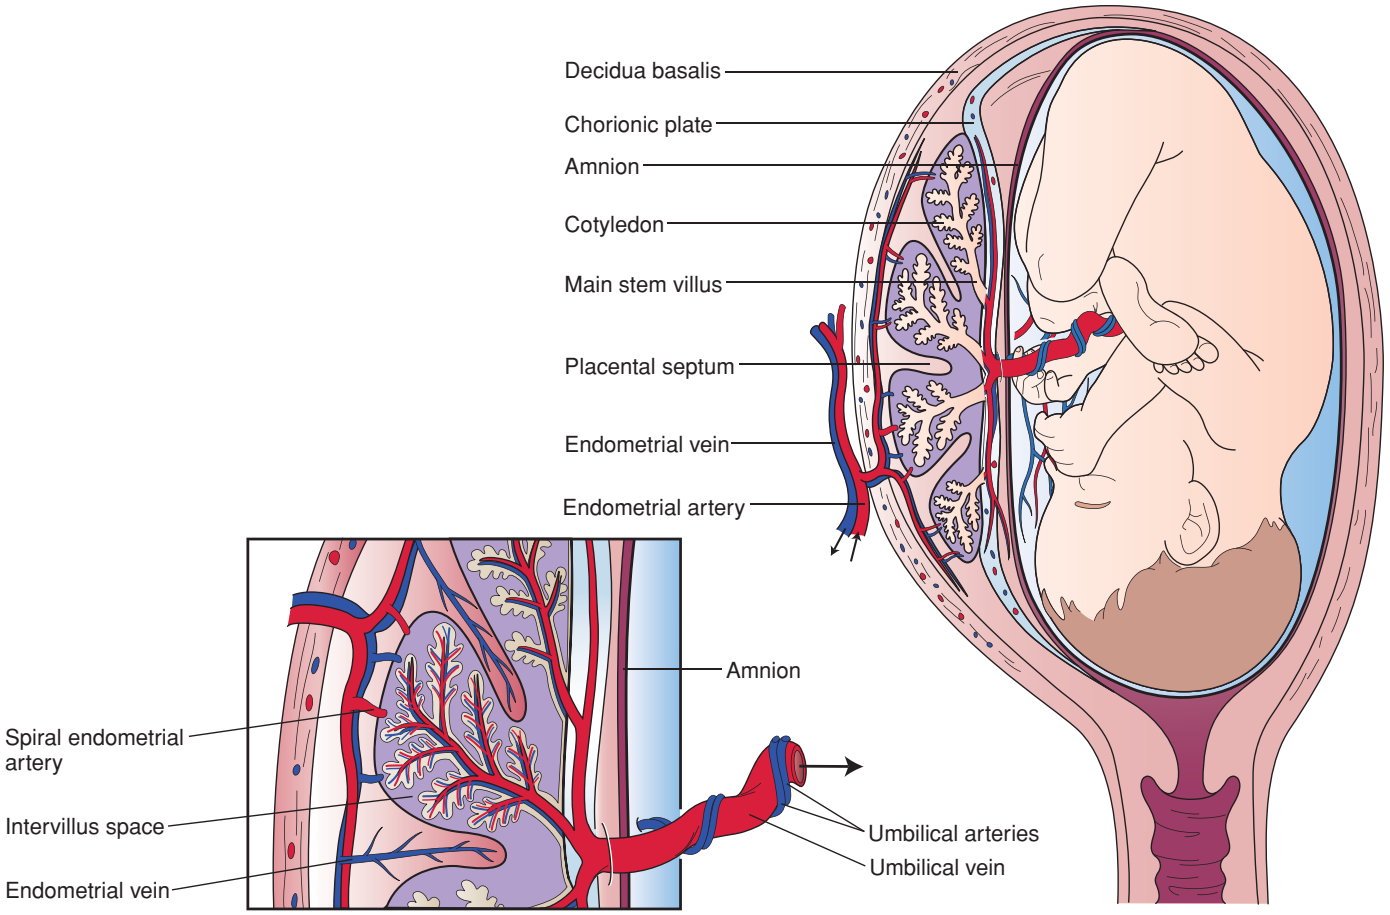

FIGURE 14-1. Modern diagram of the pregnant uterus including fetus, placenta and circulation.

arterioles, branches of the myometrial arteries), which supply the placenta with maternal blood (Fig. 14-2). These arteries undergo a series of **remodeling** changes that decrease vascular resistance to uterine blood flow and support the developing placenta and fetus. Each spiral arteriole delivers maternal blood to the center of an anatomic subunit of the placenta, the **cotyledon**. Maternal blood entering the placental disc is no longer confined to a vessel, but instead occupies a cavity, the **intervillous space,** where it exchanges oxygen and nutrients. The maternal and fetal circulations in the placenta are entirely separate systems (Fig. 14-3).

The terminal villus is the placenta's functional unit of exchange. The chorionic villous tree is covered by the trophoblastic layer (Greek *trephein:* "to feed," *blastos:* "germinator"). It consists of an inner layer of **cytotrophoblast (Langhans cells),** a middle layer of **intermediate trophoblast** and an outer layer of **syncytiotrophoblast**. The villous stroma is loose mesenchyme containing embryonal macrophages, termed **Hofbauer cells.** In the third trimester, syncytiotrophoblast nuclei aggregate to form multinuclear protrusions **(syncytial knots)**. In other areas along the villous surface, syncytium between the knots becomes markedly attenuated. At these points, the trophoblastic cytoplasm comes into direct contact with the endothelium of the fetal capillaries to form the **vasculosyncytial membrane**. These specialized zones facilitate gas and nutrient transfer across the placenta.

In addition to releasing waste and absorbing oxygen and nutrients, the villi are hormonally active. The syncytiotrophoblast secretes **human chorionic gonadotropin (hCG)**, which prevents degeneration of the corpus luteum. It also secretes **progesterone** to maintain the integrity of the decidua and **human placental lactogen (HPL)**, which raises maternal glucose levels and so assists in adequate fetal nutrition.

Placental Size

The placenta increases in size as gestation progresses. For example, the mean placental weight at 30 weeks' gestation is 316 grams, at 35 weeks 434 grams and at term (40 weeks) 537 grams. An abnormally small placenta (≤10th percentile for gestational age) is associated with maternal hypertensive disease of pregnancy and low birth weight. It can cause a poor fetal outcome, including neurologic abnormalities and perinatal death. Abnormally large placentas (≥90th percentile) also occur and can result from villous edema, fetal hydrops, placental hemorrhage, syphilis, placental tumors and maternal diabetes. At term, 1 gram of placenta can oxygenate 7 grams of fetal tissue. This relationship, called the **fetal–placental weight ratio,** determines how chronic uteroplacental malperfusion, or placental insufficiency, can occur. If the fetus is too large for its placenta, or the placenta is too small, the increased fetal–placental weight ratio can

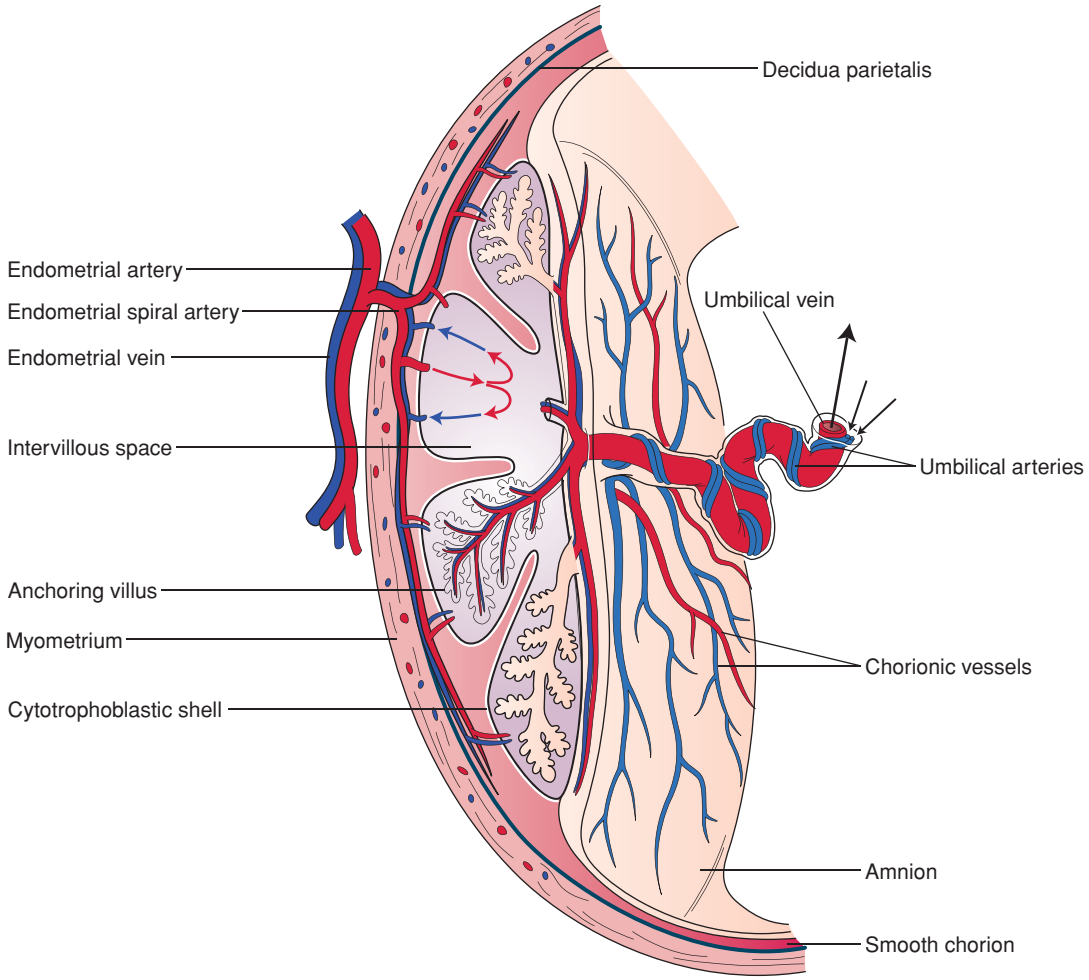

FIGURE 14-2. Cross-sectional diagram of the placenta and its circulation.

contribute to a poor obstetric outcome. Abnormally thin placentas (<2 cm thickness at term) can also be associated with neonatal problems.

Placental Shape

A typical placental disc is round or ovoid.

- **Bilobed placenta** (2%–8%) appears as two equal-sized discs, separated by membranes.
- **Succenturiate placenta** (5%) is bilobed, with one lobe smaller than the other. Bilobed and succenturiate placentas have membranous blood vessels connecting each lobe, which can be susceptible to damage by compression, thrombosis or rupture.
- **Vasa previa** (1 in 2500) refers to membranous vessels situated between the fetus and the internal cervical os. Rupture of these vessels before or during delivery produces fetal bleeding and can rapidly result in fetal exsanguination.
- **Circumvallate placenta** (1%–6%) features membranes that extend away from the margin toward the center of the placental disc. The margin exhibits fibrin and clotted blood. It is thought to result from either marginal hemorrhage early in development or a deep implantation of the fetus into the decidua.
- **Circummarginate placenta** (4%) differs from circumvallate placenta by not having the reflected membranes fold back.

Placental Implantation

The placenta is normally implanted in the uterine wall above the internal cervical os. It may implant at the lower portion of the uterus and either partially or completely cover the internal os, a condition termed **placenta previa** (0.3%–1% of pregnancies). Risk factors include smoking, increased age, multiple prior pregnancies, previous cesarean sections and prior abortions. Placenta previa must be recognized before delivery to avoid the fetus being delivered through its own placenta, risking life-threatening hemorrhage. Placenta previa is one of the most frequent causes of 3rd-trimester bleeding and entails a high risk of abruption, postpartum hemorrhage, prolapsed umbilical cord, fetal malpresentation, intrauterine growth restriction and fetal and perinatal mortality. Placenta previa is often associated with another abnormal condition, placenta accreta (see below), in which case it is **placenta previa accreta**.

Ectopic pregnancy occurs when a placenta implants outside the uterine cavity. It usually occurs in the fallopian tube, but 2% of ectopic pregnancies occur in the ovary, cervix or abdomen. Unless removed surgically, abdominal pregnancy carries a high maternal mortality.

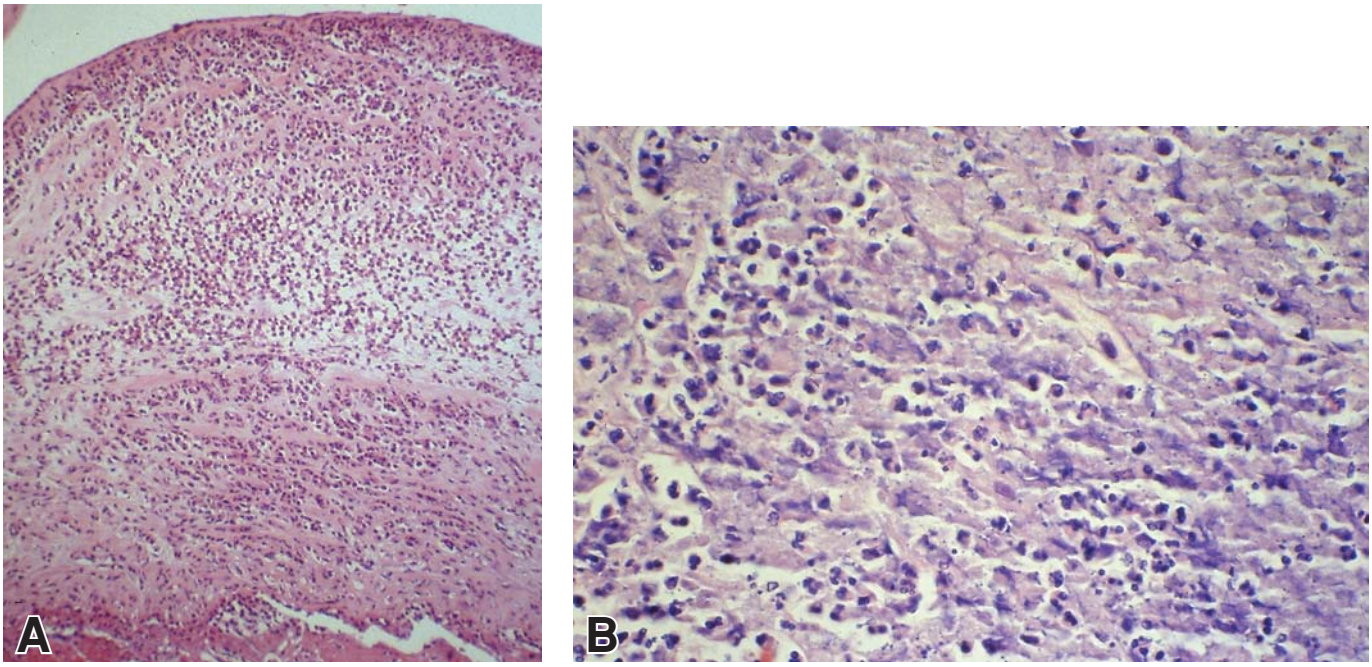

FIGURE 14-3. Maternal inflammatory responses to ascending infection. A. Acute chorioamnionitis (maternal inflammatory response [MIR]). The chorion contains numerous acute inflammatory cells, recruited from the maternal intervillous space. **B. Acute necrotizing deciduitis (MIR).** The decidua contains numerous inflammatory cells of maternal origin and is necrotic.

Abnormalities of the Umbilical Cord

At term, the umbilical cord normally measures 35–100 cm long. Abnormally short umbilical cords are associated with increased perinatal mortality, intrauterine fetal distress and intrauterine growth restriction. The point of insertion of the cord is usually at or near the center of the placental disc, but 7% show a **marginal insertion,** at the placenta's edge. About 1% of umbilical cords insert into the membranes, called a **velamentous** or **membranous insertion**. Velamentous and marginal cord insertions are often seen in spontaneous abortions and fetuses with congenital anomalies. A serious potential complication of velamentous vessels is **vasa previa** (see above).

IMMUNE TOLERANCE IN PREGNANCY

The Mother Tolerates the Fetus and Placenta as Allografts

The conceptus is genetically different from the mother and thus represents an allograft. Why, then, does the mother not reject her fetus as foreign tissue, as she would with transplantation of other genetically disparate tissues? **Immune tolerance in pregnancy** describes the absence of a maternal immune response against the fetus and its placenta.

PATHOPHYSIOLOGY: The placenta is the major immunologic barrier between the mother and the conceptus and creates an immunologically privileged site.

- The placental trophoblast does not express major histocompatibility complex (MHC) class I isotypes human leukocyte antigen (HLA)-A and HLA-B. The absence of these molecules prevents recognition of the fetus as "foreign tissue."
- The trophoblast expresses atypical MHC class I isotypes HLA-E and HLA-G, which may prevent attack by maternal natural killer (NK) cells.
- The trophoblast forms a continuous syncytium, lacking intercellular spaces or connections between cells. This situation serves to restrict passage of migratory immune cells between the maternal and fetal bloodstreams.
- The placenta permits some maternal immunoglobulin G (IgG) antibody to cross the vasculosyncytial barrier and enter the fetal circulation to provide immune protection against infectious diseases.
- Fetal cells that have entered the maternal circulation elicit antibodies targeting fetal antigens. If there are major blood group differences between mother and fetus, maternal antibodies against fetal ABO antigens can develop and cause antibody-mediated destruction of fetal erythrocytes, leading to **hemolytic disease of the newborn (HDN)**. However, ABO HDN is rare because maternal anti-A and anti-B antibodies are of the IgM class, which does not cross the placenta.
- The placenta secretes **neurokinin B,** a peptide that binds the immune-cloaking molecule **phosphocholine**.
- Regulatory T lymphocytes (T_{reg}; see Chapters 4 and 11) and NK cells are thought to play a role in avoidance of the maternal immunologic rejection by fetal tissues, but the mechanisms are uncertain.

PLACENTAL INFECTIONS

Chorioamnionitis Is the Hallmark of Ascending Infection

Infectious organisms, almost exclusively bacteria, can ascend from the maternal birth canal, pass through the cervical os and infect the decidua and placental tissues, the amniotic fluid and, potentially, the fetus.

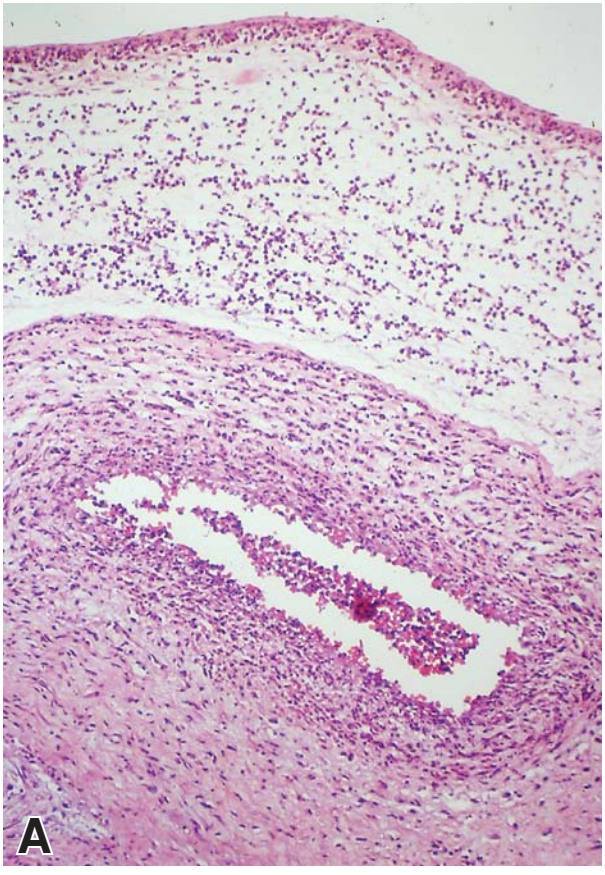
ETIOLOGIC FACTORS: Acute chorioamnionitis is usually caused by bacteria that are normally present in the maternal cervicovaginal canal. The most common bacterial causes of chorioamnionitis are group B *Streptococcus* sp., *Escherichia coli, Enterococcus,* other streptococcal species, *Staphylococcus* sp., Gram-negative bacilli, *Bacteroides, Mycoplasma hominis* and *Ureaplasma.*

PATHOLOGY: Upon reaching the uterine cavity, bacteria elicit a maternal inflammatory response (MIR). Maternal neutrophils circulating in the intervillous space migrate upward toward the fetal surface, or chorionic plate, resulting in **acute subchorionitis**. The neutrophils then migrate up from the subchorion into the chorion. Maternal neutrophils are recruited from the decidual blood vessels and enter the chorion of the extraplacental membranes (Fig. 14-3A). Maternal neutrophil infiltration of either the chorion of the placenta or its membranes is termed **acute chorioamnionitis**. Maternal inflammatory cells can also migrate from the decidual and spiral arteries into the decidua underlying the extraplacental membranes or the placental disc to cause **acute deciduitis**. Deciduitis may be so severe as to cause necrosis of the decidua **(necrotizing deciduitis)** (Fig. 14-3B), or it can form small collections of neutrophils, called **decidual microabscesses**. Because the maternal spiral arteries, which supply the placenta with oxygenated maternal blood, are in the decidua, decidual infection can threaten the pregnancy.

PATHOLOGY: A fetal inflammatory response (FIR) may also develop. **Acute chorionic vasculitis,** a component of FIR, occurs when fetal neutrophils migrate from the fetal bloodstream into the walls of the large chorionic plate vessels (branches of the umbilical cord vessels) at the surface of the placental disc (Fig. 14-4A). Fetal neutrophils also migrate from the lumen of the umbilical cord blood vessels into the muscular vessel walls, resulting in a vasculitis of the cord vessels termed **acute funisitis** (Fig. 14-4B). Fetal neutrophils can migrate completely through umbilical vessel walls and infiltrate the mesenchyme (Wharton jelly). Cerebral palsy is statistically associated with severe FIR but not with mild to moderate MIR (see below).

CLINICAL FEATURES: Acute chorioamnionitis (10% of placentas) can cause preterm labor, premature rupture of membranes, fetal and neonatal infections and intrauterine hypoxia. The mother may have fever, uterine tenderness and foul-smelling or cloudy amniotic fluid. Major risks are postpartum endometritis and pelvic sepsis with venous thrombosis.

In preterm, low–birth-weight (<2500 grams) infants, especially very low weight (<1500 grams), acute chorioamnionitis often leads to severe neurologic disease, stillbirth,



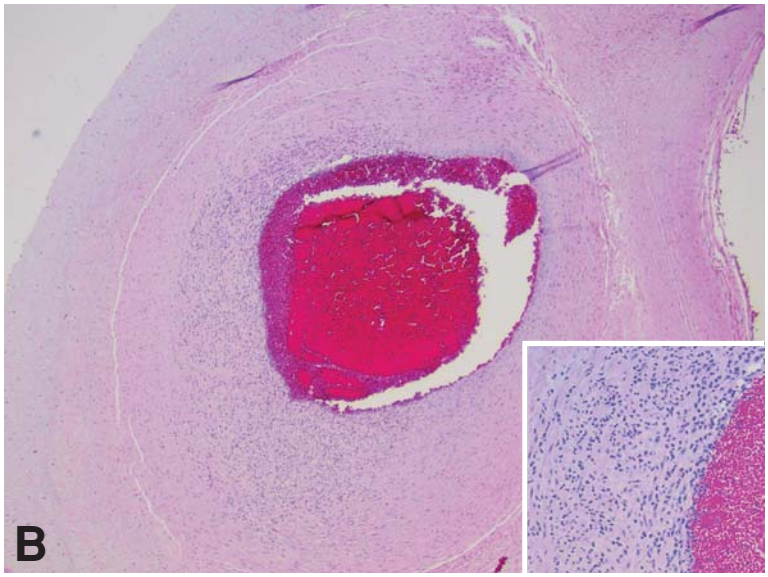


FIGURE 14-4. Fetal inflammatory responses to ascending infection. A. Acute chorionic vasculitis (fetal inflammatory response [FIR]). The wall of this large chorionic plate blood vessel is infiltrated by fetal neutrophils. The overlying chorion shows acute chorioamnionitis. **B. Acute funisitis (FIR).** The muscular wall of this umbilical vessel contains numerous fetal inflammatory cells (**inset:** higher magnification).

neonatal sepsis and death. However, it can also cause morbidity in full-term infants. The risks of chorioamnionitis to the fetus include (1) pneumonia after inhalation of infected amniotic fluid; (2) skin or eye infections from direct contact with organisms in the fluid; and (3) neonatal gastritis, enteritis or peritonitis from ingestion of infected fluid.

Amniotic Infection Syndrome Can Cause Intrauterine Fetal Infection

Amniotic Fluid

Amniotic fluid is initially formed as a transudate of maternal fluids, but later a combination of the amnion, fetal lungs and kidneys contributes to its formation. The fetus also inhales and exhales amniotic fluid during breathing movements before birth.

Intra-Amniotic Infection

Amniotic fluid is normally sterile, but in some cases it can be seeded with bacteria. Amniotic fluid infection gives microorganisms a portal of entry into the fetus, most frequently the respiratory tract, from which intrauterine infection can enter the bloodstream and disseminate to other fetal organs. These infants can be born with "congenital" or early-onset neonatal infections, including pneumonia, sepsis and meningitis. Placentas of these infants typically demonstrate acute chorioamnionitis, often with a component of FIR. Amniotic infections can portend a serious or fatal outcome for the neonate.

Villitis Can Indicate a Maternal Infection

Villitis is an inflammatory infiltrate involving the chorionic villi. Microorganisms in the maternal blood, usually viruses, or less commonly bacteria, can gain access to the placenta. Villitis can also be of unknown etiology. Potential agents include (1) bacteria (*Listeria, Treponema pallidum, Mycobacterium. tuberculosis, Mycoplasma* sp., *Chlamydia* sp.), (2) viruses (rubella, cytomegalovirus, herpes), (3) parasites and protozoa (*Toxoplasma* sp., *Trypanosoma cruzi*) and (4) fungi (*Candida* sp.). Villitis can interfere with oxygen transport to the fetus, and transmission of the etiologic agent through the villi can infect the fetus.

Cytomegalovirus

Cytomegalovirus (CMV) is one of the TORCH agents (see Chapter 6) that can cause congenital infection in a newborn. Intrauterine infection can occur when the mother acquires a primary (first-time) infection while pregnant—this form of transplacental infection is potentially the most serious to the fetus. Less dangerous to the infant is reactivation of latent maternal CMV infection during pregnancy. In Western nations, 8% of women develop primary infection during pregnancy, of which 1/2 will transmit the virus to their fetus. In developing nations and in poorer socioeconomic groups, congenital CMV infections are less common, because those women most likely were exposed to CMV previously.

CLINICAL FEATURES: Among fetuses infected with CMV, 1/4 are born with clinical symptoms. Some 5%–10% of neonates will not have symptoms at birth but will subsequently develop hearing loss, visual impairment and mental retardation. In more severe cases, generalized infections of the infant can occur, including low birth weight, microcephaly, seizures and skin manifestations. Multiorgan dissemination is characterized by cerebral abnormalities, splenomegaly and hepatitis. Occasionally, congenital CMV may be lethal for the infant.

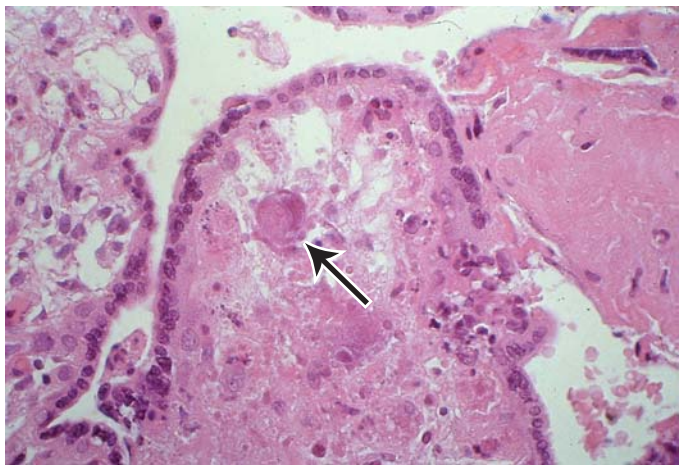

FIGURE 14-5. Chronic villitis caused by cytomegalovirus (CMV). The villi are infiltrated by chronic inflammatory cells. An enlarged cell with a CMV inclusion is present (*arrow*).

PATHOLOGY: CMV enters the placenta from maternal blood and results in chronic villitis. Endothelial infection causes cellular swelling, luminal occlusion, endothelial necrosis and eventual vascular destruction. These effects result in thrombosis, ischemic villous necrosis and, eventually, avascular villi with villous scarring (fibrosis). Villous stromal macrophages (Hofbauer cells) may be increased. Remote CMV infection can be reflected in villous microcalcifications. When CMV infection occurs near the time of delivery, characteristic intranuclear and intracytoplasmic inclusions of CMV may be identifiable (Fig. 14-5), but they are rare or absent in cases of remote intrauterine infection.

Syphilis

The agent of syphilis, *T. pallidum* (see Chapter 9), can pass from the maternal circulation to the fetal circulation through chorionic villi, most frequently during the secondary phase.

CLINICAL FEATURES: Syphilis is an important cause of stillbirth, and liveborn infants with early congenital syphilis may be premature. Nevertheless, more than half of newborns with congenital syphilis are asymptomatic. Symptomatic infants suffer hepatosplenomegaly, snuffles, lymphadenopathy, mucocutaneous lesions, pneumonia, edema, rash, hemolytic anemia or thrombocytopenia at birth or within the first 4–8 weeks of age. Children with late congenital syphilis show numerous facial and other defects (see Chapter 6).

PATHOLOGY: The placenta in infants with congenital syphilis can be unusually heavy, and may weigh 1000 or more grams. Villi appear hypercellular and enlarged, usually with Hofbauer cell hyperplasia

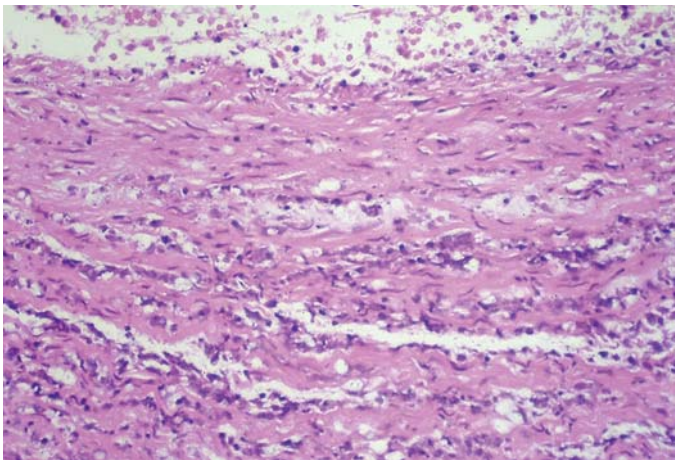

FIGURE 14-6. Necrotizing funisitis due to syphilis. The smooth muscle cells of the umbilical vessels are necrotic, and "smudgy" chronic inflammatory cells are causing a funisitis.

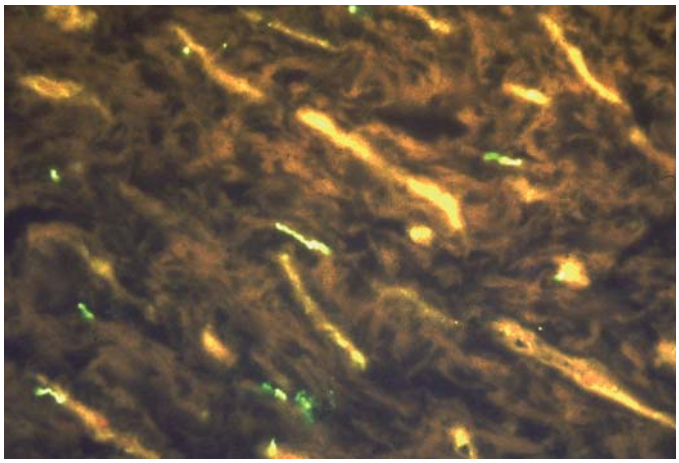

FIGURE 14-7. Spirochetes of *Treponema pallidum* in the wall of an umbilical cord blood vessel with necrotizing funisitis. The organisms are visible using a fluorescent antibody stain.

and stromal fibrosis. Chronic villitis is usually present and plasma cells may also be abundant in the decidua. The umbilical cord can demonstrate an unusual finding, termed **necrotizing funisitis**. This condition grossly resembles a "barber pole" and microscopically demonstrates smooth muscle necrosis of muscular walls of umbilical vessels and perivascular concentric rings of smudgy-appearing chronic inflammatory cells, necrotic debris or calcium deposits (Fig. 14-6). Spirochetes in placental tissues are visualized using the Warthin-Starry silver stain or fluorescent antibodies (Fig. 14-7).

Listeria

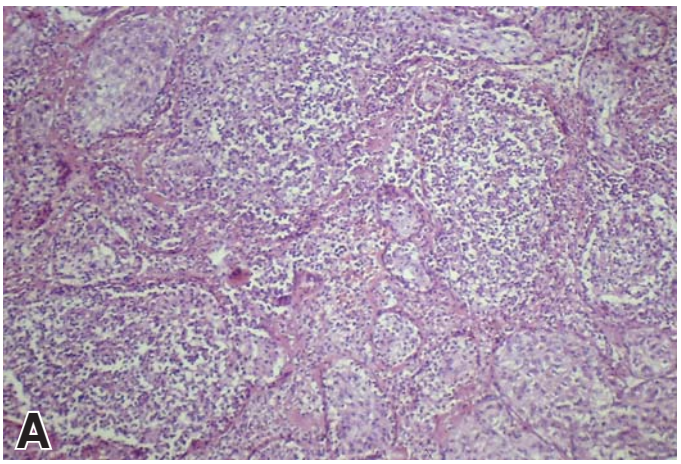
Listeriosis is a potentially serious infection most commonly acquired by eating food contaminated with the Gram-positive bacillus *Listeria monocytogenes*. Pregnant women and their infants are at increased risk for *listeriosis*. The bacteria can circulate in the maternal blood and infect the placenta and the fetus, causing miscarriage, stillbirth and premature delivery. In infants, *Listeria* infection is characterized by granulomatous rash and pyogenic granulomas throughout the body. *Listeria* is also responsible for 5% of cases of neonatal meningitis.

PATHOLOGY: Placentas infected with *Listeria* contain numerous microabscesses that destroy villi and produce an acute intervillositis (Fig. 14-8). Necrotizing chorioamnionitis and severe funisitis are frequent.

Toxoplasma

Toxoplasma gondii, a parasite in cats, is a protozoan that is a potential health problem in pregnancy. Infections acquired by the fetus early in pregnancy are more likely to be severe than those acquired later.

CLINICAL FEATURES: The classical triad of congenital toxoplasmosis, namely, hydrocephalus, intracranial calcifications and chorioretinitis, is well known but does not occur in most infants infected in



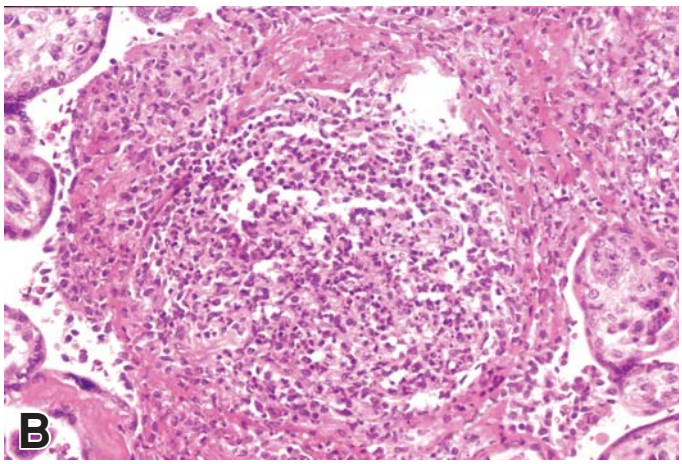


FIGURE 14-8. *Listeria* infection. A. Necrotizing villitis and intervillositis with microabscesses caused by *Listeria monocytogenes*. B. Higher magnification of acute villitis caused *by L. monocytogenes*. The central villus has been destroyed by acute inflammation and has the appearance of a microabscess. Neutrophils extend from the inflamed villus into the intervillous space and adjacent villi.

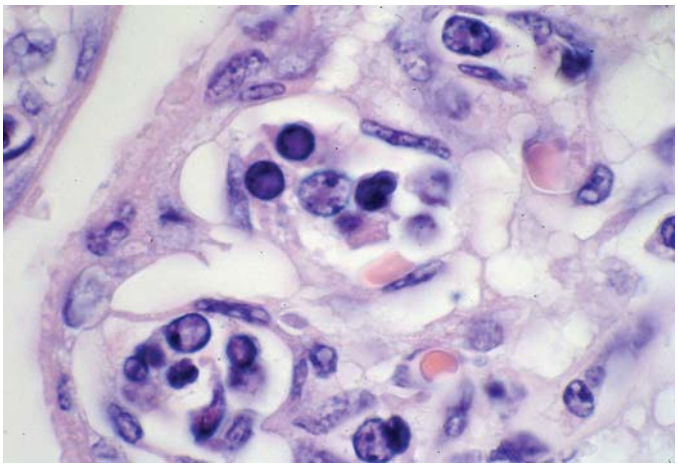

FIGURE 14-9. Intranuclear inclusions ("lantern cells") of erythrovirus (parvovirus) in nucleated fetal red blood cells in the placenta.

utero. Severe manifestations of congenital toxoplasmosis include encephalitis, multiple organ infection, epilepsy, mental retardation, blindness and stillbirth.

PATHOLOGY: Characteristic cysts of *Toxoplasma* can be present in the subamnionic connective tissue, chorionic villi, trophoblast and umbilical cord. Like syphilis and CMV, Hofbauer cell hyperplasia can also occur in toxoplasmosis. In some cases, thrombosis of placental blood vessels occurs, with or without calcification.

Erythrovirus (Parvovirus B19) Causes Fetal Hydrops and Stillbirth

Erythrovirus, formerly called parvovirus B19, is a DNA virus that causes ecthyma infectiosum, a benign disease with fever and rash in children. When a pregnant woman becomes infected, the risk for stillbirth rises, especially if the infection occurs in the first and second trimester. Mothers transmit the agent to their fetus in 30% of cases of acute maternal infection. The virus produces distinctive ground-glass intranuclear inclusions, termed "lantern cells," which are most evident in nucleated fetal red blood (Fig. 14-9). Placentas are typically enlarged and villi are edematous. Newborns tend to be hydropic (Fig. 14-10) and anemic, and may have cardiac involvement.

Human Immunodeficiency Virus Can Be Transmitted from Mother to Fetus

When an woman infected with HIV becomes pregnant, her infant can become infected via 3 major routes. The virus can cross the placenta; it can infect the newborn at the time of delivery; or infection can be transmitted through breastfeeding. Risk factors for transmission of HIV from a mother to her fetus are shown in Table 14-1.

Malaria Remains a Perinatal Infection in Endemic Areas

Malaria occurring during pregnancy remains an important problem in parts of the world where *Plasmodium* infections are endemic. Pregnant women with no preexisting

FIGURE 14-10. Stillbirth due to erythrovirus (parvovirus). The infant is hydropic (edematous).

TABLE 14-1
RISK FACTORS FOR PERINATAL TRANSMISSION OF HIV

Maternal Factors	
	Low $CD4^+$ lymphocyte counts (T cells)
	High HIV-1 RNA levels (viral load)
	Acute retroviral syndrome during pregnancy
	Presence of coinfections (hepatitis C, bacterial vaginosis, CMV)
	Injection drug use
	Absence of antiretroviral therapy or prophylaxis
	Absence of prenatal care
Obstetric Factors	
	Duration of placental membrane rupture and/or chorioamnionitis
	Invasive procedures
	Vaginal delivery
Infant Factors	
	Premature delivery
	Breastfeeding

CMV = cytomegalovirus.

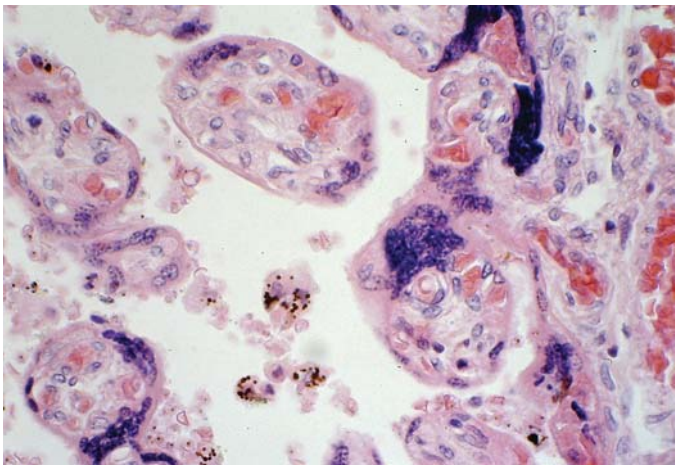

FIGURE 14-11. Placenta from mother with malaria. There is abundant intracellular brown pigment (hemosiderin) in the intervillous space.

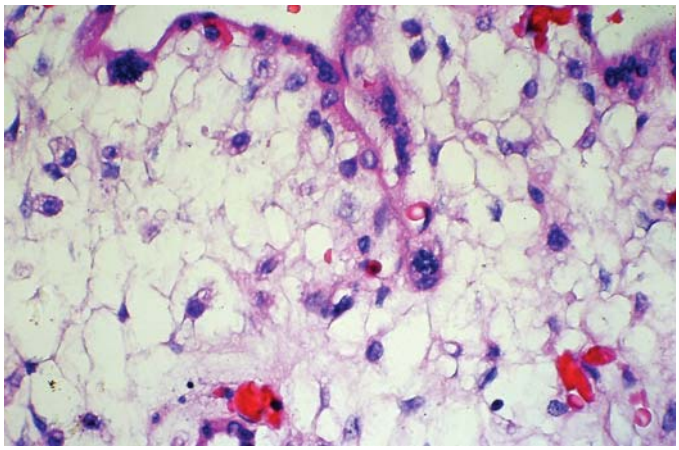

FIGURE 14-12. Villous edema. This villus is enlarged and hydropic, and the fetal capillaries appear compressed. Especially in premature infants, the stromal edema can inhibit oxygen transfer from maternal to fetal circulations.

immunity are at high risk for cerebral malaria, hypoglycemia, pulmonary edema, severe hemolytic anemia and death. Malaria infection can cause low birth weight, and possibly abortion and stillbirth. In malaria-endemic African countries, 15% of all infant deaths can be attributed to low birth weight.

PATHOLOGY: Placentas of mothers with malaria may show maternal red blood cells infected with *Plasmodium* in the intervillous space. Malarial pigment may be abundant in the intervillous space, the villous stroma and fibrin deposits (Fig. 14-11). Chronic intervillositis is common.

NONINFECTIOUS CONDITIONS AFFECTING CHORIONIC VILLI

Villitis of Unknown Etiology Results in Reproductive Loss, Brain Damage and Recurrence in Subsequent Pregnancy

Villitis of unknown etiology (VUE) is an abnormal inflammatory process of chorionic villi in which no infectious agent is found. Severe cases of VUE are associated with a significant rate of recurrence and with poor obstetric outcomes. Pregnancy failures occur in about 60% of pregnancies complicated by recurrent VUE.

PATHOLOGY: VUE may be focal or diffuse. If it destroys chorionic villi, it is called necrotizing villitis of unknown etiology. This is an ominous prognosis for the fetus. Chronic uteroplacental malperfusion and insufficiency often coexist with other pathologic findings, including fetal thrombotic vasculopathy and avascular chorionic villi.

Villous Edema Results from Fetal Stress

Villous edema, derived from the fetal chorionic circulation, is one of the most frequent causes of an enlarged placenta, especially in preterm deliveries.

ETIOLOGIC FACTORS: Villous edema has many causes. When it accompanies immunologic reactions and certain infectious diseases, it is **villous hydrops** and is often associated with **hydrops fetalis** (see Chapter 6), such as occurs in maternal–fetal Rh incompatibility and intrauterine erythrovirus infection (see above). However, villous edema can also occur without an edematous fetus, in which case intrauterine fetal stress is usually the trigger. Other causes of villous edema include abruptio placentae, chorioamnionitis, umbilical cord accidents, fetal malformations and genetic disorders. If edema is severe, it can compress the fetal villous vessels, causing fetal hypoxia and stillbirth.

PATHOLOGY: Terminal villi are enlarged and edematous (Fig. 14-12). Edema fluid may be phagocytized by villous Hofbauer cells, where it appears as intracellular microdroplets. As edema accumulates in the chorionic villi, it can cause clefts, or lacunae, in the villous interstitium, imparting a "bubbly" appearance. Villous edema tends to be most severe in immature placentas and in preterm infants.

VASCULAR DISORDERS OF THE PLACENTA

Fetal Thrombotic Vasculopathy Reflects Clotting in Placental Vessels

Thrombosis occurring anywhere in the circulation of the placenta is called fetal thrombotic vasculopathy (FTV) and indicates an unfavorable intrauterine environment for the fetus. Clots can develop in either the arterial or venous circulation of the placenta and umbilical cord, although the venous circulation is most often affected. Risk factors for development of FTV include villitis and disorders of coagulation, particularly hypercoagulable syndromes (see Chapter 26). A variety of poor outcomes are associated with FTV, including stillbirth, neonatal death, intrauterine growth restriction and, in surviving infants, neurologic injury. FTV may occur with similar clots in fetal organs.

PATHOLOGY: Thrombi of varying ages are often seen in chorionic villous blood vessels. In cases of acute FTV, large thrombi may be present in the

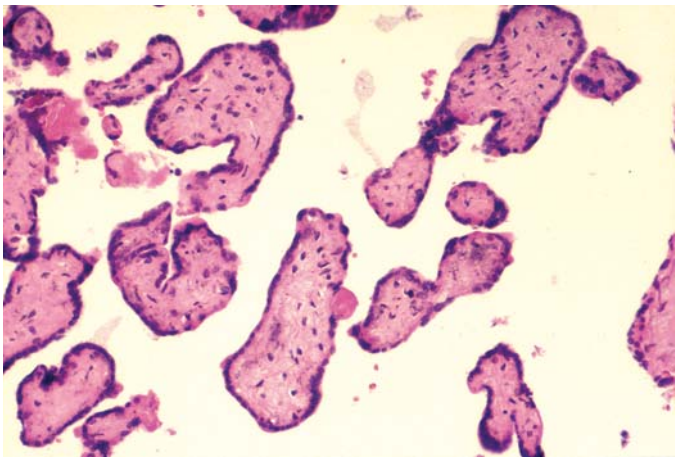

FIGURE 14-13. Avascular villi. The villous capillaries have been replaced by fibrous tissue as a result of a chronic thrombus in a larger upstream stem villus.

umbilical cord vessels or in the large-sized vessels of the chorionic plate. Microscopically, acute thrombi may involve smaller fetal vessels, including the secondary and tertiary villi. In chronic FTV, chorionic villi downstream from thrombosed vessels undergo progressive fibrosis, giving a distinctive appearance to clusters of scarred, **avascular villi** (Fig. 14-13). A thrombus can be incorporated into the vessel wall to form a mural thrombus, or **cushion defect**. Microcalcifications, stromal fibrosis and deposition of hemosiderin result from degeneration of red blood cells.

FTV in the umbilical cord vessels (Fig. 14-14) can be catastrophic and can complicate abnormally long or excessively twisted cords, velamentous cord insertion, entanglement of the cord and cord knots.

Hemorrhagic Endovasculopathy Is Ischemic Injury to Chorionic Blood Vessels

Hemorrhagic endovasculopathy (HEV, formerly termed **hemorrhagic endovasculitis)** results from irreversible injury to the endothelial cells lining fetal blood vessels in the chorionic villi. It is associated with increased perinatal morbidity and mortality, neurologic impairment and abnormalities of fetal growth and development. HEV often occurs together

FIGURE 14-14. Thrombus within an umbilical cord blood vessel.

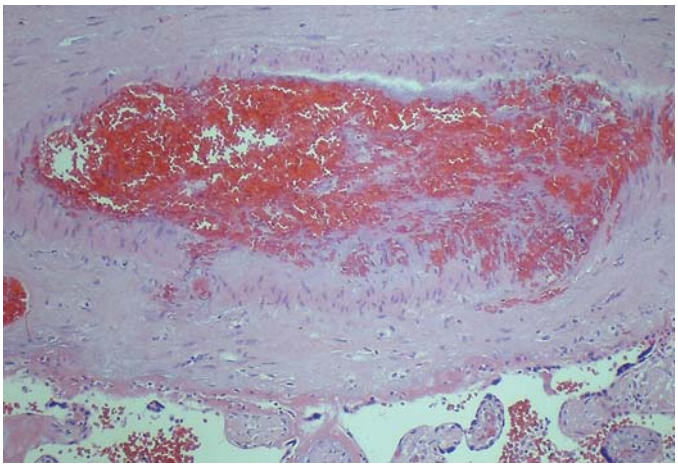

FIGURE 14-15. Hemorrhagic endovasculopathy (HEV). Fetal red blood cells in a large chorionic villus vessel extend from the lumen, through the ischemic endothelium and into the surrounding villous stroma.

with other placental abnormalities, including fetal thrombotic vasculopathy, villitis of unknown etiology, villous fibrosis, infarcts, erythroblastosis and meconium staining. Hypertensive disease of pregnancy is the only known risk factor.

PATHOLOGY: HEV can affect any vessel in the chorionic villous tree. Extravasated fetal red blood cells extend from the lumen through the intimal lining and into the surrounding blood vessel wall or stroma (Fig. 14-15). The vessel wall may be necrotic. Red blood cells can be fragmented, and karyorrhexis of endothelial and nucleated red blood cells is common. HEV may accompany inflammatory infiltrates in the villi, in which case it is called **hemorrhagic villitis**.

Abruptio Placentae Causes Retroplacental Hematoma

Retroplacental hematoma occurs between the basal plate of the placenta and the uterine wall and accounts for 8% of perinatal deaths. Hemorrhage derives from a ruptured maternal (spiral) artery or premature separation of the placenta. Retroplacental hemorrhage can be due to placental abruption **(abruptio placentae),** but in 1/3 of cases it occurs without clinical abruption, and the reverse is also true. Although abruptio placentae is often the final dramatic consequence of a chronic placental disorder, most cases result from maternal vascular disease. Key risk factors for retroplacental hematoma include maternal smoking, hypertensive disease of pregnancy, late maternal age, acute chorioamnionitis, uterine malformation, placenta previa, history of previous abruption, short umbilical cord, thrombophilia, multiparity and cocaine use.

CLINICAL FEATURES: Abruptio placentae complicates 1% of pregnancies worldwide. Symptoms depend on the extent of abruption and include vaginal bleeding, uterine tenderness, abdominal or back pain, uterine tetanic contractions, fetal distress, maternal shock, hypofibrinogenemia, coagulopathy and maternal or fetal death.

Figure 14-16. Retroplacental hematoma. The occurrence of a retroplacental hemorrhage such as this large hematoma may correlate with the presence of a clinical abruption.

PATHOLOGY: Premature detachment of the placenta or rupture of a uterine blood vessel causes blood to accumulate between the placenta and the decidua basalis, forming a hematoma (Fig. 14-16). When a retroplacental hematoma is present for some time, overlying villous tissue may show ischemic infarction.

In the half of placental abruptions that are mild, neither the fetus nor the mother suffers ill consequences. However, many abruptions result in poor fetal outcomes, including neonatal shock from hypoxia and anemia, irreversible neurologic injury and perinatal death.

In some cases, blood forces its way into the underlying myometrium, resulting in a **"Couvelaire uterus."** In such cases, mothers may develop anemia, coagulopathy, disseminated intravascular coagulation, adult respiratory distress syndrome (ARDS), shock and death. Maternal death due to abruptio placentae is rare in developed nations (0.4 per thousand cases of abruption), but it continues to be an important cause of maternal death in the resource-poor regions of the world.

Intervillous Thrombi Represent Fetomaternal Hemorrhage

Rupture of a chorionic villous blood vessel causes blood to accumulate in the placenta and to form an intervillous thrombus or hematoma. Since the pressure of the fetal circulation in the placenta is higher than that of the maternal circulation, this represents a **fetomaternal hemorrhage**. Entry of fetal blood into the maternal circulation can have clinical implications if there are blood group incompatibilities between the fetus and mother. Small intervillous thrombi occur in up to 20% of full-term-gestation placentas and are usually clinically insignificant. A larger thrombus or multiple thrombi cause fetal blood loss or hypoxia. Intervillous thrombi can develop as a result of preeclampsia or maternal thrombophilias, and when there is thrombosis in the maternal circulation.

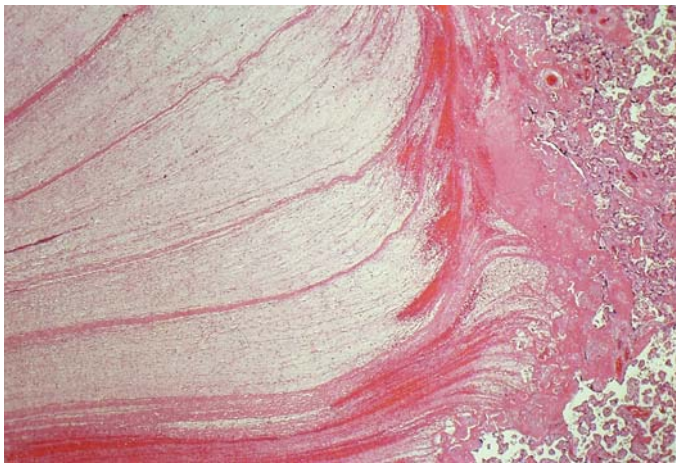

FIGURE 14-17. Intervillous thrombus (hematoma). This intraplacental hematoma represents an area of fetal–maternal hemorrhage. It is surrounded by a zone of fibrin and ischemic villi.

PATHOLOGY: Intervillous thrombi appear as well-demarcated areas of red firm areas, much different from the surrounding spongy placental parenchyma. Hemorrhage compresses the surrounding villi (Fig. 14-17). When intervillous thrombi occur remotely from the time of delivery, the rim of surrounding compressed villi show infarction or avascular scarring.

If significant amounts of fetal blood enter the maternal bloodstream from an intervillous thrombus, the fetal red blood cells may be detected using the **Kleihauer-Betke (KB)** test, which utilizes the differing sensitivity of fetal and adult hemoglobin to acid.

Placenta Accreta Is Abnormal Adherence of the Placenta to the Uterus

Placenta accreta is caused by failure to form decidua. Normally, decidual endometrium separates the base of the placenta from the underlying uterine muscle. Placenta accreta occurs when the decidual layer is partially or totally absent, so that the villi are in direct contact with the underlying decidua or uterine muscle. In this case, the placenta does not separate normally from the uterine wall at the time of delivery, which may lead to life-threatening maternal hemorrhage. Risk factors for placenta accreta include placenta previa, prior cesarean sections, advanced maternal age, high parity and endometrial defects.

PATHOLOGY: Placenta accreta is classified by the depth of myometrial invasion by the villi:

- **Placenta accreta** refers to attachment of villi to the surface of the uterine wall without further invasion (Fig. 14-18A).
- **Placenta increta** occurs when villi invade underlying myometrium, penetrating either superficially or deep into the myometrium (Fig. 14-18B).
- **Placenta percreta** describes villi penetrating the full thickness of the uterine wall. In some cases, placenta percreta penetrates through the uterine serosa and invades adjacent organs such as the colon or urinary bladder; it can also result in uterine rupture.

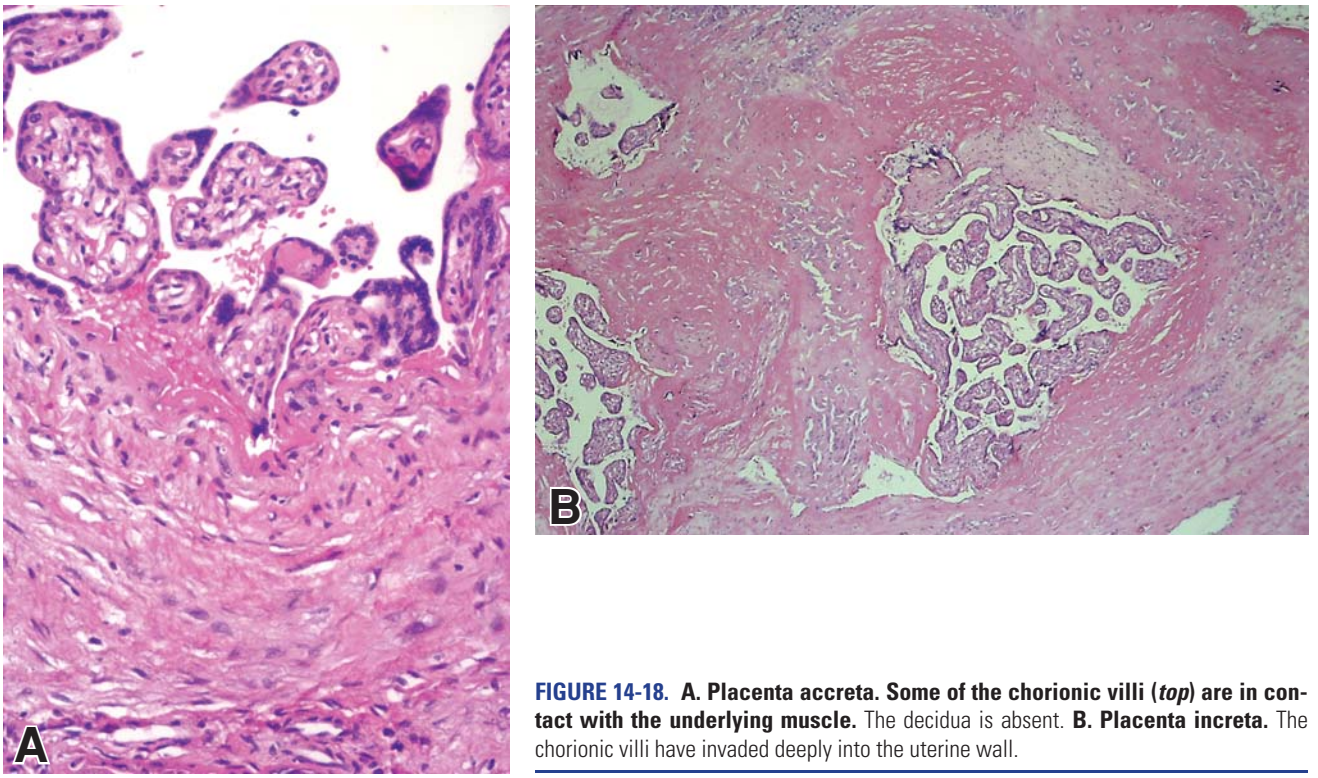

FIGURE 14-18. A. Placenta accreta. Some of the chorionic villi (*top*) are in contact with the underlying muscle. The decidua is absent. **B. Placenta increta.** The chorionic villi have invaded deeply into the uterine wall.

CLINICAL FEATURES: Patients with placenta accreta can have a normal pregnancy and delivery. However, complications may occur during pregnancy, during delivery or especially in the immediate postpartum period. Third-trimester bleeding is the most common presenting sign; substantial fragments of placenta may remain adherent after delivery and cause hemorrhage, endometritis and disseminated intravascular coagulation. Bleeding may threaten the lives of both mother and baby and necessitate emergency hysterectomy.

Chronic Uteroplacental Malperfusion Can Cause Poor Obstetric Outcomes

Adequate oxygenation of the fetus during pregnancy requires that both fetal and maternal circulations between the uteroplacental and fetal structures operate properly. Chronic uteroplacental malperfusion and insufficiency are important causes of perinatal morbidity and mortality. They can result in stillbirth, neonatal death, preterm birth, intrauterine growth restriction and, if the infant lives, neurologic damage. Some of the most frequent causes include villous hypoplasia, maternal floor infarction, massive perivillous fibrin deposition, diabetes, autoimmune diseases, villitis, placental infarcts, chronic abruption, fetal thrombotic vasculopathy, abnormally small or thin placentas, chorangiomas, large remote intervillous thrombi and chronic umbilical cord abnormalities.

Villous Hypoplasia Is Caused by Insufficient Maternal Blood Flow to the Placenta

Villous hypoplasia (also called uneven accelerated maturation) results from chronic underlying disease of the spiral arterioles, including stenosis, fluctuating vasoconstriction or, as occurs with preeclampsia, defective remodeling (see below). Decreased maternal perfusion of the intervillous space of the placenta leads to ischemic degeneration of chorionic villi (Fig. 14-19A, B). Resulting fetal hypoxia can produce stillbirth, neonatal death, intrauterine growth restriction, preterm birth and neurologic injury in infants who survive.

Increased Fibrin Results in a Spectrum of Placental Disorders

Small amounts of fibrin from the maternal circulation deposit in the placenta under normal conditions. **Rohr fibrin** is a necessary component of the basal plate of the placenta, where it faces the intervillous plate. **Nitabuch fibrin** deposits in the deep part of the basal plate. It is a deficiency of Nitabuch fibrin that causes placenta accreta.

Increased Perivillous Fibrin

Excess deposition of fibrin around villi can cause placental insufficiency by interfering with perfusion of the villi. Ischemic necrosis of the villi may eventuate (Fig. 14-20) and can cause placental insufficiency.

Massive perivillous fibrin deposition (MPFD) can cause perinatal death. The cause of MPFD is unknown. The fibrin extends from the basal (decidual) part of the placenta up to the fetal (chorionic) surface. Dense fibrin fills the intervillous space and results in villous ischemic necrosis (Fig. 14-21). MPFD often leads to poor pregnancy outcomes.

Maternal Floor Infarction

Maternal floor infarction (MFI) is not a true infarct but shares some morphologic features with MPFD. Excessive

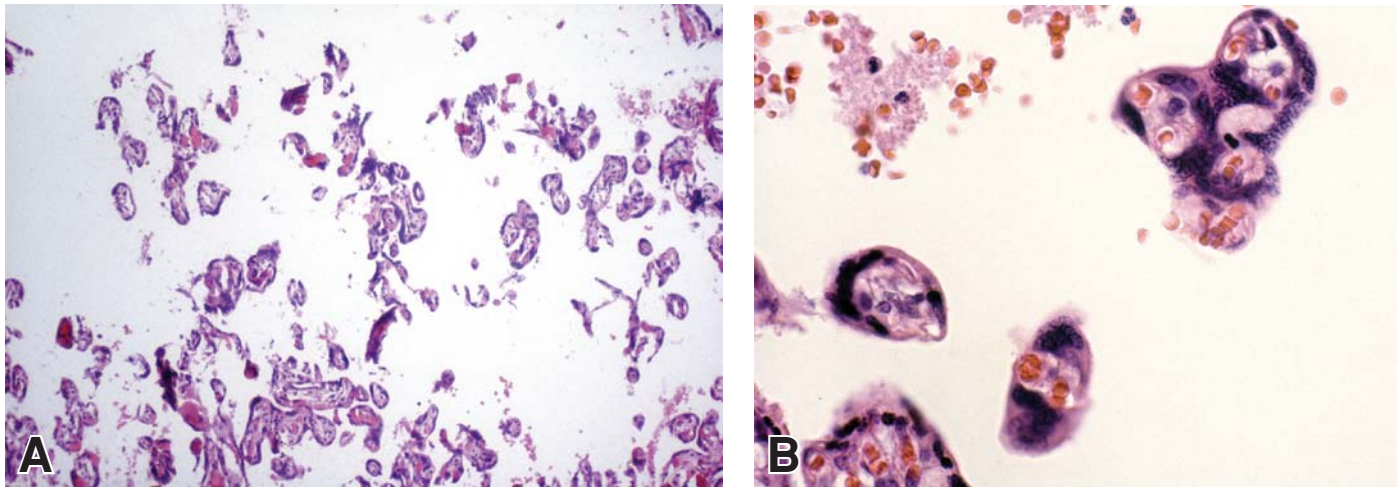

FIGURE 14-19. Villous hypoplasia. A. The diameter of the villi is decreased, resulting in an apparent increase in the intervillous space between villi. **B. High magnification of villous hypoplasia.** The characteristic features of chronic ischemia are present, including small, shrunken villi with stromal fibrosis and clumped trophoblast.

fibrin extends confluently across the width of the placenta. It mainly affects the basal surface and decidua and extends upward to involve the villi. The floor of the placenta is firm, thickened and often discolored tan-yellow. Like MPFD, villi involved with MFI are embedded in dense fibrin and are necrotic. MFI has the same perinatal outcomes as does MPFD.

Infarcts Are the Most Frequently Diagnosed Vascular Condition of the Placenta

Placental infarcts consist of an area of placental tissue that has undergone irreversible ischemic injury and death owing to complete interruption of maternal vascular supply to the infarcted area. The most frequent causes of placental infarction are hemorrhage between the base of the placenta and the uterine wall (retroplacental hemorrhage and abruptio placentae) and occlusion or thrombosis of the uterine spiral artery.

Placental infarcts often accompany hypertensive diseases of pregnancy, including preeclampsia, maternal thrombophilia and cigarette smoking. Multiple infarcts, especially if they are large or in the central part of the placenta, can result in placental insufficiency and give rise to intrauterine growth restriction, neurologic injury and perinatal death.

PATHOLOGY: Infarcts are dark red areas that are firmer than surrounding placental tissue. With increasing age, they become firmer, change in color from dark red to yellow and then to tan, and finally become white and more sharply delineated from the adjacent tissue.

Chorangiosis Is Increased Chorionic Vasculature

Terminal chorionic villi have a markedly increased number of vessels. This endothelial proliferation increases the capillary surface area of the villi in the face of chronic intrauterine hypoxia. Chorangiosis does not cause fetal damage but is a microscopic marker of significant uteroplacental

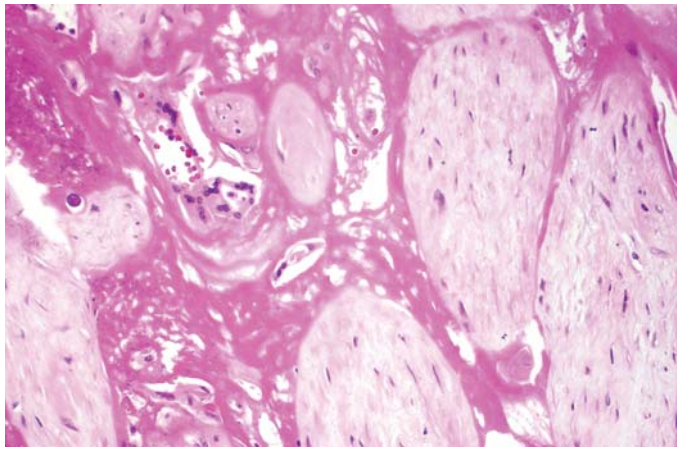

FIGURE 14-20. Increased villous fibrin. The fibrin has covered the chorionic villi, obstructed the intervillous space and resulted in villous necrosis.

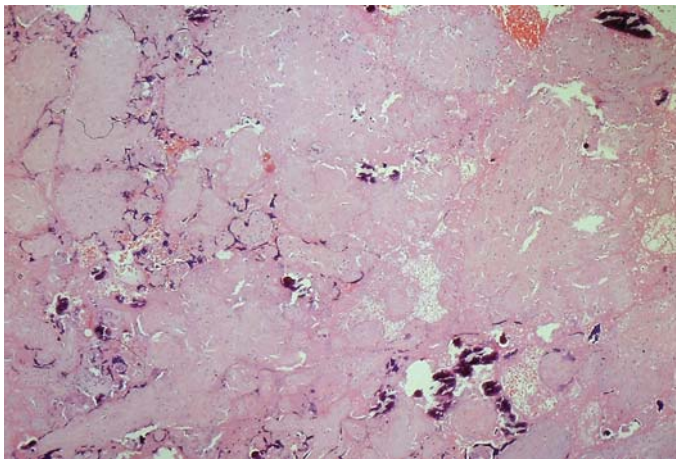

FIGURE 14-21. Massive perivillous fibrin deposition (MPFD). Low magnification showing confluent villous necrosis and fibrin deposition in the intervillous space. The small, dark purple microcalcifications attest to the chronicity of this process.

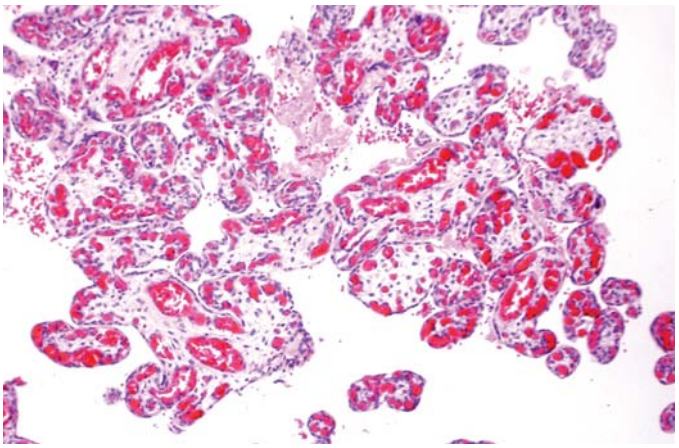

FIGURE 14-22. Chorangiosis. Chorangiosis results from chronic fetal hypoxia. Normal chorionic villi contain 5 or fewer capillaries. The chorionic villi in these villi are hypervascular—most contain greater than 10 capillary cross-sections, and a few villi contain 20 or more vessels.

insufficiency and fetal hypoxia that may arise from any variety of causes.

PATHOLOGY: Chorangiotic villi contain 10 or more vessels, affecting numerous villi. The increased vascularity may be so marked that some villi have 30–40 or more fetal vessels (Fig. 14-22).

Increased Syncytial Knots Indicate Uteroplacental Malperfusion

Chorionic villi are covered by a layer of multinucleated cells, the syncytiotrophoblast (see above). In the face of chronic uteroplacental malperfusion, the syncytiotrophoblast forms prominent bulbous knots or folds, often bridging the intervillous space and touching the trophoblast of adjacent villi (Fig. 14-23). This abnormality, termed **syncytiotrophoblast hyperplasia**, often affects placentas with chronic malperfusion from all causes.

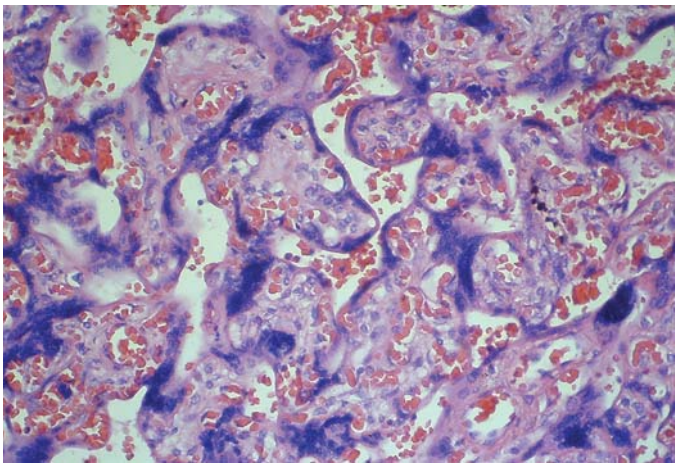

FIGURE 14-23. Tenney-Parker change (syncytiotrophoblast hyperplasia). The syncytiotrophoblast is knotted and hyperbasophilic and bridges the intervillous space to connect to adjacent villi. This is caused by chronic uteroplacental malperfusion of either maternal or fetal origin.

MECONIUM DISORDERS

Meconium is the earliest stools of the fetus or newborn. The term is derived from the Greek *mēkōn,* or "poppy," referring to its tarry appearance. It is stored in the intestine of the fetus until it is discharged, which may be prior to birth, during labor and delivery or following birth. Its composition is different from feces formed later in life—meconium is composed of materials ingested by the fetus while in utero. It includes water (80%), amniotic fluid, mucopolysaccharides, intestinal enzymes, bile, lanugo and epithelial cells from the skin and intestines. Typically, meconium is sticky and tarry, dark olive green and usually odorless.

Meconium Passage by the Fetus May Indicate Fetal Stress

Physiologic passage of meconium can be facilitated in full-term fetuses because of the maturity of the fetal gastrointestinal tract. It can also be released in the term fetus as a result of fetal hypoxia or fetal distress. Chorioamnionitis and amniotic infection syndrome, compression of the fetal head or umbilical cord, fetal asphyxia and acidosis and gestational cholestasis in the mother may all trigger meconium release. In preterm infants (<37 weeks), passage of meconium is always abnormal.

PATHOLOGY: Following delivery, the fetal surfaces of the placenta, membranes or umbilical cord appear discolored, varying from brown to green to golden yellow. Within 1–3 hours after meconium passage, the amnion will be stained. Beyond 3 hours prior to delivery, intracellular meconium is evident within the resident macrophages in the membranes or chorionic surface of the placenta (Fig. 14-24). When meconium has been present for more than 24 hours, it may been seen in the umbilical cord mesenchyme (Wharton jelly) or in the trophoblast or decidual layers of the extraplacental membranes. In remote meconium passage, the amnionic epithelium is thickened or thrown up into finger-like projections owing to irritation, which is called **amnionic papillary hyperplasia**.

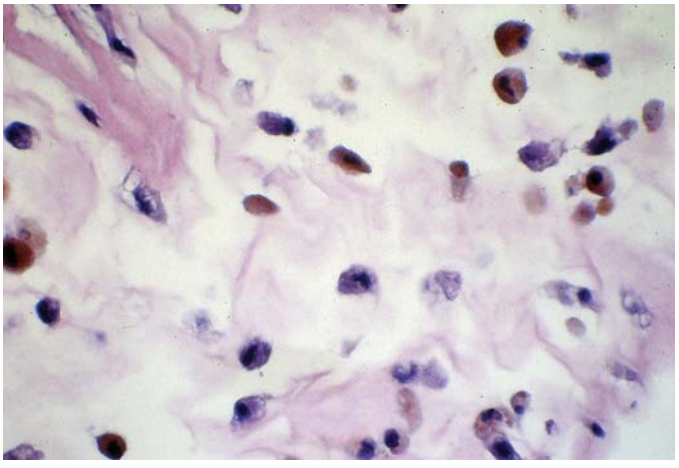

FIGURE 14-24. Abundant meconium present in chorionic macrophages in a premature infant. It takes a minimum of 3–4 hours for meconium to be absorbed into the chorion and macrophages from the amniotic fluid following its passage by the fetus.

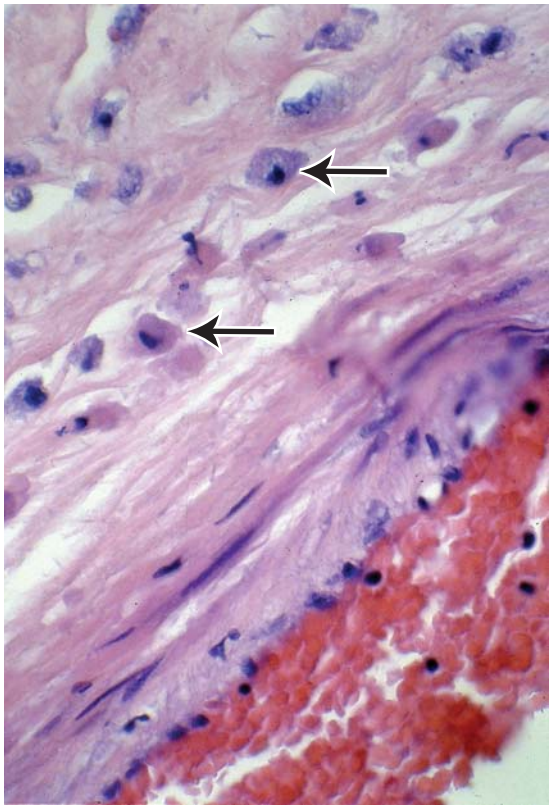

FIGURE 14-25. Meconium-induced vascular necrosis (MIVN). Smooth muscle cells of the fetal blood vessel have undergone ischemic degeneration and necrosis, and appear rounded and hyperchromatic (*arrows*).

Meconium-Induced Vascular Necrosis Can Threaten the Life of the Fetus or Cause Brain Damage

An important potential complication of meconium discharge is **meconium-induced vascular necrosis** (MIVN). In MIVN, meconium passed by the fetus long before delivery has sufficient time to penetrate the connective tissue of the umbilical cord or through the chorionic plate, to reach and permeate the muscular walls of the umbilical cord or large chorionic plate blood vessels. This causes necrosis of blood vessels, which compromises fetal blood flow and leads to poor obstetric outcomes.

PATHOLOGY: The umbilical cord vessels and the large-sized chorionic plate blood vessels can be involved in MIVN (Fig. 14-25). In affected blood vessels, only eosinophilic remnants of the cytoplasm remain visible. In remote cases of MIVN, muscular walls of the affected vessel are thinned. Meconium is often identified within connective tissues near the injured vessels.

INTRAUTERINE GROWTH RESTRICTION AND LOW BIRTH WEIGHT

Intrauterine growth restriction (IUGR) is an abnormality of fetal growth and development that affects 3%–10% of deliveries and reflects chronic uteroplacental insufficiency. IUGR can be asymmetric (70%–80%) or symmetric (20%–30%). In the more common asymmetric form, head size, length and weight are often normal, but subcutaneous fat and muscle mass and abdominal circumference are decreased (see below).

The newborn with asymmetric IUGR has a 5–10-fold increased risk for perinatal mortality and morbidity. Asymmetric IUGR is also associated with neonatal hypoglycemia, meconium aspiration, persistent fetal circulation and neurologic injury due to chronic fetal hypoxia. Placentas from neonates with asymmetrical IUGR are almost always abnormal. ***Maternal cigarette smoking is the most important preventable cause of asymmetric IUGR.*** Symmetric IUGR results in an abnormally and proportionally small infant, with low birth weight, small head and short stature. It begins early in pregnancy and is usually due to genetic disorders, early fetal infections and chromosomal and congenital anomalies. Morbidity and mortality are increased in infants with symmetric IUGR, and 30% of infants who survive have neurodevelopmental problems.

Small- or Large-for-Gestational-Age Infants May Have Normal Development

Infants who are **small for gestational age,** or **SGA,** have birth weights below the 10th percentile for gestational age and gender. Similarly, **large-for-gestational-age,** or **LGA,** infants have birth weights above the 90th percentile. Average birth weights vary with geography, ethnicity and socioeconomic status. However, infants who are SGA or LGA may be so as a result of an abnormal intrauterine exposure or disease. Related terms for infant birth weight are as follows:

- **Low birth weight (LBW)**: a newborn weighing less than 2500 grams regardless of gestational age
- **Very low birth weight (VLBW)**: infants weighing less than 1500 grams
- **Extremely low birth weight (ELBW)**: newborns weighing less than 1000 grams

Low Birth Weight Causes Neonatal Morbidity

LBW is a principal contributor to neonatal morbidity and mortality worldwide. In some countries, it accounts for up to 70% of neonatal deaths. LBW infants are 20 times more likely to die than are normal–birth-weight infants. They tend to remain malnourished and to have lower IQs and cognitive disabilities. More than 95% of LBW babies are born in developing countries. IUGR is the most common form of LBW in the developing world, whereas most LBW in developed countries is due to prematurity.

Extremely-Low-Birth-Weight Infants Have Perinatal Complications

Most **ELBW** infants are born at less than 27 weeks' gestation. ELBW infants represent less than 1% of all live births in Western nations. For infants with birth weights less than 500 grams, the first-year survival rate is 14%; between 500 and 749 grams, 51% survive the first year; infants weighing between 750 and 1000 grams at birth have a 1-year survival rate of 85%. In the resource-poor nations of the world, data for ELBW infants are scarce, and survival is most likely rare.

Macrosomia Can Be Constitutional or Caused by Intrauterine Disease

Depending on the criteria used, macrosomic newborns weigh greater than 4000 grams (8 lbs, 13 oz) or greater than 4500 grams (9 lbs, 15 oz), regardless of gestational age or gender. They differ from being large for gestational age, in that the classification LGA is based on a birth weight greater than the 90th percentile.

Fetal macrosomia presents problems for both the mother and infant. Potential maternal complications include difficulty in labor, genital tract lacerations, postpartum bleeding and uterine rupture. Complications affecting the infant include shoulder dystocia and brachial plexus injuries, impaired glucose tolerance and childhood obesity. The stillbirth rate for macrosomic infants is twice as high as that for normal-sized infants, irrespective of maternal diabetes.

ETIOLOGIC FACTORS: The most frequent cause of neonatal macrosomia is maternal diabetes. Gestational diabetes increases maternal serum glucose levels, leading to increased fetal insulin, which stimulates fetal growth. Male infants are at greater risk than females. Additional risk factors for macrosomia include maternal obesity, excessive maternal weight gain, a history of a previous macrosomic infant, prolonged pregnancy (>41 weeks) and advanced maternal age.

SPONTANEOUS ABORTION

A pregnancy that ends with expulsion of a conceptus before the 20th week of gestation is called a spontaneous abortion, or miscarriage. Some 15% of recognized pregnancies abort spontaneously. An additional 30% of women abort without being aware that they were pregnant. Thus, about half of all pregnancies miscarry, making it the most common complication of early pregnancy. The most common symptom of spontaneous abortion is bleeding.

ETIOLOGIC FACTORS: Most spontaneous abortions occur before 12 weeks of gestation. Karyotypic anomalies are present in 50% of all spontaneous abortions, and in as many as 70% of those occurring before the 7th week of gestation. The principal factors responsible for spontaneous abortion are:

- Infection early in pregnancy (e.g., *Listeria,* CMV, *Toxoplasma,* coxsackievirus)
- Mechanical factors (e.g., uterine leiomyoma, septate uteri, cervical incompetence)
- Endocrine factors (e.g., maternal diabetes, polycystic ovary, luteal phase defects, progesterone deficiency, hypothyroidism)
- Immunologic factors
- Cigarette smoking
- Cocaine usage
- Congenital fetal malformations (e.g., neural tube defects)
- Chromosomal abnormalities
- Increasing maternal age
- Multiple gestation (e.g., twins, triplets, etc.)

PATHOLOGY: An empty gestational sac with hydropic swelling of the chorionic villi (blighted ovum) suggests early fetal demise. The embryo may be grossly disorganized or show defects such as spina bifida, anencephaly or cleft palate. Chorionic villi may be histologically normal or show intravillous fibrosis or hydropic change. If infection preceded the miscarriage, there is often microscopic evidence of the infectious agent (see Chapter 9).

RECURRENT PREGNANCY LOSS

Pregnancy loss is the most common complication of human pregnancy, affecting 10%–15% of all human conceptions. For most fertile couples miscarriage is a sporadic event, but 1%–5% of fertile couples suffer from **recurrent pregnancy loss** (RPL; also termed **habitual abortion**).

ETIOLOGIC FACTORS: The **antiphospholipid syndrome** accounts for 3%–15% of recurrent pregnancy loss. Another important cause of RPL is **thrombophilia,** mostly **factor V Leiden** and **prothrombin G20210A** (factor II) mutations. In 4% of couples with RPL, there are chromosomal aberrations in one or both partners. Diverse endocrine factors can cause RPL, including hypothyroidism, polycystic ovary disease, diabetes and inadequate production of progesterone. Anatomic conditions, such as cervical incompetence and uterine malformations, or immune factors including antithyroid autoantibodies and maternal immunization against male-specific minor histocompatibility (H-Y) antigens are also involved in some cases. Certain ovarian factors are risk factors for RPL. These include luteal phase defects and advanced maternal age, with decreased ovarian reserve and decreased egg quality.

MULTIPLE GESTATIONS

Slightly less than 1% of normal pregnancies yield dizygotic or monozygotic twins (Fig. 14-26).

DIZYGOTIC TWINS: Fertilization of two separate ova results in genetically different twins, of the same or opposite sex. Dizygotic twinning has a strong hereditary component, which is limited to the maternal side. Dizygotic twinning and multiple gestations occur more commonly in women who have used hormones to induce ovulation artificially or who have been impregnated after in vitro fertilization.

Separate placentas develop when two fertilized ova implant apart from one another. If they implant near each other, the two placentas show varying degrees of fusion, and may appear to be one. If the ova implant apart, there are discrete conceptuses, each placenta having its own amniotic sac. In cases when the placentas fuse, the membranes between the two fetuses show two amnions and two chorions (diamnionic, dichorionic gestation).

MONOZYGOTIC TWINS: Early division of a single fertilized ovum results in genetically identical twins of the same sex. If a fertilized ovum divides within 2 days of fertilization, before the trophoblast has differentiated, two separate embryos develop, each with its own placenta and amniotic sac (dichorionic, diamniotic twinning). Hence, dichorionic placentas may be either monozygotic or dizygotic, while monochorionic placentas are always monozygous. If division occurs from the third to eighth days after conception, the trophoblast (but not the amniotic cavity) has already differentiated. A single placenta with two amniotic sacs develops

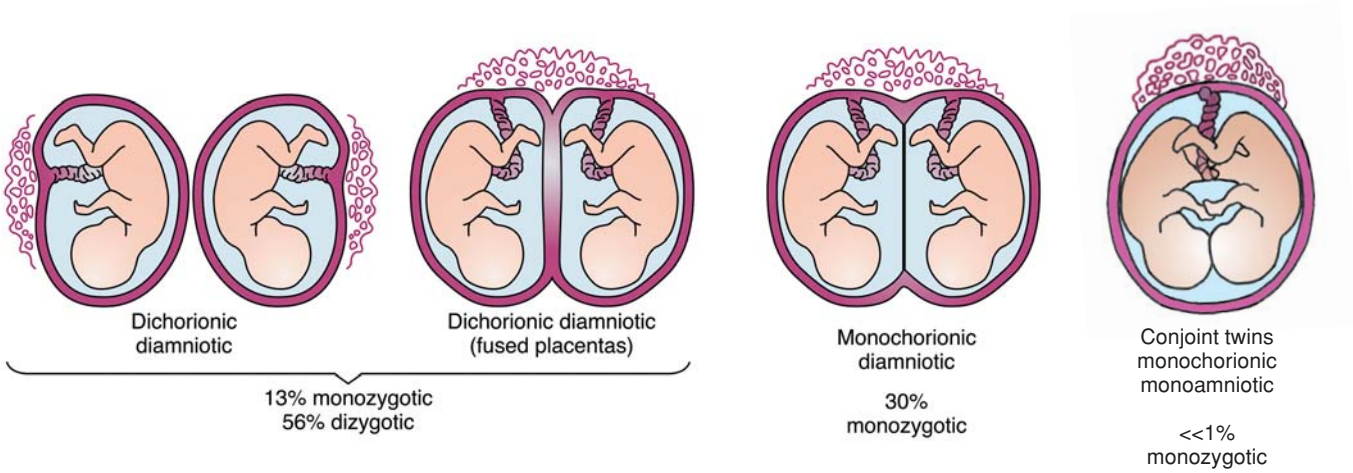

FIGURE 14-26. Placental structure in twin pregnancies. The percentages in the figure refer to the proportion of total twin pregnancies (100%) accounted for by each variant.

(monochorionic, diamniotic twinning). A monochorionic, monoamniotic placenta is formed if division occurs between the 8th and 13th day after conception, because the amniotic cavity has already developed. Incomplete separation of monozygous twins results in **conjoint (formerly Siamese) twins** within a monoamniotic, monochorionic placenta.

HYPERTENSIVE DISORDERS OF PREGNANCY

Preeclampsia and eclampsia define a syndrome of hypertension, proteinuria and edema and, most severely, convulsions. Preeclampsia occurs in 6% of pregnant women in their last trimester, especially with their first child. If convulsive seizures appear, the syndrome is called eclampsia. (The archaic term "toxemia" is rarely used anymore.) Preeclampsia causes some 50,000 maternal deaths worldwide each year.

ETIOLOGIC FACTORS: Preeclampsia probably arises because of faulty remodeling of uterine spiral arteries that supply maternal blood to the placenta. Immunologic and genetic factors, as well as altered vascular reactivity, endothelial injury and coagulation abnormalities, may also contribute. The characteristics of preeclampsia are (Fig. 14-27):

- Maternal blood flow to the placenta is markedly reduced because of ineffective remodeling of maternal spiral arteries of the decidua.
- Renal involvement contributes to hypertension and proteinuria.
- Disseminated intravascular coagulation may occur in preeclampsia.
- The risk of preeclampsia in a first pregnancy is manyfold higher than in subsequent pregnancies.
- Rarely, preeclampsia may not occur until the time of labor and delivery, or shortly thereafter (postpartum preeclampsia).
- Eclampsia is a cerebrovascular disorder characterized by seizures, worsening hypertension and cerebral edema. It may precede other symptoms and does not necessarily evolve from preeclampsia.

PATHOPHYSIOLOGY: Faulty cytotrophoblastic remodeling of the maternal uterine (spiral) arteries in early pregnancy (Fig. 14-27) is believed to result from abnormal expression of integrins by the fetal-derived cytotrophoblast, as well as generalized apoptosis of the cytotrophoblast. This situation leads to limited invasion of the decidua and spiral arteries, in which case, the spiral arteries cannot perfuse the growing fetus adequately. Resulting placental ischemia promotes release of cytokines such as tumor necrosis factor-α (TNF-α) and interleukin-6 (IL-6).

Upregulation and production of such placental antiangiogenic factors as vascular endothelial growth factor (VEGF) and soluble endoglin may play a role in the onset of the clinical features of preeclampsia, including hypertension and proteinuria. The roles, if any, of other factors are unclear.

The fundamental pathophysiology of preeclampsia reflects reduced maternal blood flow to the uteroplacental unit, as the spiral arteries of the uteroplacental bed never fully dilate.

Early in a normal pregnancy, fetal cytotrophoblast cells extend downward into the decidua and uterus. They invade the uterine spiral arteries and progressively replace the maternal-derived endothelium, medial elastic tissue, smooth muscle and neural tissue. By the end of the second trimester, the normally narrow spiral arteries are dilated tubes lined by fetal-derived cytotrophoblast. This low-resistance arterial circuit supplies the increasing oxygen and nutrient demands of the developing fetus.

In preeclampsia, many spiral arteries escape invasion by trophoblastic tissue and so never dilate. The combination of vasoconstriction and structural changes in spiral arteries contributes to inadequate blood flow, placental ischemia, villous hypoplasia and fetal hypoxia. The effectiveness of vasodilators in treating preeclampsia, including nitric oxide (NO•), prostacyclin (PGI_2) and endothelium-derived hyperpolarizing factor (EDHF), is further evidence for endothelial dysfunction in preeclampsia.

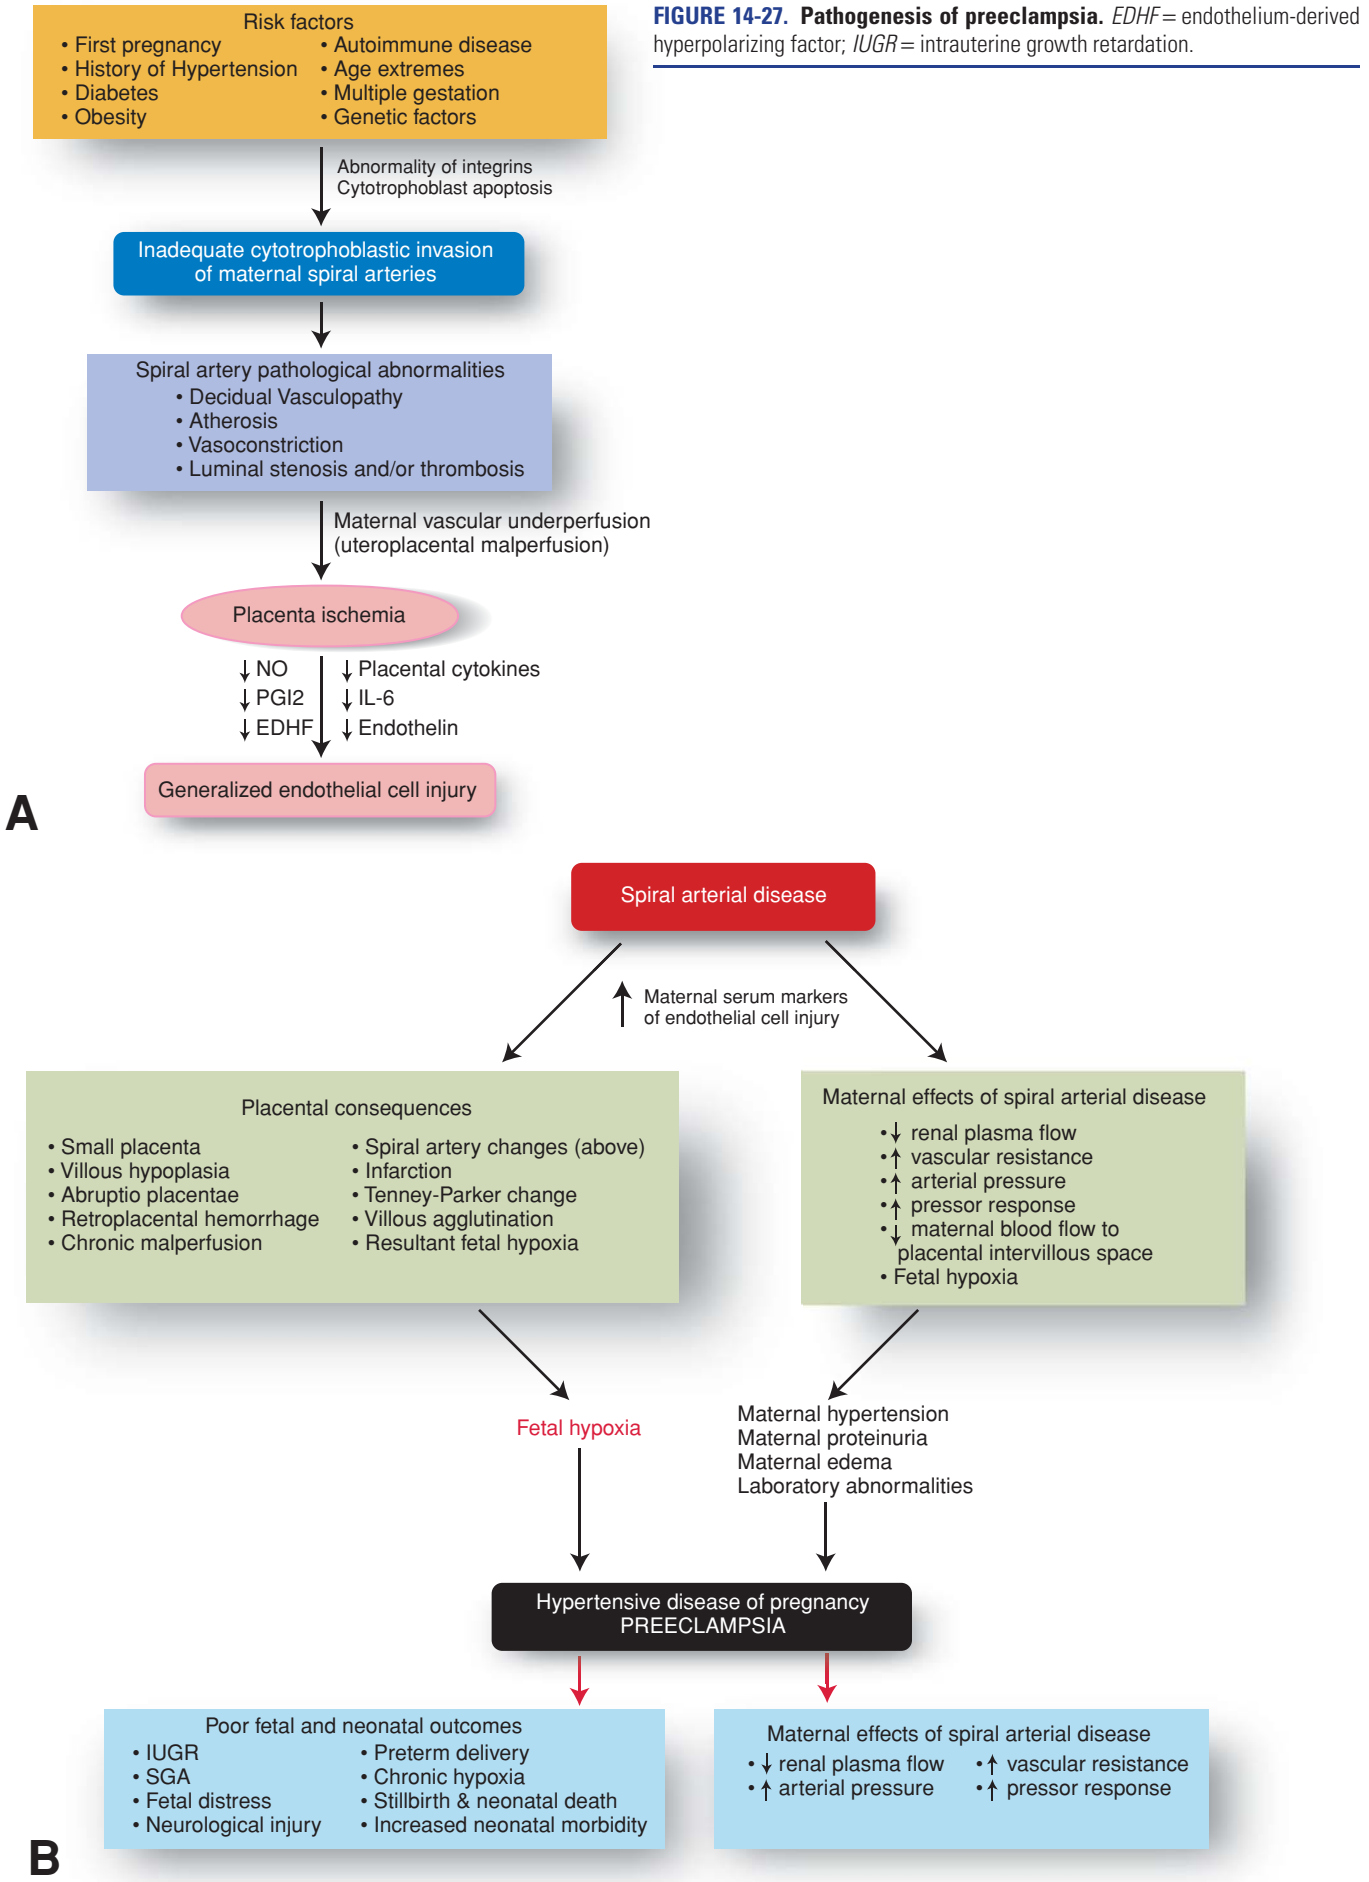

FIGURE 14-27. Pathogenesis of preeclampsia. *EDHF* = endothelium-derived hyperpolarizing factor; *IUGR* = intrauterine growth retardation.

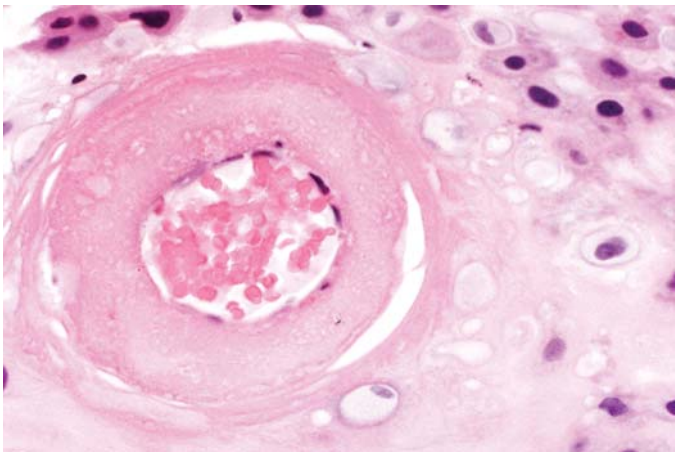

FIGURE 14-28. Decidual atherosis in preeclampsia. A small decidual artery shows fibrinoid thickening of the vessel wall.

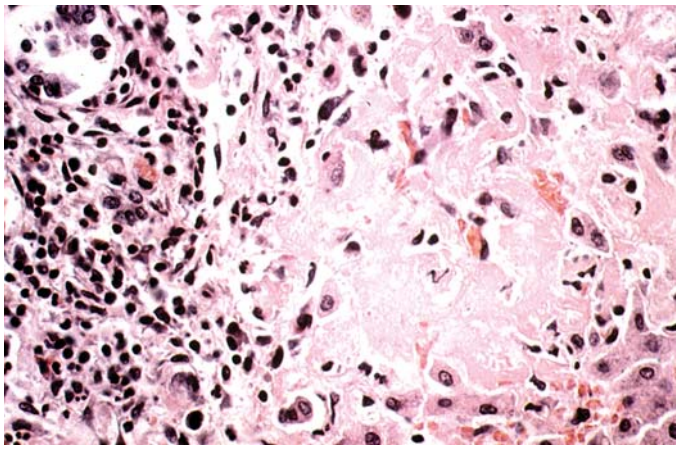

FIGURE 14-30. Liver of a woman with HELLP syndrome. The periportal area (zone 1) demonstrates fibrin deposition.

PATHOLOGY: ***Placental pathology usually precedes the clinical onset of maternal hypertension.*** Extensive placental infarction is seen in 1/3 of women with severe preeclampsia, although it is often negligible in mild preeclampsia. Retroplacental hemorrhage or abruptio placentae occurs in 15% and abnormally small placentas (<10th percentile) in 10% of cases (Fig. 14-16). Chorionic villi show signs of chronic maternal underperfusion, consisting of ischemically degenerated chorionic villi (villous hypoplasia; Fig. 14-19), fibrin (Fig. 14-20), increased placental site giant cells, syncytiotrophoblastic hyperplasia (Tenney-Parker change) (Fig. 14-23) and mural hypertrophy of membrane arterioles. The spiral arteries commonly show fibrinoid necrosis, clusters of lipid-rich macrophages and a perivascular infiltrate of mononuclear cells; this constellation of findings is called **acute atherosis** (Fig. 14-28). These vessels are often thrombosed, causing focal placental infarcts.

Maternal kidneys always show glomerular changes. Glomeruli are enlarged and endothelial cells are swollen, forming classic "bloodless" glomeruli of preeclampsia (glomerular endotheliosis) (Fig. 14-29). Fibrin deposits between endothelial cells and the glomerular capillary basement membrane. Mesangial cell hyperplasia is the rule. These maternal renal changes are reversible with therapy or after delivery.

Fatal cases of eclampsia often show cerebral hemorrhages, ranging from petechiae to large hematomas. ***Liver abnormalities are present in 60% of women dying from preeclampsia,*** including periportal fibrin deposits and necrosis (Fig. 14-30), lobular hemorrhage and hepatic infarction.

CLINICAL FEATURES: Preeclampsia usually begins insidiously after the 20th week of pregnancy, with excessive weight gain due to fluid retention, increased maternal blood pressure and proteinuria. As preeclampsia progresses from mild to severe, diastolic pressure persistently exceeds 110 mm Hg, proteinuria is greater than 3 g/day and renal function declines. Disseminated intravascular coagulation (DIC) often supervenes. Preeclampsia is treated with antihypertensive and antiplatelet drugs, but definitive therapy requires removing the placenta. Eclampsia is treated with magnesium sulfate, which reduces cerebrovascular tone.

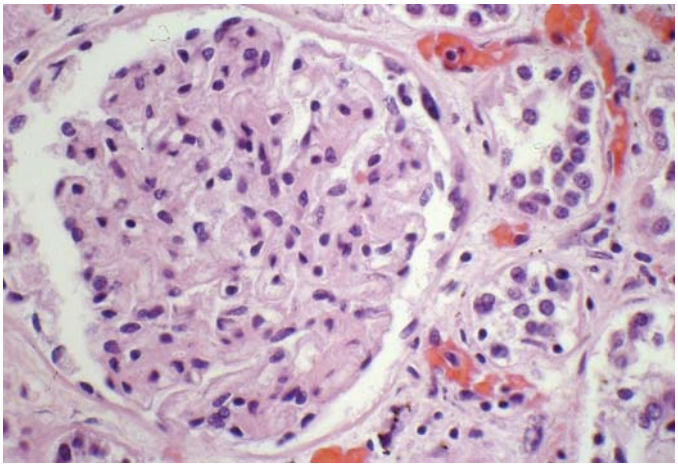

FIGURE 14-29. Glomerular endotheliosis. This is the "bloodless glomerulus" from a woman dying from preeclampsia.

HELLP SYNDROME

HELLP syndrome is a potentially fatal condition of pregnant women and their infants that most often follows the diagnosis of preeclampsia in the third trimester. Its name is an acronym for its major findings—hemolytic anemia, elevated liver enzymes and low platelet count. It occurs in 0.2%–0.6% of all pregnancies, and in 4%–12% of women with preeclampsia or eclampsia. Some 70% of cases occur antepartum and 30% develop in the postpartum period.

PATHOPHYSIOLOGY: The trigger for developing HELLP syndrome is unknown, but generalized activation of the coagulation cascade is thought to be the major problem. The syndrome is the final manifestation of an event that provokes microvascular endothelial damage and intravascular platelet activation. The latter causes vasospasm, platelet agglutination and aggregation and further endothelial damage. Excessive

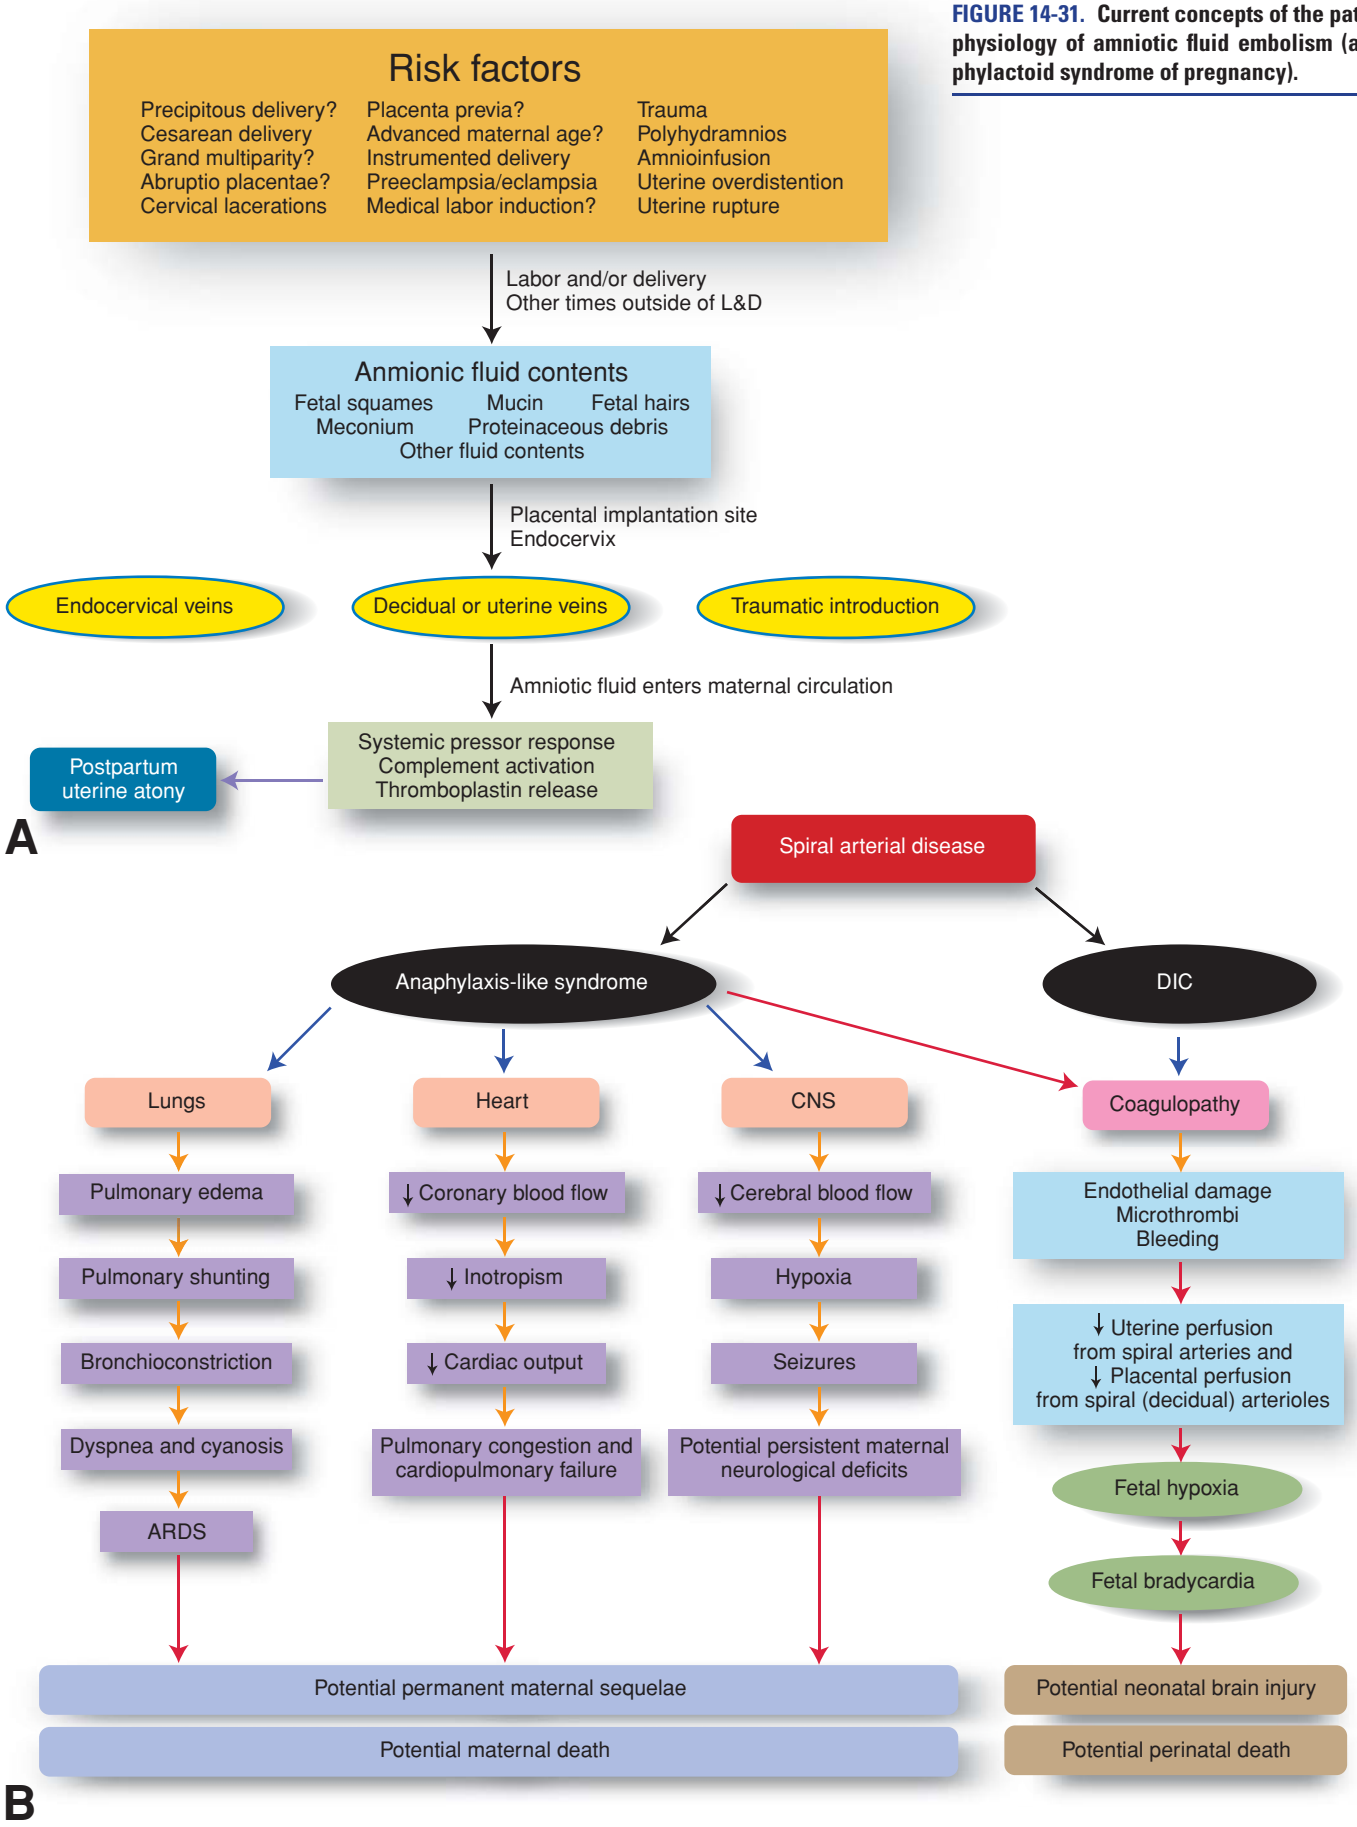

FIGURE 14-31. Current concepts of the pathophysiology of amniotic fluid embolism (anaphylactoid syndrome of pregnancy).

platelet consumption results in DIC and microangiopathic anemia in 20% of women with HELLP syndrome. Obstruction of hepatic blood flow by fibrin deposits in the sinusoids gives rise to liver ischemia, resulting in periportal necrosis, increased levels of liver enzymes and, in severe cases, intrahepatic hemorrhage, subcapsular hematoma formation or hepatic rupture. Additional complications include hemorrhage from DIC, pulmonary edema, placental abruption, ARDS, acute hepatorenal failure and fetal death. The maternal mortality rate is 1%. Infant morbidity and mortality rates vary from 10%–60%, depending on the severity of maternal disease.

AMNIOTIC FLUID EMBOLISM

Amniotic fluid embolism (AFE), also called anaphylactoid syndrome of pregnancy, is a rare, life-threatening obstetric emergency that results in an anaphylaxis-like syndrome. It occurs when amniotic fluid, fetal squamous cells, hair, vernix and other amniotic materials enter the maternal circulation through the uterine veins in the decidual bed at the base of the placenta. Maternal mortality has declined to 25%, but it accounts for 5%–10% of maternal deaths in the United States. About 20% of infants die after their mothers develop AFE.

ETIOLOGIC FACTORS: The entry of amniotic fluid elements into the maternal bloodstream is thought to trigger the acute onset of symptoms of AFE. However, amniotic fluid cellular elements are not always identified in women with AFE, and they may be present in women who do not develop the disorder. Amniotic fluid materials that enter the maternal bloodstream at the time of labor and delivery trigger an anaphylactic reaction, complement activation or both. The pathophysiology of amniotic fluid embolism is summarized in Fig. 14-31.

PATHOLOGY: In fatal cases of AFE, the lungs show diffuse alveolar damage (see Chapter 18). Platelet–fibrin aggregates are present in pulmonary vessels, and increased megakaryocytes are often seen in alveoli, indicative of the onset of DIC. Distinctive fetal squamous epithelial cells are often present in both alveolar capillaries and larger blood vessels (Fig. 14-32A). Rarely, other fetal elements are present, including fetal hair (Fig. 14-32B).

CLINICAL FEATURES: Initially, pulmonary arterial vasospasm, pulmonary hypertension and elevation of right ventricular pressure cause hypoxia. Myocardial and pulmonary capillary damage ensue. Left heart failure and ARDS develop, further endangering the patient. Women surviving the first phase of AFE may develop a second phase, including uterine atony, hemorrhage and DIC. A fatal consumptive coagulopathy may be the initial presentation.

INTRAHEPATIC CHOLESTASIS OF PREGNANCY

Intrahepatic cholestasis of pregnancy (ICP) is the second leading cause of jaundice during pregnancy and may endanger the health of the fetus. ICP occurs in only 1 or 2 women per 1000 pregnancies. It typically presents as intense pruritus. ICP usually begins in the third trimester but can occur any time during pregnancy. It can result in fetal distress, spontaneous premature delivery, meconium aspiration syndrome, intrauterine fetal demise and neonatal death.

ETIOLOGIC FACTORS: The etiology of ICP is not known, but pregnancy hormones and genetic factors are probably involved. ICP most commonly occurs in the third trimester, when maternal pregnancy hormone levels are at their highest, and it occurs more often in multifetal pregnancies, which are associated with higher levels of hormones. Estrogens and glucuronides can cause cholestasis, and high-dose estrogen oral contraceptives can result in features of ICP in nonpregnant women.

CLINICAL FEATURES: The most common maternal complaint is intense itching without a rash, most often involving the palms and soles. Levels of liver enzymes and serum bile acids can be elevated.

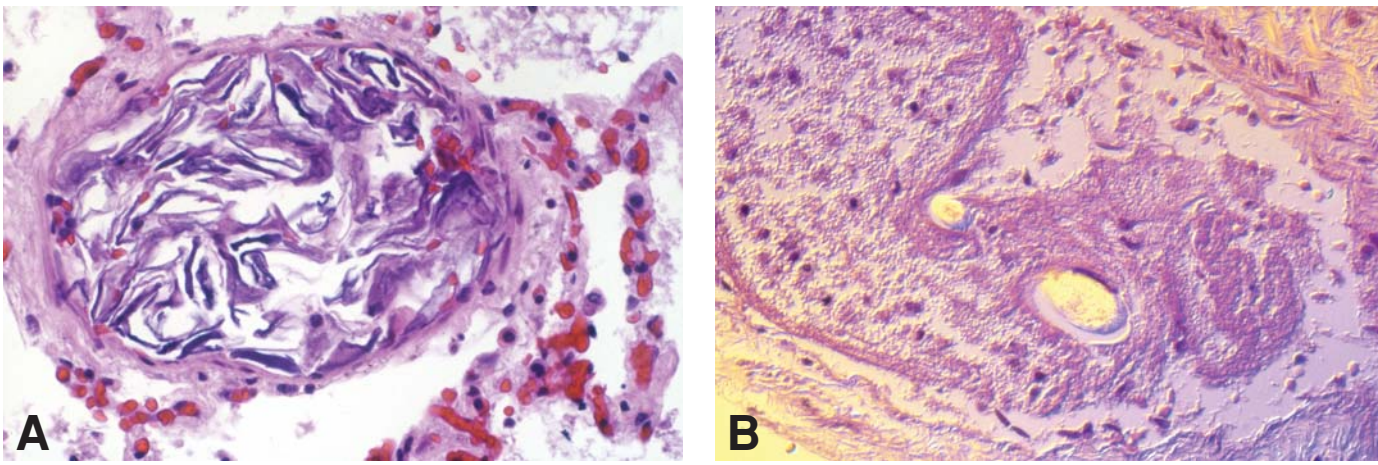

FIGURE 14-32. Amniotic fluid embolism. A. Lung from a woman who died from amniotic fluid embolism. Numerous tightly packed fetal squamous epithelial cells obstruct the lumen of this pulmonary blood vessel. **B.** Amniotic fluid embolism from another woman dying of this condition. Nomarski interference contrast highlights two golden brown cross-sections of a fetal hair in the maternal pulmonary circulation.

Less common symptoms include jaundice, dark urine, right upper quadrant pain and lighter stools. Risks of recurrence may be 90% in subsequent pregnancies.

GESTATIONAL DIABETES

In gestational diabetes, a pregnant woman without previous diabetes develops abnormally high blood glucose levels. The condition develops in 3%–10% of pregnancies. Gestational diabetes usually reverses after delivery, but entails an increased risk (30%–80%, depending on ethnicity) for recurring in future pregnancies. There is also a 50% risk of diabetes within 6 years postpartum, which is highest in women who need insulin treatment during pregnancy, had antibodies (e.g., anti-islet cell antibodies) associated with diabetes, had more than two previous pregnancies and who are obese.

PATHOPHYSIOLOGY: The hallmark of gestational diabetes is resistance to maternal insulin (Fig. 14-33). Pregnancy hormones and other factors interfere with insulin binding to its receptor, leading to hyperglycemia.

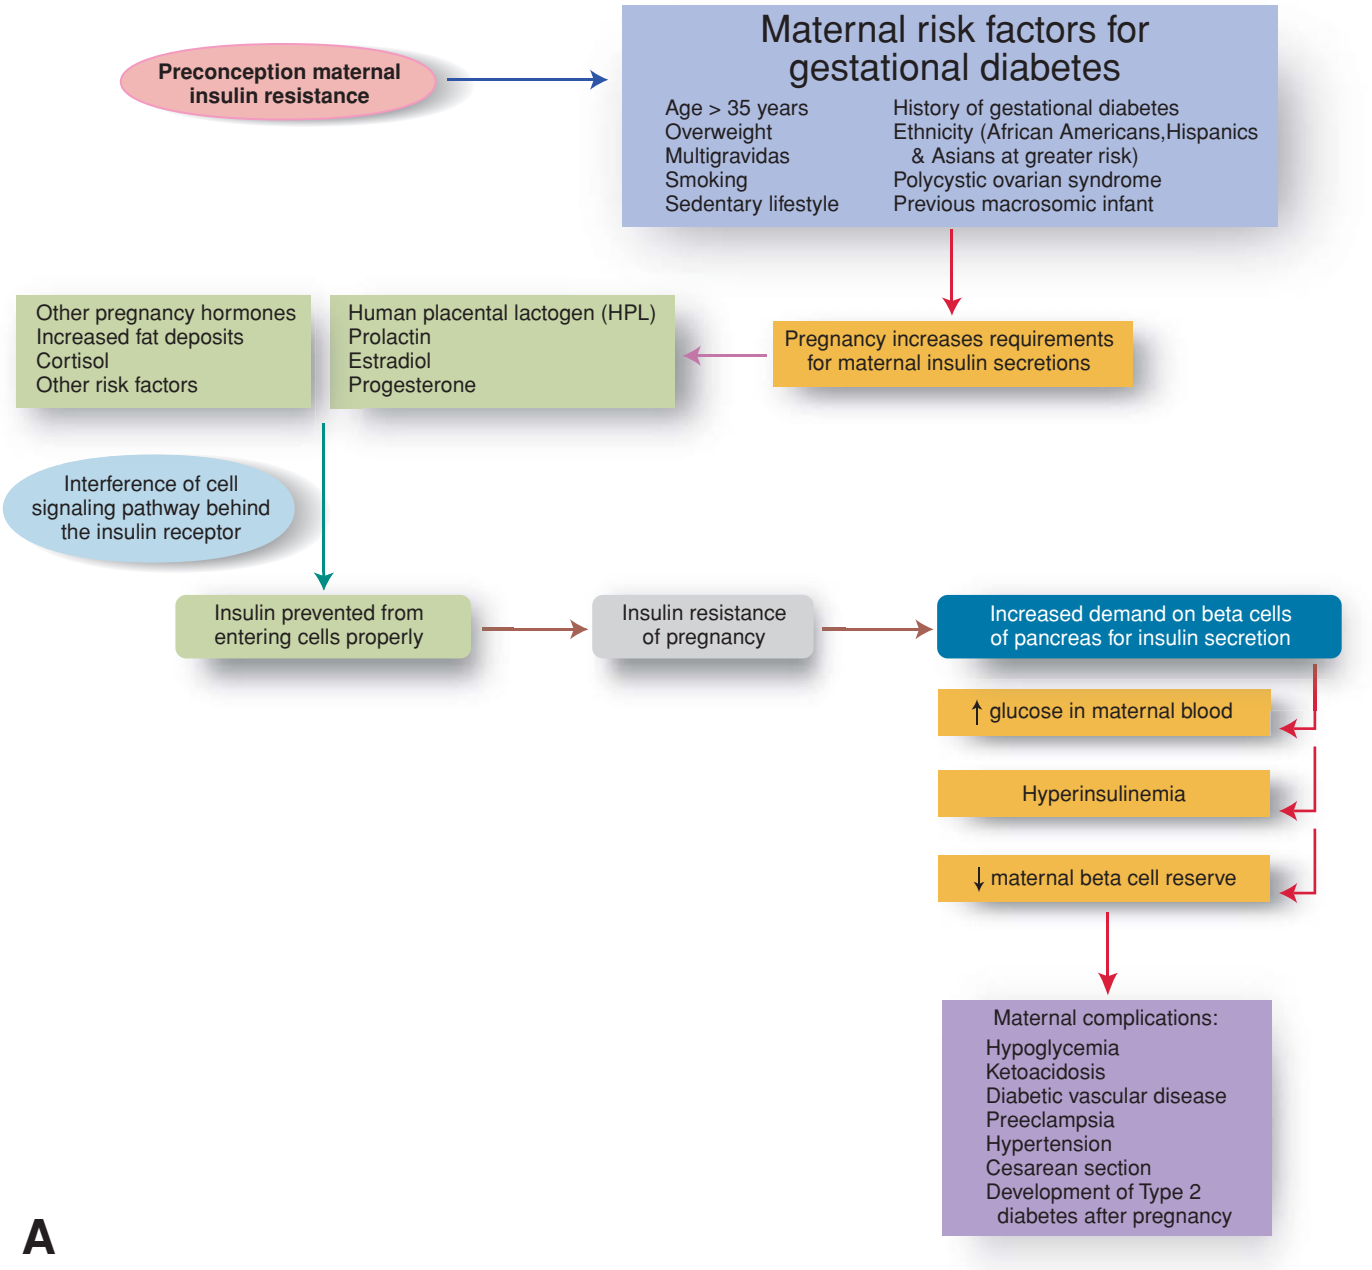

FIGURE 14-33. Current concepts of the pathophysiology of gestational diabetes.

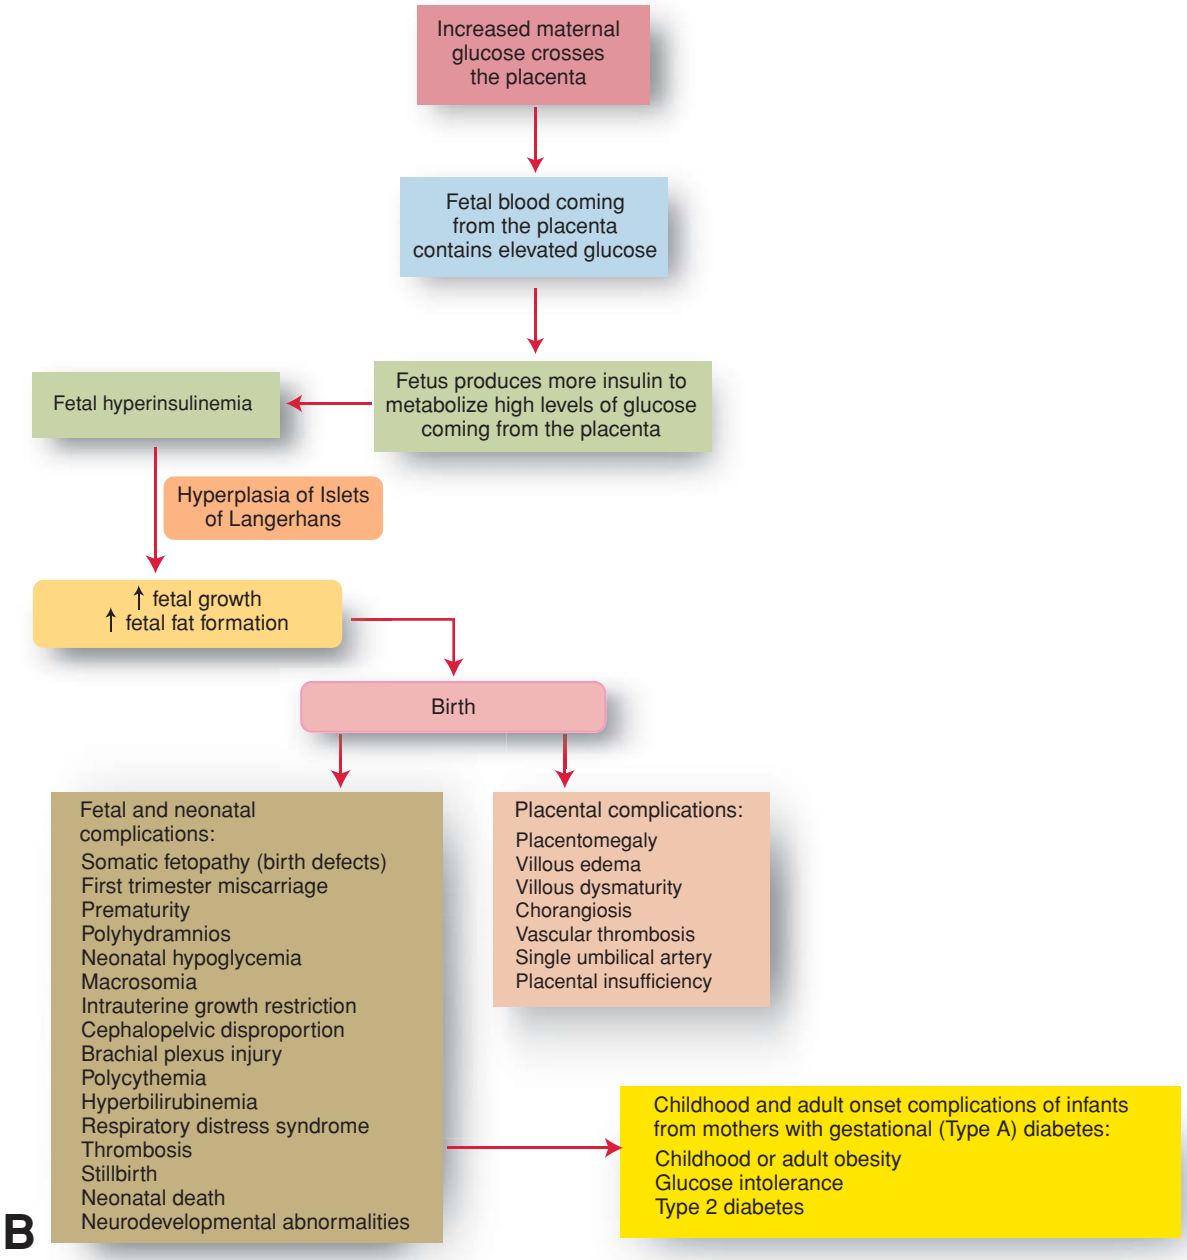

FIGURE 14-33. (*Continued*)

CLINICAL FEATURES: As mentioned above, infants of women with gestational diabetes may be abnormally large (macrosomia), unusually small or growth restricted. Congenital fetal malformations are increased with gestational diabetes, as are fetal and placental thrombosis. Neonates are at risk for a variety of metabolic abnormalities, including hypoglycemia, jaundice, polycythemia, hypocalcemia and hypomagnesemia.

ACUTE FATTY LIVER OF PREGNANCY

Acute fatty liver of pregnancy (AFLP) is a rare, life-threatening complication of pregnancy caused by disordered metabolism of fatty acids by maternal mitochondria. It is commonly (50%–100%) associated with preeclampsia and can recur in subsequent pregnancies. AFLP occurs almost exclusively in the third trimester and is characterized by the onset of abdominal pain, jaundice and anorexia, with elevated levels of liver enzymes and bilirubin. DIC may occur in severe cases. Additional complications include pancreatitis and encephalopathy. AFLP is associated with 18% maternal mortality and 23% fetal mortality.

MOLECULAR PATHOGENESIS: Acute fatty liver of pregnancy is caused by a mitochondrial dysfunction, generally thought to be a deficiency in long-chain 3-hydroxyacyl-coenzyme A dehydrogenase (LCHAD). When fatty acid oxidation is deficient in the fetus, unmetabolized fatty acids reenter the maternal bloodstream

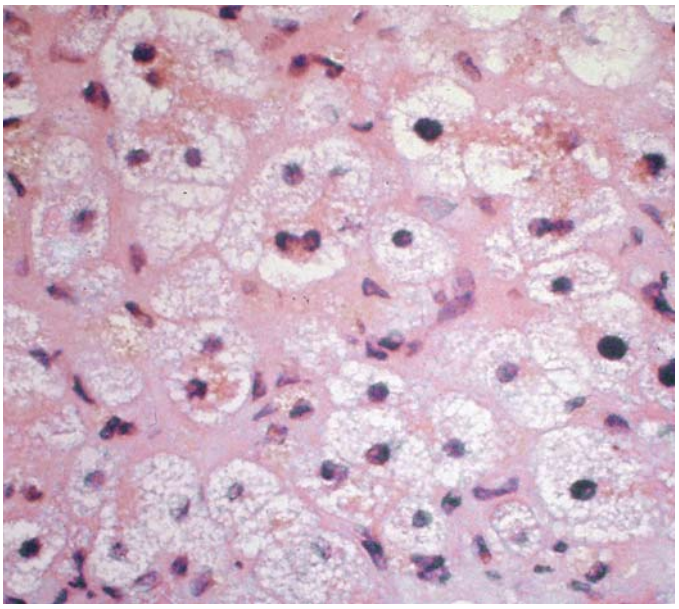

FIGURE 14-34. Acute fatty liver of pregnancy (AFLP). The hepatocytes contain microvesicular fat droplets.

through the placenta, overwhelming maternal β-oxidation enzymes. Microvesicular steatosis in the mothers' liver occurs as a result.

PATHOLOGY: Livers in AFLP show characteristic microvesicular fat droplets in the cytoplasm of enlarged hepatocytes (see Chapter 20) (Fig. 14-34). Hepatocellular necrosis is usually absent, but severe cases may show hepatocyte dropout, collapse of reticulin fibers and portal tract inflammation.

MATERNAL CARDIAC DISEASE

In developed nations, maternal cardiac disease has become one of the most frequent causes, and in some studies the primary cause, of maternal morbidity and death. The probability of death in women with preexisting cardiac disease who become pregnant is 1%. Preexisting maternal cardiac disease also increases the risk of death of the infant 10-fold. Pregnancy is contraindicated in women with severe cardiac conditions, owing to a 25%–50% probability of maternal death.

Peripartum Cardiomyopathy Is Rarely Diagnosed before Delivery

This type of cardiomyopathy accounts for only 1% of cardiac events during pregnancy, but it is the cause of an increasing number of pregnancy-related maternal deaths. Only 10% of cases are diagnosed prior to delivery, with 75% detected in the postpartum period. Although the exact cause of peripartum cardiomyopathy is unknown, it is associated with increased maternal age, obesity, hypertension, multiparity, tocolysis with β-agonists, preeclampsia, low socioeconomic status and black race. Mortality is 25%–50%.

The large majority (65%) of pregnant women who die from preexisting heart conditions have congenital cardiac disease. The second leading cause of death is vascular heart disease (25%); 6% have cardiomyopathy.

GESTATIONAL TROPHOBLASTIC DISEASE

The spectrum of gestational trophoblastic disease reflects abnormal trophoblast proliferation and maturation and includes neoplasms derived from trophoblast (Fig. 14-35).

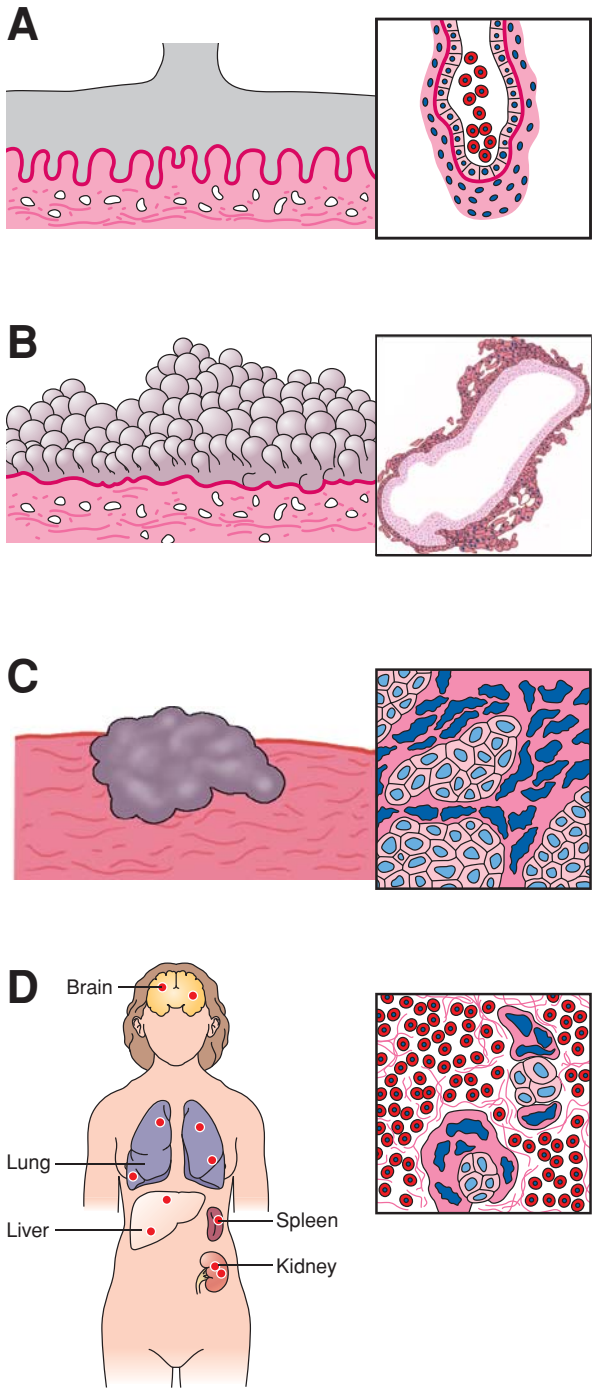

FIGURE 14-35. Proliferative disorders of the trophoblast. A. Normal chorionic villus of 8-week fetus, with blood vessel containing nucleated red blood cells. **B.** Complete hydatidiform mole with hydropic villi (also see Fig. 14-38). The villi are enlarged by an edematous stroma devoid of blood vessels. The trophoblastic epithelium is hyperplastic and exhibits variable atypia. **C.** Choriocarcinoma that has arisen in a molar pregnancy invades the myometrium and consists of admixed syncytiotrophoblastic and cytotrophoblastic elements. **D.** Common sites of metastasis from choriocarcinoma.

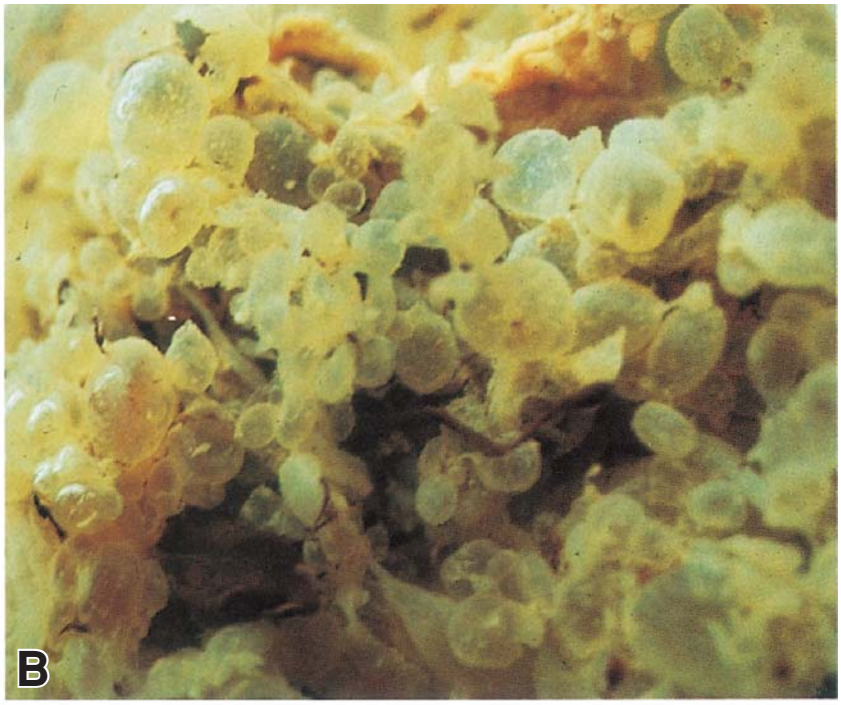
Complete Hydatidiform Mole Does Not Contain an Embryo

Complete hydatidiform mole is a placenta with grossly swollen chorionic villi, resembling bunches of grapes and showing varying degrees of trophoblastic proliferation. Villi are enlarged, often exceeding 5 mm in diameter (Fig. 14-36).

MOLECULAR PATHOGENESIS AND ETIOLOGIC FACTORS: Complete mole results from fertilization of an empty ovum that lacks functional maternal DNA. Most commonly, a haploid (23,X) set of paternal chromosomes introduced by monospermy duplicates to 46,XX, but dispermic 46,XX and 46,XY moles also occur. ***Moles characteristically lack maternal chromosomes.*** Paternally imprinted genes, such as *p57*, in which only the maternal allele is expressed, are not expressed in villous trophoblasts of androgenetic-derived complete moles. Since the embryo dies very early, before placental circulation has developed, few chorionic villi develop blood vessels, and fetal parts are absent.

EPIDEMIOLOGY: The risk of hydatidiform mole relates to maternal age and has two peaks. Girls under 15 years of age have a 20-fold higher risk than women 20–35 years old. Risk increases progressively for women over 40 years. In fact, women older than 50 years of age have a 200-fold greater risk than those between 20 and 40 years. The incidence is manyfold higher in Asian women than in white women. In Taiwan, the risk is 25 times that in



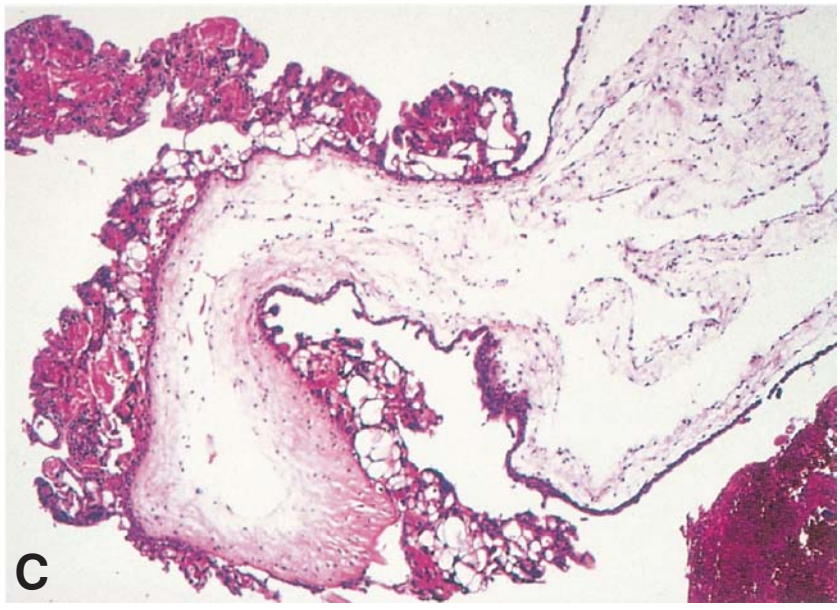


FIGURE 14-36. Complete hydatidiform mole. A. Complete mole in which the entire uterine cavity is filled with swollen villi. **B.** The villi are each 1–3 mm in diameter and appear grape-like. **C.** Individual molar villi, many of which have cavitated central cisterns, exhibit considerable trophoblastic hyperplasia and atypia. The blood vessels of the villi have atrophied and disappeared.

the United States. Women with a prior hydatidiform mole have a 20-fold greater risk of a subsequent molar pregnancy than does the general population.

PATHOLOGY: Molar tissue is voluminous and consists of grossly visible villi that are obviously swollen (Fig. 14-36). Many individual villi have cisternae, which are central, acellular, fluid-filled spaces devoid of mesenchymal cells. Trophoblast is hyperplastic and composed of syncytiotrophoblast, cytotrophoblast and intermediate trophoblast. Considerable cellular atypia is present.

CLINICAL FEATURES: Patients with complete moles commonly present between the 11th and 25th weeks of pregnancy with excessive uterine enlargement and often uterine bleeding. Passage of tissue fragments, which appear as small, grape-like masses, is common. Serum hCG levels are markedly elevated and increase rapidly.

Complications of complete mole include uterine hemorrhage, DIC, uterine perforation, trophoblastic embolism and infection. The most important complication is development of choriocarcinoma, which occurs in 2% of patients whose moles were evacuated.

Treatment consists of suction curettage of the uterus and subsequent monitoring of serum hCG levels. Up to 20% of patients require adjuvant chemotherapy for persistent disease, judging by stable or rising hCG levels. With such management, survival approaches 100%.

Partial Hydatidiform Mole Features Triploid Cells

Partial hydatidiform mole is a distinct entity that almost never evolves into choriocarcinoma (Table 14-2). Partial hydatidiform moles have 69 chromosomes (triploidy), of which one haploid set is maternal and two are paternal. This abnormal chromosomal complement results from fertilization of a normal ovum (23,X) by two spermatozoa, each with 23 chromosomes, or a single spermatozoon that failed meiotic reduction and has 46 chromosomes. Fetuses associated with a partial mole usually die after 10 weeks of gestation. Moles are aborted shortly thereafter. Thus, fetal parts may be present.

PATHOLOGY: Partial moles have two populations of chorionic villi. Some are normal, whereas others are enlarged by hydropic swelling and show central cavitation, resulting from tangential histologic sections of invaginated surface epithelium ("fjord-like") (Fig. 14-37). Trophoblastic proliferation is focal and less pronounced than in complete mole. Blood vessels are typically found within chorionic villi and contain fetal (nucleated) erythrocytes.

Invasive Hydatidiform Mole Penetrates the Underlying Myometrium

PATHOLOGY: The villi of a hydatidiform mole may be limited to the superficial myometrium, or they may invade the uterus and even the broad ligament. They tend to enter the venous channels of the myometrium, and one third spread to distant sites, mostly the lungs. Unlike choriocarcinoma (see below), distant deposits of an invasive mole remain within the blood vessels in which they lodge, and death from such spread is unusual.

TABLE 14-2
COMPARATIVE FEATURES OF COMPLETE AND PARTIAL HYDATIDIFORM MOLE

Features	Complete Mole	Partial Mole
Karyotype	46,XX	47,XXY or 47,XXX
Parental origin of haploid genome sets	Both paternal	1 maternal, 2 paternal
Preoperative diagnosis	Mole	Missed abortion
Marked vaginal bleeding	3+	1+
Uterus	Large	Small
Serum hCG	High	Less elevated
Hydropic villi	All	Some
Trophoblastic proliferation	Diffuse	Focal
Atypia	Diffuse	Minimal
hCG in tissue	3+	1+
Embryo present	No	Some
Blood vessels	No	Common
Nucleated erythrocytes	No	Sometimes
Persists after initial therapy	20%	7%
Choriocarcinoma	2% after mole	No choriocarcinoma

hCG = human chorionic gonadotropin.

Clinical distinction between invasive mole and choriocarcinoma is often difficult.

Histologically, invasive moles show less hydropic change than do complete moles. Trophoblastic proliferation is usually prominent. Uterine perforation is a major complication,

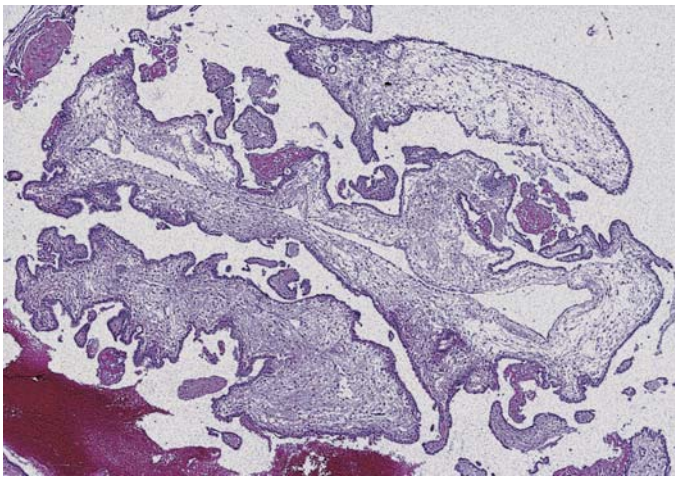

FIGURE 14-37. Partial hydatidiform mole. Two populations of chorionic villi are evident. Some are normal; others are conspicuously swollen. Trophoblastic proliferation is focal and less conspicuous than in a complete mole.

but occurs in only a minority of cases. Theca lutein cysts (see Chapter 24), which may occur with any form of trophoblastic disease as a result of hCG stimulation, are prominent with invasive moles.

Gestational Choriocarcinoma Is Derived from Trophoblast

EPIDEMIOLOGY: Choriocarcinoma occurs in 1 in 30,000 pregnancies in the United States; in eastern Asia, the frequency is far greater. The incidence seems related to abnormalities of pregnancy. In whites, 25% arise from term deliveries, 25% from spontaneous abortions and 50% from complete hydatidiform moles. Although the risk that a complete hydatidiform mole will transform into choriocarcinoma is only 2%, it is still several orders of magnitude higher than if the pregnancy were normal.

PATHOLOGY: Uterine lesions of choriocarcinoma range from microscopic foci to huge necrotic and hemorrhagic tumors. Viable tumor is usually confined to the rim of the neoplasm because, unlike most other cancers, choriocarcinomas lack intrinsic tumor vasculature. These tumors contain a dimorphic population of cytotrophoblast and syncytiotrophoblast, with varying degrees of intermediate trophoblast (Fig. 14-38). The tumor resembles the trophoblast of an early implanting blastocyst. Rims of syncytiotrophoblast surround central cytotrophoblastic cores, in addition to being arranged around maternal blood spaces, which resemble the intervillous space of normal placentation. hCG is localized to the syncytiotrophoblastic element. ***By definition, tumors containing any villous structures, even if metastatic, are considered hydatidiform mole and not choriocarcinoma.***

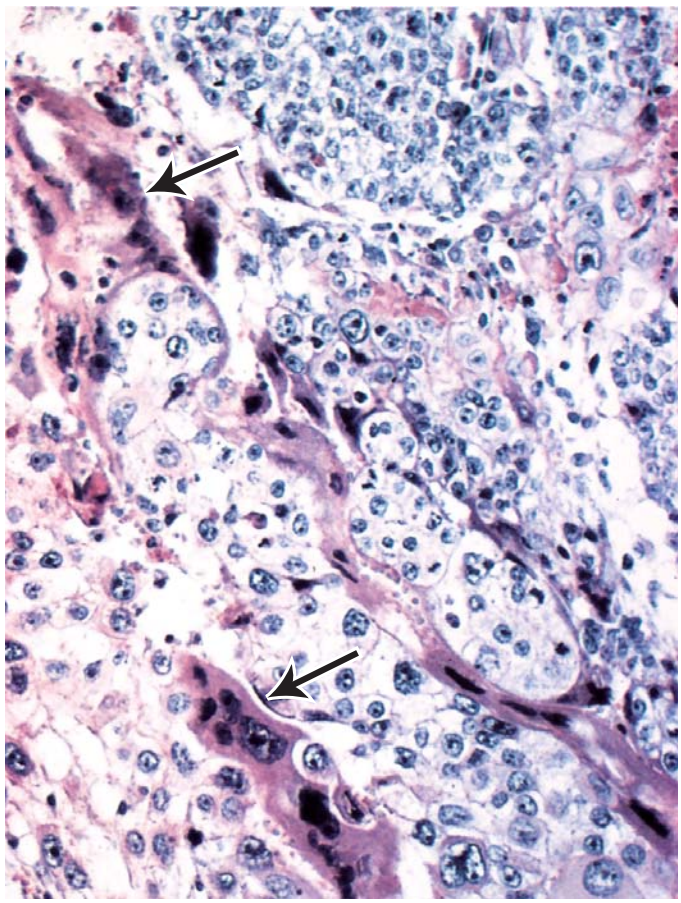

FIGURE 14-38. Choriocarcinoma. Malignant cytotrophoblast and syncytiotrophoblast (*arrows*) are present.

TABLE 14-3
CLINICAL STAGING OF GESTATIONAL TROPHOBLASTIC TUMORS

I	Confined to the uterus
Ia	0 risk factors
Ib	1 risk factor
Ic	2 risk factors
II	Extends outside of the uterus but limited to genital structures
III	Extends to lungs
IV	All other metastatic sites

Risk factors affecting stage include (1) human chorionic gonadotropin (hCG) >100,000 mIU/mL and (2) duration of disease >6 months from termination of antecedent pregnancy.

Choriocarcinomas invade mainly via venous sinuses in the myometrium. They metastasize widely hematogenously, especially to lungs (>90%), brain, gastrointestinal tract, liver and vagina (Table 14-3).

CLINICAL FEATURES: Abnormal uterine bleeding is the most common first symptom of choriocarcinoma. Occasionally, the tumor first presents with metastases to lungs or brain. In some cases, it may only become evident 10 or more years after the last pregnancy.

With current chemotherapy, survival rates exceed 70% even for tumors that have metastasized. Virtually 100% remission is expected if a tumor is localized. Serial serum hCG levels are used to monitor the effectiveness of treatment.

Placental Site Trophoblastic Tumor Outcomes Are Unpredictable

Placental site trophoblastic tumors are the least common trophoblastic tumors. They are mainly composed of intermediate trophoblastic cells.

PATHOLOGY: The gross appearance of placental site trophoblastic tumor is more variable than that of choriocarcinoma. Often, the myometrium shows an ill-defined, yellowish tumor without conspicuous hemorrhage. The extent of myometrial invasion varies, and patterns of infiltration resemble that of normal trophoblast in the placental bed. Since intermediate trophoblast in a normal pregnancy anchors the pregnancy to the superficial myometrium, the microscopic appearance of these tumors is typically that of an exaggerated placental site. Mononuclear and multinuclear trophoblast may be present as single cells or as cords, islands and sheets of cells interspersed among myometrial cells. Neither necrosis nor chorionic villi

are present. Placental site trophoblastic tumor is also distinguished from choriocarcinoma by its monomorphic (intermediate) trophoblastic proliferation, unlike the dimorphic pattern of trophoblast in choriocarcinoma. Most trophoblastic cells express human placental lactogen (hPL), but a few express hCG.

CLINICAL FEATURES: The age and parity of patients with placental site trophoblastic tumor are like those of patients with choriocarcinoma. Half of patients report amenorrhea, whereas vaginal bleeding usually occurs with choriocarcinoma. Past history of a molar pregnancy is much less common than in women with choriocarcinoma (5% vs. 50%).

Placental site trophoblastic tumors must be excised completely (hysterectomy) to prevent local recurrence. They sometimes metastasize and may be fatal. Large tumors and high mitotic indices are associated with a worse prognosis. Because of the short half-life of hPL, serum levels of hCG are more useful in monitoring response to treatment. Conservative management usually suffices. If hCG persists, even at low levels, or mitotic count is elevated, aggressive treatment with hysterectomy or chemotherapy is indicated.

The Amyloidoses

Philip Hawkins

Constituents of Amyloid

Staining Properties of Amyloid Deposits

Clinical Classification of the Amyloidoses and Fibril Proteins
Acquired Amyloidosis
Hereditary Amyloidosis

Morphologic Features of Amyloidosis

Clinical Features and Organ Involvement in Amyloidosis

Treatment of Amyloidosis

CONSTITUENTS OF AMYLOID

Amyloid refers to a group of diverse extracellular protein deposits that have (1) common morphologic properties, (2) affinities for specific dyes and (3) a characteristic appearance under polarized light. All proteins that form amyloid are folded so they share common ultrastructural and physical properties, despite different amino acid sequences. **Amyloidosis** encompasses the clinical disorders caused directly by localized or systemic amyloid deposition.

Diseases associated with amyloid deposition have been recognized for more than 300 years, but only in the mid-19th century were attempts made to define these tissue deposits by their staining properties. Amyloid stained blue with acidified iodine, a method that demonstrates cellulose or starch. Hence, the term **amyloid** (Greek for "starch-like") was coined, and has been retained, although the protein nature of these deposits has been recognized for over 100 years. Protein misfolding and aggregation are increasingly being recognized in various other diseases, but amyloidosis—the disease directly caused by extracellular amyloid deposition—is a precise term with critical implications for patients with a specific group of life-threatening disorders.

More than 25 different unrelated proteins can form amyloid in vivo, and clinical amyloidosis is classified by the identity of the fibril protein. Amyloid deposition is remarkably diverse: it can be systemic or localized, acquired or hereditary, life-threatening or merely incidental. Clinical consequences occur when amyloid accumulates sufficiently to disrupt the structure of tissues or organs and to impair function. Patterns of organ involvement vary among the amyloidoses, but clinical phenotypes overlap greatly. In **systemic amyloidosis,** virtually any tissue may be involved. This form of the disease is often fatal, although prognosis has improved due to better treatments for many of the underlying conditions. **Localized amyloid deposits** are confined to a particular organ or tissue and range from being clinically silent to life-threatening (e.g., cardiac amyloidosis).

In addition to clinical disorders classified as amyloidoses, local amyloid deposits are seen in other important disorders including Alzheimer disease (see Chapter 32), prion disorders and pancreatic islets in type 2 diabetes mellitus (see Chapter 13).

MOLECULAR PATHOGENESIS: Amyloidosis defies the dogma that tertiary structure of proteins is determined solely by primary amino acid sequence. Amyloid-forming proteins can exist in two completely different stable structures: (1) **a native form** and (2) transformation by massive refolding of the native form into predominantly **β-sheets** that can autoaggregate in a highly ordered manner to produce characteristic fibrils. Such amyloid fibrils are rigid, nonbranching, 10–15 nm in diameter and indeterminate in length. Acquired biophysical properties that are common to all amyloid fibrils include insolubility in physiologic solutions, relative resistance to proteolysis and the ability to bind **Congo red dye** in a spatially ordered manner to produce the diagnostic green birefringence under cross-polarized light (Fig. 15-1).

There are several circumstances in which amyloid deposition occurs (Fig. 15-2):

- ***Sustained, abnormally high abundance of certain proteins that are normally present at low levels,*** such as serum amyloid A protein (SAA) in chronic inflammation and β_2-microglobulin in renal failure, which underlie susceptibility to AA and Aβ_2M amyloidosis, respectively (see below)
- ***Normal concentrations of a normal, but to some extent inherently amyloidogenic, protein over a very prolonged period,*** such as transthyretin in senile amyloidosis (ATTR) and β-protein in Alzheimer disease
- ***Presence of an acquired or inherited variant protein with an abnormal, markedly amyloidogenic structure,*** such as certain monoclonal immunoglobulin light chains in AL amyloidosis and the genetic amyloidogenic variants of transthyretin, lysozyme, apolipoprotein AI and fibrinogen Aα chain in hereditary amyloidosis

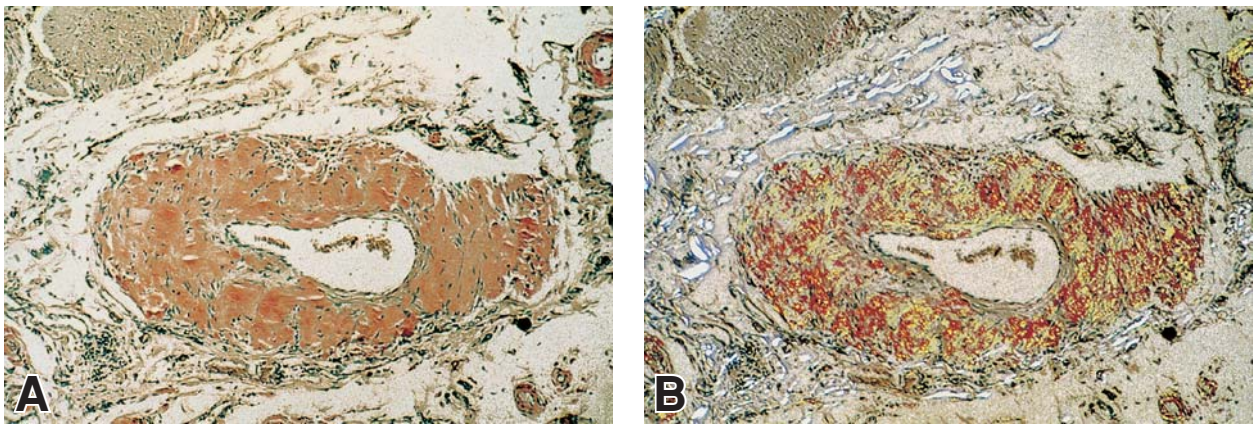

FIGURE 15-1. AL amyloid involving the wall of an artery stained with Congo red is shown under **(A)** ordinary light and **(B)** polarized light. Note the red-green birefringence of the amyloid. Collagen has a silvery appearance.

Although it is not clear why only the 20 or so known amyloidogenic proteins adopt the amyloid fold and persist as fibrils in vivo, a unifying theme is that amyloid precursors are relatively unstable. Even under normal physiologic conditions, these proteins can exist in partly unfolded states involving loss of tertiary structure but retention of β-sheet secondary structure, and which can autoaggregate into protofilaments and thence mature amyloid fibrils.

Amyloid deposits consist mainly of these protein fibrils but also contain some common minor constituents, including certain **glycosaminoglycans** (GAGs), the normal plasma protein **serum amyloid P component** (SAP) and various other trace proteins such as **apolipoprotein E** (apoE), **laminin** and **collagen IV** (Fig. 15-3).

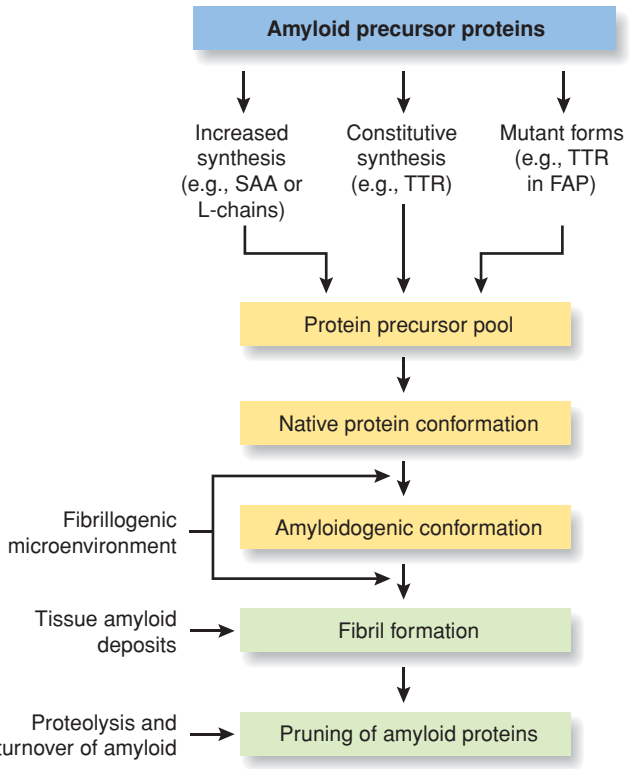

FIGURE 15-2. General scheme for amyloidogenesis. *FAP* = familial amyloidotic polyneuropathy; *SAA* = serum amyloid A protein; *TTR* = transthyretin.

- SAP binds in a specific calcium-dependent manner to a domain that is present on all amyloid fibrils but not on their respective precursor proteins. This phenomenon is the basis for the use of SAP scintigraphy for diagnostic imaging and quantitative monitoring of amyloid deposits. Animal studies indicate that SAP contributes to amyloidogenesis. SAP is also a minor, structural component of normal basement membranes.
- Amyloid fibril-associated GAGs are mainly heparan and dermatan sulphates. Their universal presence, restricted heterogeneity and intimate relationship with the fibrils are consistent with their contribution to the development or stability of amyloid deposits. This hypothesis has been supported by the inhibitory effect of low–molecular-weight GAG analogs on the experimental induction of AA amyloidosis in mice and people.

The genetic and/or environmental factors that determine the individual susceptibility and timing of amyloid deposition are unclear, although several factors may be at play:

- Once the process has begun, further accumulation of amyloid is unremitting so long as there is a continuous supply of the respective precursor protein. Initiation of amyloid accumulation may involve a "seeding" process, consistent with observations that amyloid deposition can be remarkably rapid following its initiation. Seeding may be a stochastic event. The notion of seeding is supported by observations in experimental murine AA amyloidosis, in which nanogram quantities of parenterally administered amyloid material result in massive amyloid deposition within 24 hours of developing an acute phase SAA response. The existence of an "amyloid-enhancing factor" (AEF) has been proposed.
- Both increasing age and male sex appear to be potent susceptibility factors in wild-type TTR amyloid deposition. Clinical sequelae of this kind of amyloid are almost unheard before age 60 years, and more than 90% of patients are male.
- The factors that influence the anatomic distribution of amyloid deposits are also unclear, but there is reasonable consistency among the organ involvement associated with AA and most hereditary types of amyloidosis in

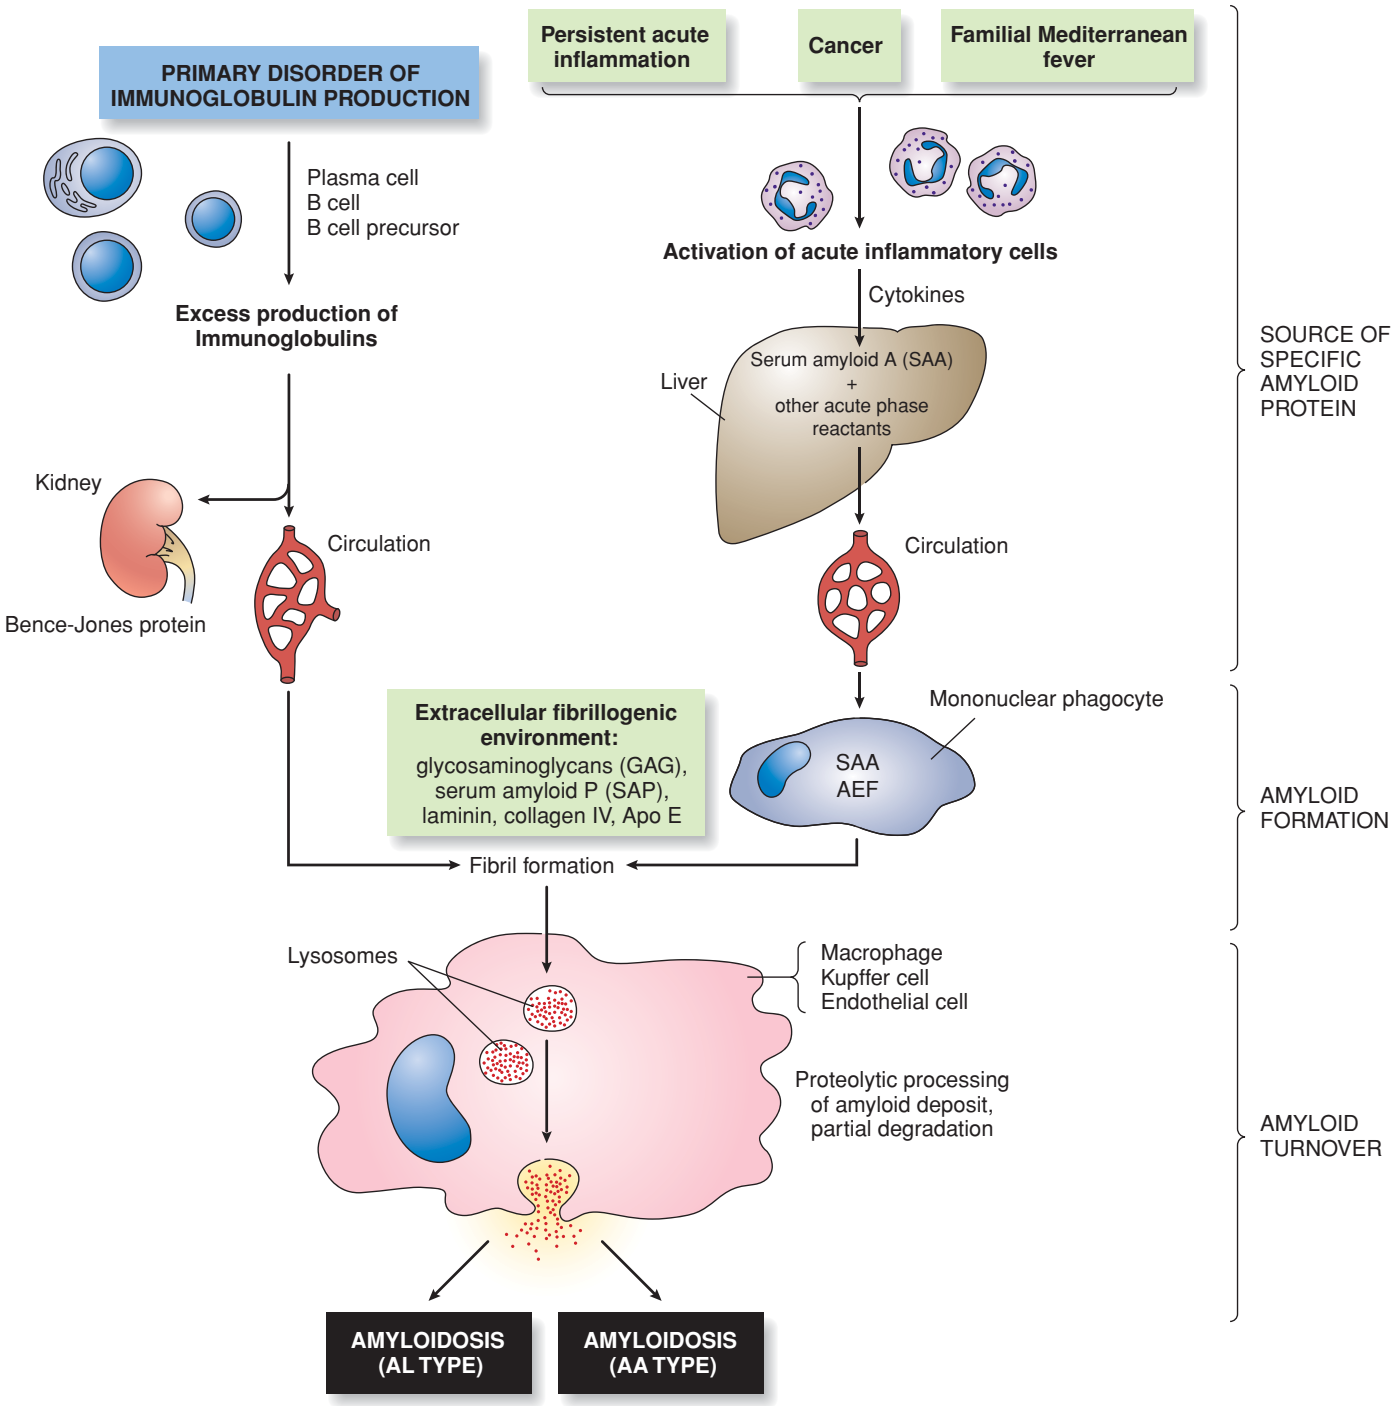

FIGURE 15-3. The mechanisms of amyloid deposition. For **AL amyloid:** Certain lymphocyte- and plasma cell–derived immunoglobulin light chains are amyloidogenic within a fibrillogenic environment. For **AA amyloid** deposition: A variety of diseases are associated with the activation of polymorphonuclear leukocytes and macrophages, which in turn leads to the synthesis and release of acute phase reactants by the liver, including serum amyloid A protein (SAA). SAA may undergo cleavage by macrophages, and its conversion into AA fibrils is promoted by amyloid-enhancing factor (AEF). In a fibrillogenic environment, the released products complex with glycosaminoglycans and serum amyloid P component (SAP). Macrophages are also involved in turnover of amyloid.

which the fibril protein has the same structure in all individuals. By contrast, the organ distribution in AL amyloidosis is extremely heterogeneous, probably reflecting the unique sequence of the respective monoclonal immunoglobulin light chain in each patient.

The pathologic effects of amyloid are due to its physical presence. Extensive deposits may total kilograms, are structurally disruptive and impair normal function, as do strategically located smaller deposits (e.g., in glomeruli or nerves). It is possible that amyloid fibrils or prefibrillar

aggregates may sometimes be directly cytotoxic, but amyloid deposits evoke little or no local tissue inflammatory reaction. The relationship between the quantity of amyloid deposited and the degree of associated organ dysfunction differs greatly between individuals and between different organs, and there is a strong impression that the rate of new amyloid deposition may be as important a determinant of progressive organ failure as the absolute amyloid load.

Treatments that reduce the supply of amyloidogenic precursor proteins may result in stabilization or regression of existing amyloid deposits, preserving or improving the function of organs infiltrated by amyloid, although the mechanisms by which amyloid deposits can be cleared are poorly understood.

STAINING PROPERTIES OF AMYLOID DEPOSITS

The staining properties and general appearance of amyloid are governed primarily by its compact and proteinaceous nature. Because of this, amyloid has few morphologic features visible on light microscopy. With routine stains (hematoxylin and eosin), amyloid is amorphous, glassy and almost cartilage-like, appearing much like many other proteins. However, the nature and organization of amyloid deposits allow it to be stained in specific ways.

CONGO RED: All types of amyloid stain red with the Congo red dye but exhibit red-green birefringence when viewed under cross-polarized light (Fig. 15-1). The fibrillar deposits organized in one plane exhibit one color, and those opposite to that plane appear the other color. Congo red is the stain most commonly used for the diagnosis of amyloidosis, although published techniques vary in their sensitivity and specificity.

THIOFLAVIN T: Although not entirely specific for amyloid, staining with thioflavin T allows amyloid to fluoresce when viewed in ultraviolet light.

ALCIAN BLUE: The presence of glycosaminoglycans in all amyloid deposits is evident with a variety of Alcian blue stains, which cause GAGs to appear blue.

SPECIFIC ANTIBODIES: Immunohistochemistry is the best way to characterize amyloid, although its success varies with fibril protein type and depends on availability of a suitable tissue sample that contains neither too little nor too much amyloid. Antibodies to SAA virtually always stain AA deposits, as is the case with antibodies to β_2-microglobulin in hemodialysis-associated amyloid. In AL amyloid, deposits in fixed specimens are stained convincingly with antibodies to κ or λ immunoglobulin light chains in only about two thirds of cases, in part because AL fibrils are chiefly variable light-chain domains with unique sequences in each case. Immunohistochemical staining of TTR and other hereditary amyloid fibril proteins may require pretreatment of sections with formic acid, alkaline guanidine or deglycosylation, and even then, does not always yield definitive results. Demonstration of SAP, the most abundant nonfibrillar protein present in all types of amyloid, helps to corroborate that deposits are indeed amyloid and can be particularly useful in excluding light-chain deposition disease.

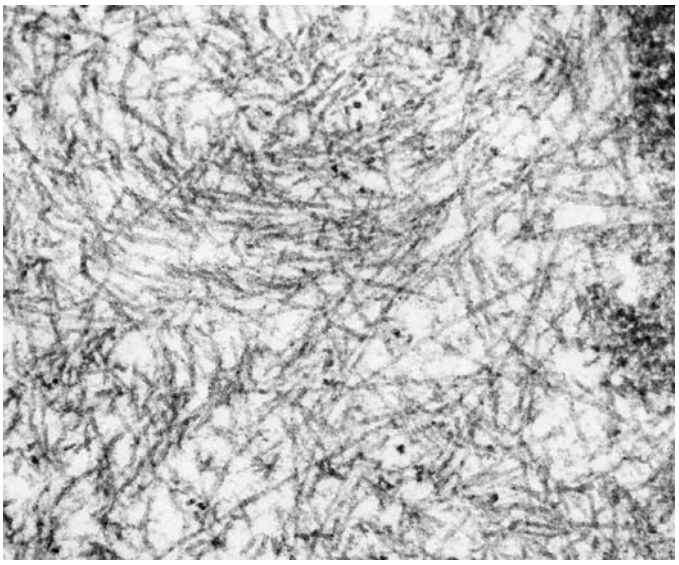

FIGURE 15-4. Amyloid deposits in tissue. Parallel and interlacing arrays of fibrils are evident in this electron micrograph.

ELECTRON MICROSCOPY: By electron microscopy, amyloid is straight, rigid nonbranching fibrils of indeterminate length, 10–15 nm in diameter (Fig. 15-4). Electron microscopy should be used to supplement other diagnostic tools, since other fibrillar deposition diseases occur. Immunogold staining of amyloidotic biopsies can sometimes be diagnostic of fibril protein type if light microscopic immunochemistry has not produced definitive results.

CLINICAL CLASSIFICATION OF THE AMYLOIDOSES AND FIBRIL PROTEINS

Older categorization of amyloidosis based on clinical presentation, such as primary (for AL) and secondary (for AA), has been abandoned in favor of classification according to the identity of the amyloid proteins (Table 15-1). ***The disease can be divided into systemic or localized distributions and acquired or hereditary etiologies, but amyloid deposits of any particular type do not necessarily have any clinical consequences and can be merely an incidental finding.***

Acquired Amyloidosis Derives from Diverse Sources

Acquired systemic amyloidosis is thought to be the cause of death in about 1 in 1000 individuals in Western countries, and is probably underdiagnosed among the elderly, who are likely to be at greatest risk of developing it. Systemic AL amyloidosis is the most common and serious type, accounting for over 60% of cases. Although less serious, dialysis-related β_2-microglobulin amyloidosis affects about 1 million patients on long-term renal replacement therapy worldwide. Senile transthyretin amyloidosis, which predominantly involves the heart, occurs in about one quarter of individuals older than 80 years, a sector of the population that is ever rising.

TABLE 15-1
CLASSIFICATION OF HUMAN AMYLOIDS

Amyloid Protein	Protein Precursor	Clinical Setting
AL	k Or λ immunoglobulin light chain	Multiple myeloma, plasma cell dyscrasias and primary amyloid
AH	γ Immunoglobulin chain	Waldenström macroglobulinemia
A2M	β_2-Microglobulin	Hemodialysis related
ATTR	Transthyretin	Familial amyloidotic polyneuropathy (FAP), normal TTR in senile systemic amyloid
AA	Apo serum AA	Persistent acute inflammation; familial Mediterranean fever; certain malignancies
AApoAI	Apolipoprotein AI	FAP Iowa
AApoAII	Apolipoprotein AII	Familial
AApoAIV	Apolipoprotein AIV	Sporadic, age associated
Aβ	β-Protein precursor	Alzheimer disease, Down syndrome, hereditary cerebral hemorrhage with amyloid (HCHWA), Dutch
ABri	ABriPP	Familial dementia, British
ADan	ADanPP	Familial dementia, Danish
APrP	Prion protein	CJD, scrapie, BSE, GSS, Kuru
ACys	Cystatin C	HCHWA, Icelandic
ALys	Lysozyme	Hereditary systemic amyloidosis, Ostertag type
AFib	Fibrinogen	Hereditary renal amyloidosis
AGel	Gelsolin	Familial amyloidosis, Finnish
ACal	(Pro)calcitonin	Medullary carcinoma of the thyroid
AANF	Atrial natriuretic factor	Isolated atrial amyloid
AIAPP	Islet amyloid polypeptide	Type 2 diabetes, insulinomas
AIns	Insulin	Iatrogenic
APro	Prolactin	Pituitary, age associated
AMed	Lactadherin	Senile aortic, media
AKer	Keratoepithelin	Cornea, familial
ALac	Lactoferrin	Cornea

Apo = apolipoprotein; BSE = bovine spongiform encephalopathy; CJD = Creutzfeldt-Jakob disease; GSS = Gerstmann-Straüssler-Scheinker syndrome; TTR = transthyretin.

Reactive Systemic Amyloidosis, AA Amyloidosis

AA amyloidosis is a complication of chronic infections and inflammatory diseases, or any condition that leads to long-term overproduction of the acute phase reactant SAA. The amyloid fibrils are composed of an N-terminal cleavage fragment of SAA (i.e., AA protein). AA amyloidosis occurs in 1%–5% of patients with rheumatoid arthritis, juvenile idiopathic arthritis and Crohn disease, and is more common in those with untreated lifelong autoinflammatory diseases such as familial Mediterranean fever. Most patients present with proteinuria, and although liver and gastrointestinal involvement may occur later, clinically significant cardiac or neuropathic involvement is very rare.

MOLECULAR PATHOGENESIS: ***AA protein is a single nonglycosylated polypeptide chain usually of mass ~8 kd making up the 76-residue N-terminal portion of the 104-residue SAA.*** Smaller and larger AA fragments occur. SAA is an apolipoprotein of high-density lipoprotein particles and is the polymorphic product of a set of genes located on chromosome 11. It is highly conserved in evolution and is a major acute phase reactant. Most SAA in plasma is produced by hepatocytes under transcriptional

regulation by cytokines, especially interleukin 1 (IL-1), IL-6 and tumor necrosis factor-α (TNF-α). After secretion, SAA rapidly associates with high-density lipoproteins, from which it displaces apolipoprotein AI. Circulating SAA can rise from normal levels (≤3 mg/L) to over 2000 mg/L within 24–48 hours of an acute stimulus, and remains elevated indefinitely in the presence of chronic inflammation.

Cleavage of circulating SAA to AA can be done by macrophages and several proteinases, but it is not known whether cleavage of SAA occurs before and/or after aggregation of monomers during AA fibrillogenesis. Long-term overproduction of SAA is a prerequisite for deposition of AA amyloid, but it is not known why the latter occurs in only some individuals. SAA isoforms are complex, but homozygosity for particular types seems to favor amyloidogenesis, as may ethnic differences in susceptibility.

SAA function is not known, but it may modulate effects on reverse cholesterol transport and on lipid functions in the microenvironment of inflammatory foci. Regardless of its physiologic role, SAA as an exquisitely sensitive acute phase protein with enormous dynamic range, making it a very valuable empirical clinical marker. It can be used to monitor the extent and activity of many infective, inflammatory, necrotic and neoplastic diseases. Frequent long-term monitoring of SAA is vital in managing all patients with AA amyloidosis, as the primary inflammatory process must be controlled sufficiently to reduce SAA production if amyloid deposition is to be halted or enabled to regress. Automated immunoassays for SAA are available standardized on a World Health Organization International Reference Standard.

AA amyloidosis occurs in association with chronic inflammatory disorders, chronic local or systemic microbial infections and, occasionally, neoplasms. In the Western world, the most common predisposing conditions are chronic inflammatory diseases, particularly rheumatoid arthritis. Amyloidosis is exceptionally rare in ulcerative colitis or systemic lupus erythematosus and related connective tissue diseases, since these conditions provoke only modest acute phase responses. Tuberculosis and leprosy are important causes of AA amyloidosis in some parts of the world. Chronic osteomyelitis, bronchiectasis, chronically infected burns and decubitus ulcers and the chronic pyelonephritis of paraplegia are other well-recognized associations. Hodgkin disease and renal carcinoma often cause a major acute phase response and are the malignancies most commonly associated with systemic AA amyloid. The associated chronic inflammatory disease in about 7% of patients with AA amyloidosis may not be clinically evident, and these patients may be erroneously assumed to have AL amyloidosis.

AA amyloid deposits are widely distributed, and so random rectal and other biopsies are often used to make the diagnosis. However, clinically, AA amyloidosis is dominated by progressive proteinuria. Treatment entails measures to suppress the underlying inflammatory disorder. Prognosis is now often excellent among patients in whom the causative acute phase response can be substantially suppressed, but about 50% of patients with persistent uncontrolled inflammation die within 10 years of diagnosis.

Amyloidosis Associated with Monoclonal B-Cell Dyscrasias, AL Amyloidosis

Systemic AL, once known as "primary," amyloidosis occurs in about 2% of people with monoclonal B-cell dyscrasias. AL fibrils are derived from monoclonal immunoglobulin light chains. These are unique in each patient, so that AL amyloidosis is highly heterogeneous in terms of organ involvement and overall clinical course. Virtually any organ other than the brain may be directly affected, but the kidneys, heart, liver and peripheral nerves bear the brunt of the clinical consequences. As the underlying monoclonal gammopathy is often missed by routine screening techniques, very sensitive methods, such as serum free light-chain analysis, may be needed to identify the causative subtle B-cell dyscrasias.

MOLECULAR PATHOGENESIS: ***AL amyloid fibrils are usually derived from the N-terminal region of monoclonal immunoglobulin light chains and consist of the whole or part of the variable (V_L) domain.*** The molecular weight of the fibril subunit protein thus varies between 8 and 30 kd. Monoclonal light chains are unique to each individual, and only a small percentage are amyloidogenic, but it is not possible to predict which light chains will form AL amyloid.

The property of "amyloidogenicity" is inherent in certain monoclonal light chains. Thus, when purified human Bence Jones proteins (urinary light-chain proteins) were injected into mice, animals receiving light chains from patients with AL amyloid developed typical amyloid deposits, while mice given light chains from myeloma patients without amyloid did not. AL fibrils develop more commonly from λ than κ light chains, despite the fact that κ-chains are more common among normal immunoglobulins and monoclonal gammopathies. Compared to light chains that do not form amyloid, some amyloidogenic light chains have distinctive amino acid replacements or insertions that can promote aggregation and insolubility, including replacement of hydrophilic framework residues by hydrophobic ones. Certain light-chain types, notably $V\lambda_{VI}$, are especially amyloidogenic, and some tend to be deposited as amyloid in particular organs. For example, $V\lambda_{VI}$ light chains often deposit in the kidney, while $V\lambda_{II}$ chains prefer the heart.

B-cell dyscrasias underlying systemic AL amyloidosis are also heterogeneous and include almost any clonal proliferation of differentiated B cells: multiple myeloma, Waldenström macroglobulinemia and occasionally other malignant lymphomas or leukemias. However, over 80% of cases are associated with low-grade and otherwise "benign" monoclonal gammopathies that may be difficult to detect. Histologically, minor and clinically insignificant amyloid deposits are seen in up to 10% of patients with myeloma, and similarly in a smaller proportion of patients with monoclonal gammopathy of undetermined significance (MGUS). Cytogenetic abnormalities common in multiple myeloma and MGUS, such as 14q translocations and 13q deletion, are also observed in AL amyloidosis, but their prognostic significance is not yet understood.

Localized AL Amyloidosis

A localized monoclonal B-cell dyscrasia may lead to AL deposits at the site of that B-cell lesion, almost anywhere in the body. Characteristic sites include the skin, airways, lungs, conjunctiva and urogenital tract. Deposits may be nodular or confluent, but the clonal B-cell infiltrate that is the culprit, producing the amyloidogenic light chains, may be inconspicuous. Lichenoid and macular forms of cutaneous amyloid are distinct and are thought to be derived from

keratin or related proteins. Nodular cutaneous amyloid deposits are usually localized AL type but can also be part of systemic AL amyloidosis. Localized AL amyloid deposits can exert serious space-occupying effects or cause serious hemorrhage but otherwise are benign and enlarge slowly.

Dialysis-Related Amyloidosis, β_2-Microglobulin Amyloidosis

β_2-Microglobulin amyloid deposition occurs in patients with dialysis-dependent chronic renal failure, mainly affecting articular and periarticular structures, and typically causing arthralgia of the shoulders, knees, wrists and small joints of the hand, joint swelling and carpal tunnel syndrome. The amyloid fibril precursor protein is β_2-microglobulin, which is the invariant chain of the major histocompatibility complex (MHC) class I molecule, and is expressed by all nucleated cells. It is synthesized at an average rate of 150–200 mg/day and is normally filtered freely at the glomerulus, reabsorbed and catabolized by proximal tubular cells. Decreasing renal function causes a proportionate rise in concentration. β_2-Microglobulin amyloidosis was first described in 1980 and occurs in patients who have been on hemodialysis for several years and peritoneal dialysis for 5–10 years. Infrequently, it occurs in patients with long-term severe chronic renal impairment. Dialysis-related amyloidosis (DRA) is present in 20%–30% of patients within 3 years of starting dialysis for end-stage renal failure. Although it is a systemic disease, manifestations outside of the musculoskeletal system are unusual: there have been notable reports of DRA causing congestive cardiac failure and gastrointestinal bleeding, perforation and pseudo-obstruction.

Senile Transthyretin Amyloidosis, ATTR Amyloidosis

In the elderly, clinically silent systemic deposits of wild-type "senile" TTR amyloid are common, involving the heart and blood vessel walls, smooth and striated muscle, fat tissue, renal papillae and alveolar walls. Unlike most other forms of systemic amyloidosis, including hereditary transthyretin amyloid caused by point mutations in the transthyretin gene, the spleen and renal glomeruli are rarely affected. Neither is the brain involved, although symptomatic leptomeningeal deposits can occasionally occur in familial TTR amyloidosis. Senile transthyretin amyloidosis almost always presents with restrictive cardiomyopathy, and other than carpal tunnel syndrome, deposits elsewhere rarely ever attain clinical significance. About one quarter of patients can be demonstrated to have gastrointestinal amyloid deposits on rectal biopsy. Most patients are at least 70 years old, and there is a very strong male preponderance. Cardiac failure progresses and death usually occurs within about 5 years.

Endocrine Amyloidosis

Many hormone-producing tumors of APUD cells have amyloid deposits in their stroma (see Chapter 27). These are probably composed of the hormone peptides, and in the case of medullary carcinoma of the thyroid, fibril subunits are derived from procalcitonin.

In insulinomas, the amyloid fibril protein is called islet amyloid polypeptide (or **amylin**) and shows appreciable homology with calcitonin gene–related peptide. It has subsequently been shown to be the same protein as in the amyloid of the islets of Langerhans in type 2 diabetes. Islet polypeptide amyloid is almost always seen in the pancreatic islets in type 2 diabetes and becomes more extensive with increasing duration and severity of the disease. The amyloid itself probably does not initiate the metabolic defect in type 2 diabetes, but progressive amyloid deposition may facilitate islet destruction.

Amyloid and the Brain

The brain is a common and important site of amyloid deposition, although there are never any deposits in the cerebral parenchyma itself in any form of acquired systemic visceral amyloidosis. However, cerebrovascular and oculoleptomeningeal amyloid deposits that can be clinically significant do occasionally occur in hereditary TTR amyloidosis.

The common and major forms of brain amyloid are associated with Alzheimer disease, the most common type of dementia (see Chapter 33). In brief, intracerebral and cerebrovascular amyloid deposits derived from β-protein (Aβ), a 39- to 43-residue cleavage product of the large amyloid precursor protein, are neuropathologic hallmarks of Alzheimer disease. It is unclear whether or how Aβ per se, small prefibrillar aggregates or the amyloid fibrils that it forms contribute to the neuronal loss that underlies the dementia.

Intracerebral amyloid plaques derived from the normal physiologic cellular prion protein PrP^C are sometimes seen in acquired and hereditary spongiform encephalopathies. The pathogenetic significance of amyloid in these disorders is not clear. However, the amyloid-like proteinase-resistant conformational isoform of PrP^C, called PrP^{Sc}, is the transmissible agent of these spongiform encephalopathies. Neuron damage may be caused by cytotoxic interaction between prefibrillar PrP^{Sc} aggregates and normal PrP^C, or by other mechanisms entirely.

In Hereditary Amyloidosis Genetically Variant Proteins Accumulate as Amyloid

In hereditary systemic amyloidosis, mutations in the genes for transthyretin, cystatin C, gelsolin, lysozyme, fibrinogen A α-chain, apolipoprotein AI and, extremely rarely, apolipoprotein AII lead to deposition of these mutant proteins as amyloid. These diseases are all inherited dominantly with variable penetrance and present clinically from teenage to old age, though usually in midadult life. Hereditary transthyretin amyloidosis is by far the commonest, most often presenting as a syndrome of familial amyloid polyneuropathy with peripheral and autonomic neuropathy and/or cardiomyopathy. Cystatin C amyloidosis presents as cerebral amyloid angiopathy with recurrent cerebral hemorrhage and clinically silent systemic deposits, and has been reported only in Icelandic families. Gelsolin amyloidosis presents with cranial neuropathy but is also extremely rare. Apolipoprotein AI, lysozyme and fibrinogen A α-chain amyloidosis usually present as nonneuropathic systemic amyloidosis that can affect any or all major viscera, with renal involvement usually being prominent. Since a family history is often absent, these latter conditions are readily misdiagnosed as acquired "primary" AL amyloidosis and are much less rare than previously thought. ***Of patients presenting with non-AA systemic amyloidosis, 5%–10% have hereditary forms of the disease.*** It is imperative that hereditary amyloidosis is

identified correctly, since prognosis, treatment and implications for family members differ substantially, compared to acquired amyloidosis.

Familial Amyloidotic Polyneuropathy, Variant Transthyretin (ATTR) Amyloidosis

Familial amyloidotic polyneuropathy (FAP) is associated with heterozygous point mutations in the TTR gene. It is an autosomal dominant syndrome with onset between the third and seventh decades. Over 100 TTR variants are associated with FAP, and amyloid fibrils are a mixture of variant and wild-type TTR protein. There are probably several thousand patients with FAP in the world. The disease is characterized by progressive and disabling peripheral and autonomic neuropathy and varying degrees of visceral amyloid involvement, prominently including cardiac amyloidosis, which can be the sole clinical feature in some cases. Deposits within the vitreous of the eye are well recognized and are pathognomonic, while deposits in the kidneys, thyroid, spleen and adrenals are usually asymptomatic. There is considerable phenotypic variation in age of onset, rate of progression, involvement of different systems and disease penetrance, even within one family. Typically the disease progresses inexorably, causing death within 5–15 years.

Familial Amyloid Polyneuropathy with Predominant Cranial Neuropathy

This is a very rare dominant form of hereditary amyloidosis that presents in mid- to late adult life with cranial neuropathy, lattice corneal dystrophy and mild distal peripheral neuropathy. It was first described in Finland but has since been reported in other ethnic groups. There may be skin, renal and cardiac manifestations, but these are usually covert and life expectancy approaches normal. There is no specific treatment and the disorder is progressively disfiguring and very distressing in its late stages. The responsible mutant gene encodes a variant form of gelsolin, which is an actin-modulating protein. The functional role of circulating gelsolin is unknown but may be related to clearance of actin filaments released by apoptotic cells.

Nonneuropathic Variants of Hereditary Systemic Amyloidosis

Hereditary lysozyme systemic amyloidosis has been ascribed to six lysozyme variants, all of which are very rare. Most patients present in middle age with proteinuria, sicca syndrome or upper gastrointestinal and liver involvement. Acute gastrointestinal hemorrhage or perforation and spontaneous liver rupture are well recognized and potentially fatal complications.

Apolipoprotein AI is a major constituent of high-density lipoprotein. Known amyloidogenic variants include single amino acid substitutions, deletions and a deletion/insertion. Associated clinical syndromes vary but often entail substantial amyloid deposits in the liver, spleen and kidneys; some mutations cause cardiomyopathy, and patients with the arginine 26 variant may develop polyneuropathy. In several C-terminal variants, laryngeal amyloid deposits lead to hoarseness. Other manifestations seen with particular mutations include male infertility and skin lesions. Many patients eventually develop renal failure, but liver function usually remains normal despite extensive hepatic amyloid deposits. Normal wild-type apolipoprotein AI amyloid is itself weakly amyloidogenic and is the precursor of small amyloid deposits that occur quite frequently in aortic atherosclerotic plaques.

Hereditary fibrinogen A α-chain amyloid is the commonest type of hereditary renal amyloidosis, caused by some 10 different mutations, the commonest being substitution of valine for glutamic acid at position 526. Penetrance in most families is low and a family history is often lacking. Most patients present in late middle age with proteinuria or hypertension and progress to end-stage renal failure during the next 5 years or so. Amyloid deposition occurs in the kidneys, spleen and sometimes the liver, but it is usually asymptomatic in the latter two sites.

MORPHOLOGIC FEATURES OF AMYLOIDOSIS

Amyloid fibrils are usually first deposited near subendothelial basement membranes (Fig. 15-5). Because amyloid accumulates along stromal networks, deposits take on the configurations of the organs involved. Morphologic differences in amyloid deposition among organs simply reflect organ-to-organ differences in stromal organization. For example, in the renal medulla, amyloid is laid down longitudinally, parallel to tubules and vasa recta, while in glomeruli amyloid (Fig. 15-6), it follows lobular glomerular architecture. In the spleen, amyloid may be mostly in the stroma of the red pulp or that of the white pulp. Grossly, amyloid in the

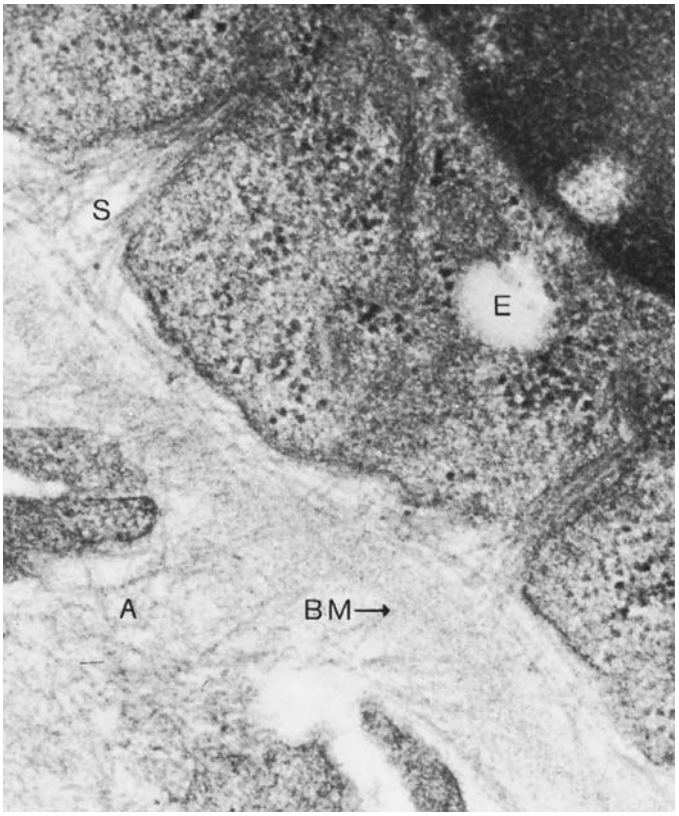

FIGURE 15-5. Electron micrograph of glomerular amyloid (*A*) illustrating its location relative to the basement membrane (*BM*). Amyloid spicules (*S*) extend into the cytoplasm of the glomerular epithelial cells (*E*).

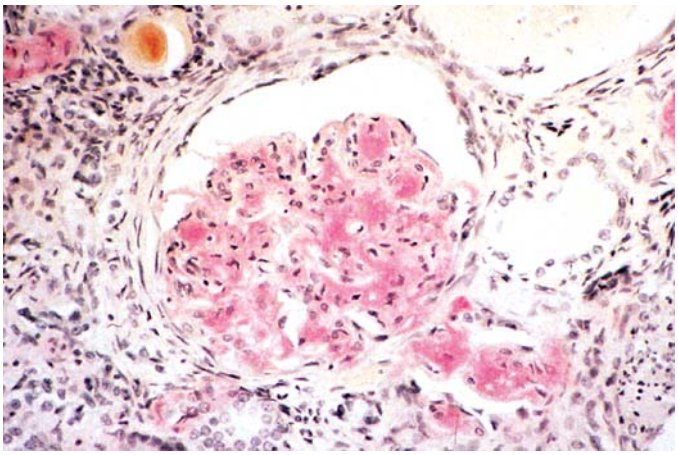

FIGURE 15-6. Microscopic appearance of AA amyloid in a glomerulus. Note the lobular pattern of the amyloid deposit and the involvement of the afferent arteriole.

FIGURE 15-8. Cerebrovascular amyloid in a case of Alzheimer disease. The section was stained with Congo red and examined under polarized light.

red pulp imparts a diffusely pale and waxy appearance, the so-called lardaceous spleen. A spleen containing white pulp amyloid shows multiple pale foci scattered throughout the organ, which is called sago spleen. Deposits in the liver follow the arteries of the portal triads or are laid down along central veins and radiate into the parenchyma along liver cell plates (Fig. 15-7).

Amyloid adds interstitial material at sites of deposition, thus increasing the size of affected organs. This increase may be counterbalanced by the deposition of amyloid in blood vessels (Fig. 15-8), which might impair circulation and lead to organ atrophy. Affected organs may thus increase or decrease in size. Amyloid deposits are essentially avascular, so the involved organs are commonly pale and firm.

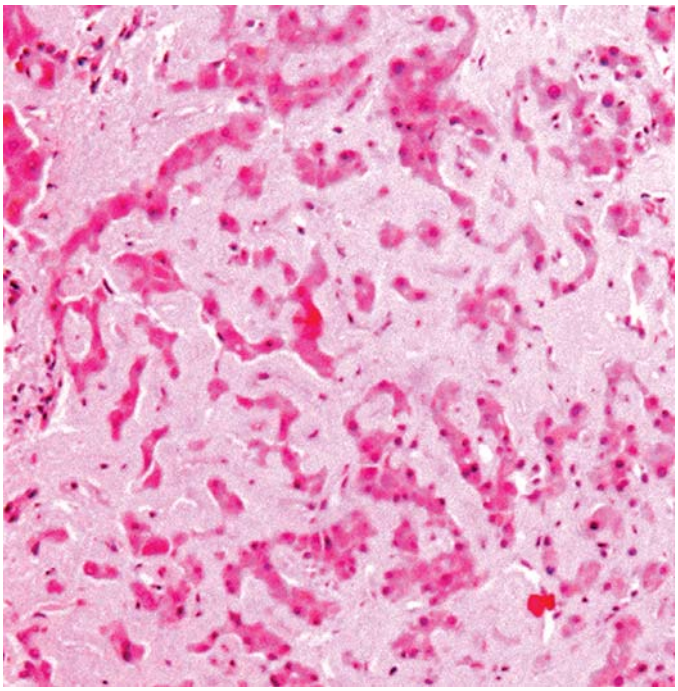

FIGURE 15-7. Hepatic amyloidosis. Amyloid is deposited along the sinusoids. Note the atrophic hepatocytes.

Regardless of whether amyloid is laid down in a systemic or local fashion, deposits tend to occur between parenchymal cells and their blood supply, interfering with normal nutrition and gas exchange. Amyloid may eventually entrap parenchymal cells. Alternatively, it may have an additional toxic effect on these cells through the interaction of protofibrils and cell membranes. In each case, amyloid deposits may lead to cell strangulation, atrophy and death (Fig. 15-9).

CLINICAL FEATURES AND ORGAN INVOLVEMENT IN AMYLOIDOSIS

No single set of symptoms points unequivocally to amyloidosis as a diagnosis. The symptoms of amyloidosis depend on the underlying disease and the type and organ locations of the amyloid deposits. Amyloidosis may also be diagnosed unexpectedly in the course of evaluation for something unrelated, with no clinical manifestations referable to the amyloidosis itself. In other cases, for example,

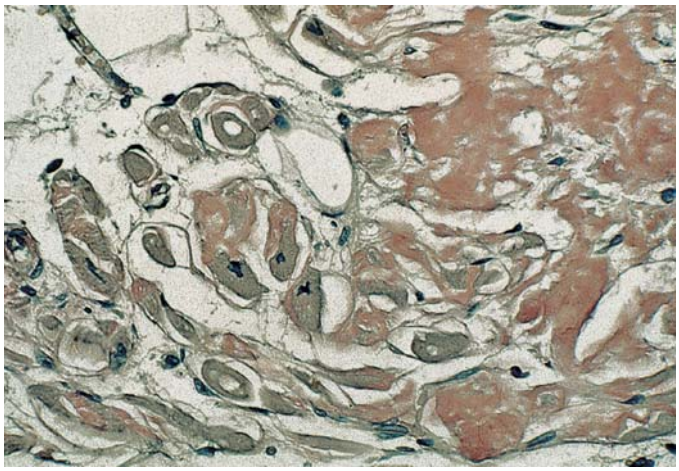

FIGURE 15-9. Myocardial amyloid (AL type), showing the encroachment upon, and strangulation of, individual myocardial fibers.

unexplained renal and cardiac dysfunction may be the presenting conditions.

KIDNEY: Patients with multiple myeloma and other clonal B-cell dyscrasias or long-standing inflammatory disorders who develop **nephrotic syndrome** should be suspected of having amyloidosis. Proteinuria, particularly in patients with plasma cell dyscrasias, may be overlooked if the patient is already excreting a Bence Jones protein. Progressive glomerular obliteration may ultimately lead to renal failure and uremia.

HEART: Amyloid involvement of the myocardium should be suspected in all patients with AL and TTR amyloidosis and in any patient with unexplained concentric thickening of the myocardium, especially if the latter is not associated with abnormally large voltage complexes on electrocardiography. Myocardial amyloid deposits cause **restrictive cardiomyopathy,** in which diastolic dysfunction is often associated with well-preserved systolic function. Short of biopsy, two-dimensional echocardiography and Doppler studies are helpful in suggesting the diagnosis. Cardiac magnetic resonance imaging with late gadolinium enhancement has been reported to be useful as well. Serum cardiac troponin and N-terminal pro-brain natriuretic peptide concentrations appear to be powerful predictors of cardiac involvement, as well as prognosis and survival after chemotherapy in AL amyloidosis. Cardiac amyloidosis is also associated with conduction abnormalities that cause arrhythmias and sudden death.

GASTROINTESTINAL TRACT: The ganglia, smooth muscle, vasculature and submucosa of the gastrointestinal tract may all be affected by amyloid. Deposits in these locations can alter gastrointestinal motility and absorption but are often clinically silent. Patients complain of either constipation or diarrhea, and insidious malnutrition is common. Enlargement of the tongue is virtually pathognomonic of AL amyloidosis, and interference with its motor function may be severe enough to affect speech and swallowing.

LIVER: AL, AA and familial forms of amyloidosis often cause amyloid deposits in the liver but rarely lead to clinically significant hepatic dysfunction. Substantial hepatomegaly may occur before any abnormalities in serum liver function tests are seen. Liver amyloidosis is typically associated with progressive elevation of serum alkaline phosphatase and γ-glutamyl transferase in these patients, but jaundice generally occurs late and is associated with frank liver failure and a very poor prognosis, particularly the AL type.

PERIPHERAL NERVES: The familial polyneuropathic forms of amyloid usually manifest as paresthesias, with loss in temperature and pain sensation of the extremities.

The diagnosis of amyloidosis generally requires histologic confirmation, although the mere demonstration of amyloid deposition does not by itself establish that it is clinically significant. While amyloidosis does not occur in the absence of amyloid deposits, the latter may be an incidental histologic finding, especially in older subjects. Immunohistochemical staining is the most accessible method for characterizing amyloid fibril protein type, but it does not always produce definitive results, especially in AL type. Amyloid deposits can be quite patchy and histology can never provide information about the overall whole body load or distribution of amyloid deposits, nor does it permit monitoring of the natural history of amyloidosis or its response to treatment. Radiolabeled human SAP is a specific, noninvasive, quantitative in vivo tracer for amyloid deposits and has been used in scintigraphy and metabolic turnover studies. This approach facilitates the diagnosis, monitoring and response of amyloidosis to treatment and has contributed the following important observations regarding amyloid:

- The different distribution of amyloid in different forms of the disease
- Major systemic deposits in forms of amyloid previously thought to be organ limited
- A poor correlation between the quantity of amyloid present in a given organ and the degree of organ dysfunction
- Evidence for surprisingly rapid progression and regression of amyloid deposits with different rates in different organs

The long-held belief that amyloid deposition is irreversible and inexorably progressive is evidently incorrect and simply reflects the usually persistent nature of the conditions that underlie it. Many case reports have described improvement in amyloidotic organ function when the underlying conditions have been controlled, suggesting that amyloid deposits may regress.

TREATMENT OF AMYLOIDOSIS

Systemic amyloidosis is a progressive disease that, without effective treatment, is ultimately fatal in most cases. Although no treatments yet exist that specifically promote the mobilization of amyloid, there have been substantial recent advances in the management of systemic amyloidosis, in particular active measures to support failing organ function while attempts are made to reduce the supply of the amyloid fibril precursor protein. Serial SAP scintigraphy has shown that control of the primary disease process, or removal of the source of the amyloidogenic precursor, often allows gradual regression of existing deposits and recovery or preservation of organ function. Thus, aggressive intervention, and relatively toxic drug regimens or other radical approaches, can be justified by the poor prognosis. However, clinical improvement is often delayed long after the underlying disorder has remitted, reflecting the very gradual regression of the deposits that is now recognized to occur in most patients. Continuing production of amyloid precursor protein should be monitored closely over time, to determine the requirement for, and intensity of, treatment for the underlying primary condition. In AA amyloidosis, this means frequent estimation of plasma SAA levels; in AL amyloidosis, it requires monitoring of serum free light chains or other markers of the underlying monoclonal plasma cell proliferation.

The treatment of AA amyloidosis ranges from potent anti-inflammatory, cytokine-inhibiting and immunosuppressive drugs in patients with rheumatoid arthritis to lifelong prophylactic colchicine in familial Mediterranean fever and surgery in conditions such as refractory osteomyelitis and the tumors of Castleman disease. Treatment of AL amyloidosis is based on that for myeloma, including oral administration of melphalan and dexamethasone, thalidomide-based regimens and the new agents such as the proteasome inhibitor bortezomib and the immunomodulatory agent lenalidomide. High-dose chemotherapy with autologous peripheral blood stem cell transplantation has high response rates but much toxicity and is restricted to selected patients. The disabling arthralgia of β_2-microglobulin amyloidosis usually responds dramatically to renal transplantation. The basis for this remarkable clinical response is unclear since although

transplantation rapidly restores normal β_2-microglobulin metabolism, regression of β_2-microglobulin amyloid may not be evident for many years.

Liver transplantation is effective in familial amyloid polyneuropathy associated with transthyretin gene mutations since the variant amyloidogenic protein is produced mainly in the liver. Outcomes are best among younger patients with the methionine 30 variant, though even in this group the peripheral neuropathy usually only stabilizes. Unfortunately, paradoxical progression of established cardiac amyloidosis with wild-type transthyretin has been noted in many older patients. On a similar basis, hepatic transplantation has proven promising in some patients with hereditary fibrinogen A α-chain and apolipoprotein AI amyloidosis.

Supportive therapy remains critical in systemic amyloidosis, notably including attention to nutrition, rigorous control of hypertension in renal amyloidosis and diuretic and fluid balance management in cardiac amyloidosis. Dysrhythmias may respond to conventional pharmacologic therapy or to pacing. Replacement of vital organ function, notably dialysis, may be necessary, and cardiac and renal transplantation has been very successful in selected cases.

ANATOMY OF BLOOD VESSELS

Arteries Include Conducting and Resistance Vessels

The vascular portion of the circulatory system is composed of a variety of blood vessel compartments that are categorized by size, structure and function. These include arteries, which are conducting and resistance vessels; capillaries; and veins (Fig. 16-1).

Elastic Arteries

The largest blood vessels in the body, the aorta and the elastic arteries, are conduits for blood flow to smaller arterial branches and are composed of three layers:

- **Tunica intima:** This consists of a single layer of endothelial cells, a subendothelial compartment containing a few smooth muscle cells and an extracellular matrix extending to the luminal side of the internal elastic lamina. The aortic intima is thicker than the other elastic arteries and contains matrix proteins including collagen, proteoglycans and small amounts of elastin. Occasional resident lymphocytes, macrophages, dendritic cells and other blood-derived inflammatory cells are also present.
- **Tunica media:** The next layer outward is the tunica media, the thickest tunica. It is bounded by internal and external elastic laminae and itself displays numerous elastic laminae and smooth muscle cells within an extracellular connective tissue matrix. In the aorta, the media is organized into lamellar units, each consisting of two concentric elastic laminae, with smooth muscle cells and their associated matrix in between the laminae. The media of the thoracic aorta contains more elastin and the abdominal aorta contains more collagen. In elastic arteries, elastic fibers are interposed between smooth muscle cells and serve to minimize energy loss during the pressure changes between systole and diastole.

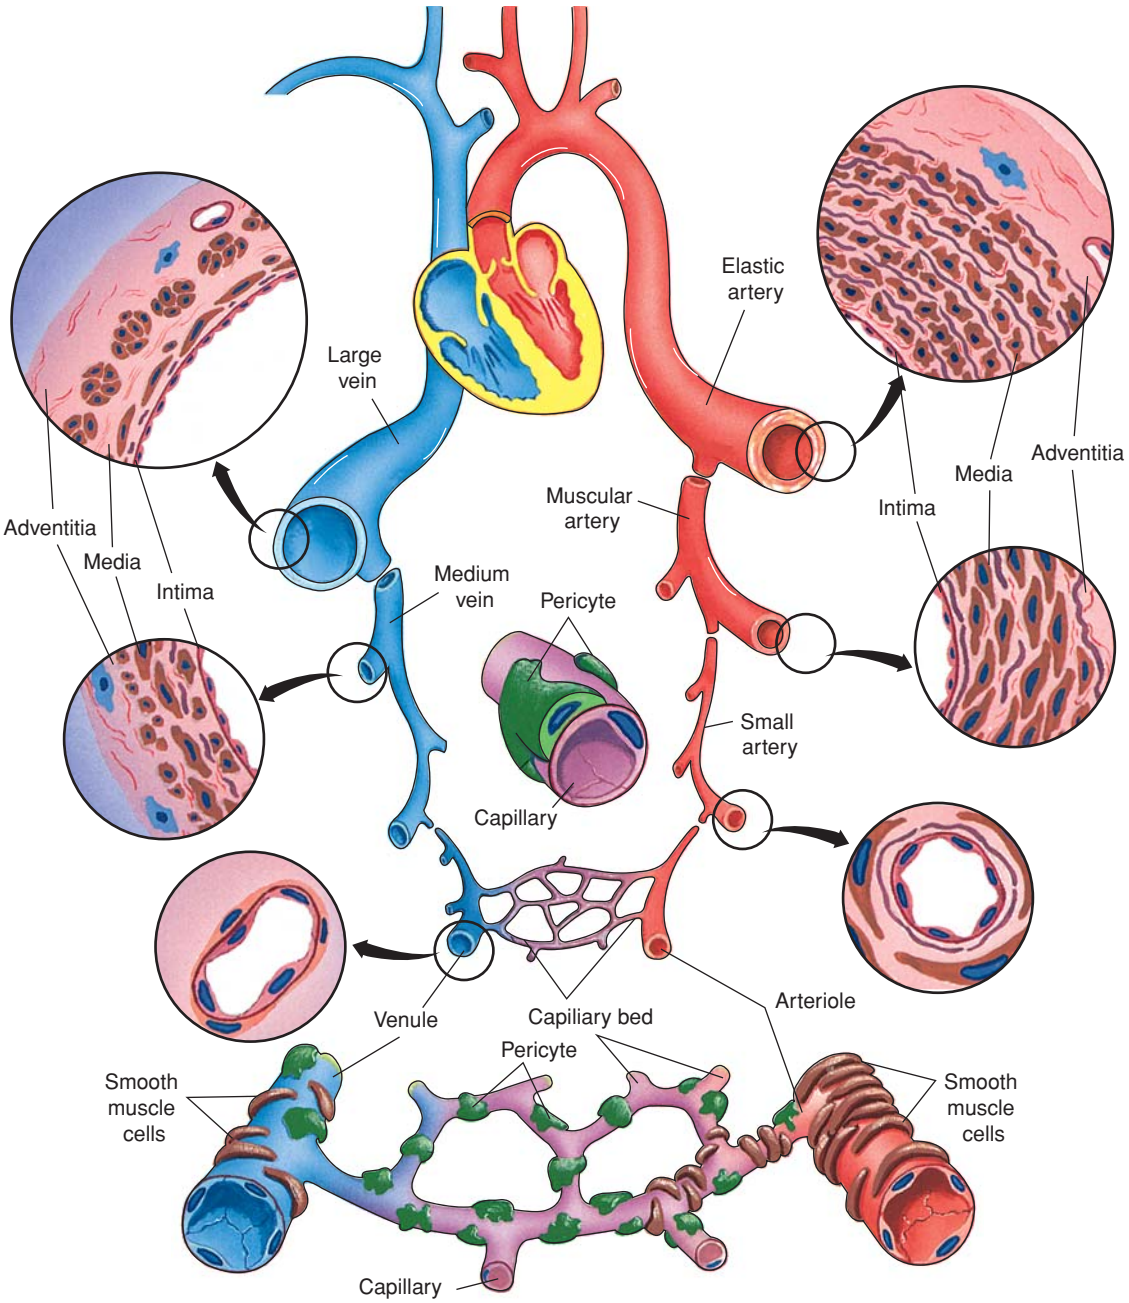

FIGURE 16-1. Subdivisions and histologic structure of the vascular system. Each subdivision is subject to a set of pathologic changes conditioned by the structure–function relationship of that part of the system. For example, the aorta, an elastic artery subject to great pressure, frequently shows a pathologic dilation (aneurysm) if the supporting elastic media is damaged. Muscular arteries are the most significant sites of atherosclerosis. Small arteries, particularly arterioles, are sites of hypertensive changes. Capillary beds, venules and veins each display their own types of pathologic changes.

In smaller elastic arteries, nutrition for the media is provided by diffusion from the blood vessel lumen through the endothelium and the layers of smooth muscle. However, blood vessels with more than 28 layers of smooth muscle cells have a vasculature of their own, the **vasa vasorum**. These small vessels arise from the visceral and parietal branches of the aorta, and both form a superficial plexus at the adventitia–media border, when they penetrate into the outer 2/3 of the media. The tunica media also contains autonomic nerve fibers that influence vascular contractility.

- **Tunica adventitia:** The most external vessel wall layer contains fibroblasts, connective tissue, nerves and small vessels that give rise to the vasa vasorum. Occasional inflammatory cells, including collections of lymphocytes, may also be present in the adventitia.

Muscular Arteries

Blood conducted by the elastic arteries is distributed to individual organs through large muscular arteries (Figs. 16-1 and 16-2). The tunica media of a muscular artery consists of

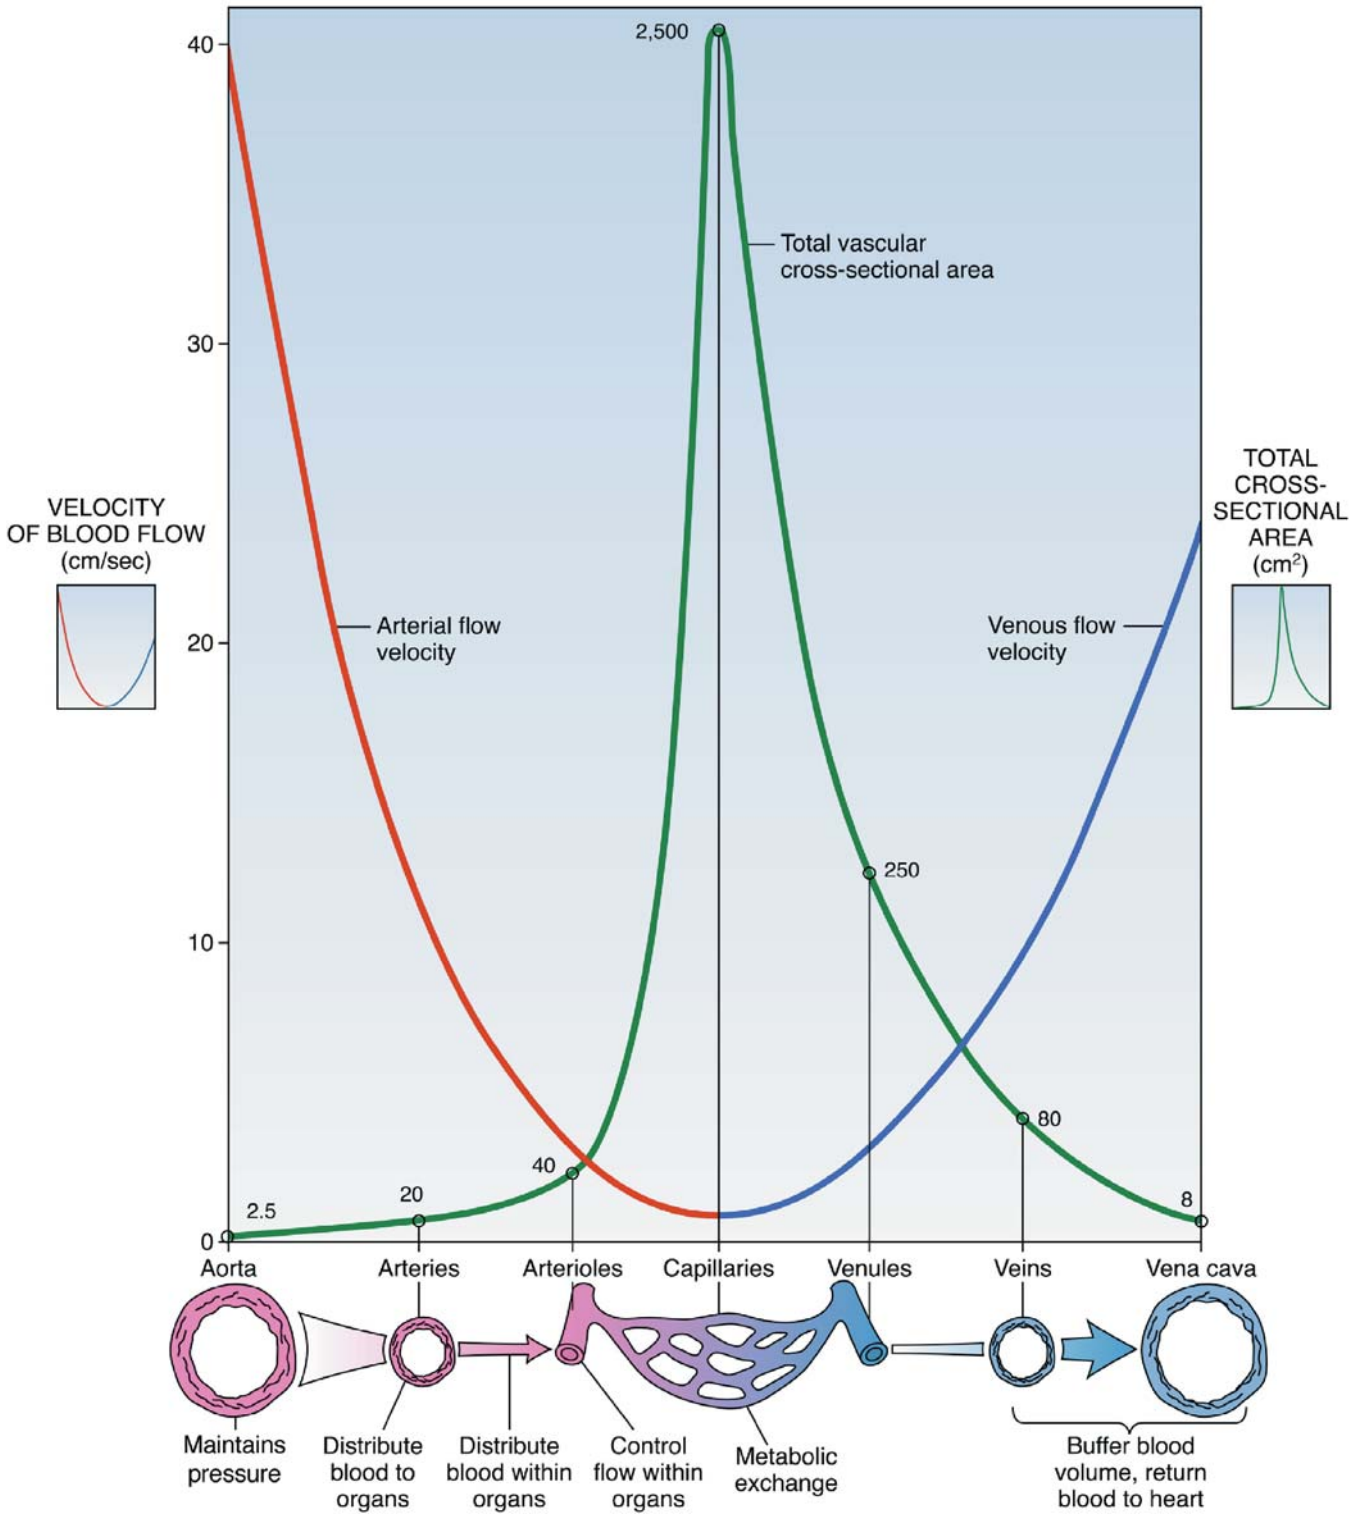

FIGURE 16-2. Relationship between velocity of blood flow and cross-sectional area in the vasculature. The vascular tree is a circuit that conducts blood from the heart through large-diameter, low-resistance conducting vessels to small arteries and arterioles, which lower blood pressure and protect the capillaries. The capillaries are thin walled and allow the exchange of nutrients and waste products between tissue and blood, a process that requires a very large surface area. The circuit back to the heart is completed by the veins, which are distensible and provide a volume buffer that acts as a capacitance for the vascular circuit.

layers of smooth muscle cells without prominent bands of elastin, but a conspicuous internal elastic lamina and usually an external elastic lamina are present. Fenestrae interrupt the continuity of the internal elastic lamina, permitting smooth muscle cells to migrate from the media into the intima. Lacking heavy elastin layers, muscular arteries contract more efficiently. The intima of muscular arteries, like that of the aorta, also contains small numbers of smooth muscle cells, connective tissue and occasional inflammatory cells. Vasa vasorum are present in the outer wall of thicker muscular arteries, but not in smaller ones. As the vascular tree branches further, the tunica media becomes thinner, and except for the endothelium, the tunica intima disappears.

The small muscular arteries are important regulators of blood flow. Their narrow lumens increase resistance, thereby reducing blood pressure to levels appropriate for exchange of water and plasma constituents across downstream thin-walled capillaries. The small muscular arteries, also called **resistance vessels,** help to maintain systemic pressure by regulating total peripheral resistance.

Arterioles

Arterioles are the smallest parts of the arterial system. They have an endothelial lining surrounded by one or two layers of smooth muscle cells. No elastic layers are evident. The smallest arterioles regulate blood flow by vasomotion (change in an artery's caliber), thus controlling blood distribution through the capillary tree.

Capillaries Permit Transport from the Blood to the Interstitium

In these smallest blood vessels, namely, capillaries, the endothelium is supported only by sparse smooth muscle cells. The capillary endothelium provides for exchange of solutes and cells between blood and extracellular fluid. A necessary feature of this exchange is a marked lowering of pressure, which prevents intravascular fluid from shifting into the extracellular space.

The capillary endothelium is a semipermeable membrane, in which exchange of plasma solutes with extracellular fluid is controlled by molecular size and charge. The permeability of capillaries depends on their endothelial cells. Brain capillaries are highly impermeable because junctions between endothelial cells are tightly sealed, preventing exchange of proteins across the vessel wall. Transport in other capillary beds is mediated either by passage of molecules through incomplete cell junctions or by pinocytosis, a process by which molecules traverse the cytoplasm through vesicular transport. Some investigators have suggested that vesicles are connected with each other to provide a channel for direct transport of plasma proteins across the cytoplasm. In some locations, the capillary endothelium itself may have permanent channels through discontinuous gaps between them. Fenestrated capillaries in renal glomeruli are specifically adapted to filter plasma. Liver sinusoids, which are not true capillaries, also show a fenestrated endothelium, which permits free access of plasma to liver cells.

Veins Return Blood to the Heart

Venules are the first vessels to collect blood from capillaries. Their thin media is appropriate for a vessel that does not face high intraluminal pressures. Venules merge into small and medium-sized veins, which in turn converge into large veins. The walls of large veins do not display the characteristic elastic lamellae of elastic arteries; even the internal elastic lamina is well developed only in the largest veins. The media is thin and is virtually absent in the smaller tributaries. Many veins, particularly in the extremities, have valves made of endothelial-lined folds of the tunica intima, which prevent backflow and help to move blood under the low pressure of the venous circulation. Postcapillary venules are the site of leukocyte transmigration into tissue in inflammatory reactions (see Chapter 2).

Lymphatics Drain Interstitial Fluid

Lymphatic circulation is composed of blind-ended lymphatic capillaries, consisting of (1) endothelium with no pericytes; (2) precollecting lymphatics; and (3) collecting lymphatics, which pump lymph toward the lymph nodes, lymphatic trunks and finally thoracic and right lymphatic ducts, which return lymph back to the blood. Filtrate from capillaries and venules enters the lymphatics, which act as a pathway to regional lymph nodes for cells, foreign material and microorganisms. The collecting lymphatics have an intrinsically contractile layer of smooth muscle cells that propel lymph forward. Intraluminal valves, as in veins, prevent backflow. Embryonic development and postnatal growth of lymphatics are regulated by vascular endothelial growth factors (VEGFs), platelet-derived growth factors (PDGFs) and angiopoietin 1 and 2.

CELLS OF THE BLOOD VESSEL WALL

The cells of the blood vessel wall have unique properties that are critical for normal physiologic functions and for the pathogenesis of vascular diseases.

A Single Endothelial Cell Layer Forms a Thromboresistant Barrier

Endothelial cells are metabolically active and are intimately involved in several biological functions, including vascular permeability, coagulation, platelet regulation, fibrinolysis, inflammation, immunoregulation and repair. They also modulate vascular smooth muscle cell function through paracrine pathways. Endothelial cells form unique mechanotransduction structures that modulate the effects of luminal hemodynamic shear stress on the vessel wall. By virtue of mechanical sensing, endothelial cell membranes may deform. This effect activates biochemical signaling and leads to expression of vasoactive compounds, growth factors, coagulation/fibrinolytic/complement factors, matrix degradation enzymes, inflammatory mediators and adhesion molecules.

Endothelial integrity depends on several types of adhesion complexes that promote cell–substratum and cell–cell adhesions (see Chapter 2).

- **Cell–substrate adhesion molecules** attach endothelial cells to their substratum (e.g., basal lamina). They complex with intracellular cytoskeleton, which participates in intracellular signal transduction. For example, integrins are transmembrane molecules that bind endothelial cells to extracellular matrix adhesive molecules, including laminin, fibronectin, fibrinogen, von Willebrand factor and thrombospondin. The cytoplasmic tails of the integrins bind the complex of proteins that regulate adhesion

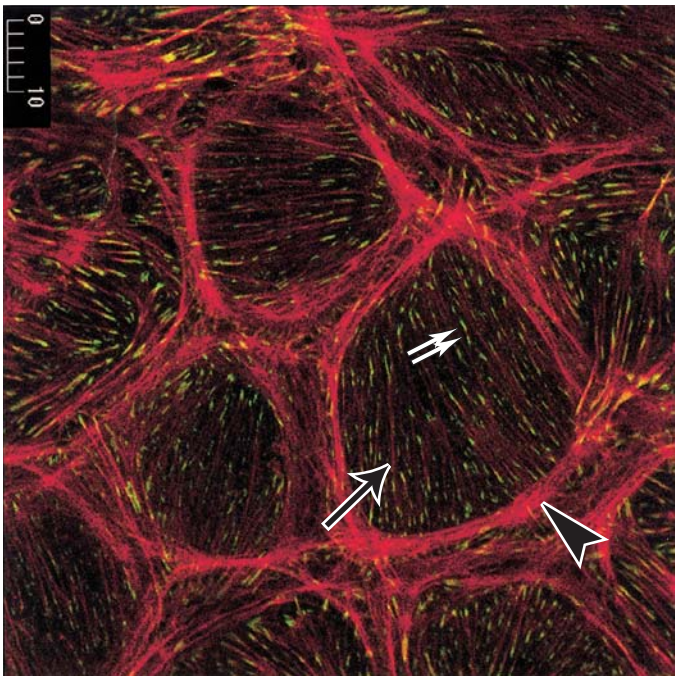

FIGURE 16-3. Focal adhesion protein, vinculin. Porcine aortic endothelial cells were grown to confluency and double-stained for actin/vinculin. Endothelial cells in confluent monolayers contain a dense peripheral band of actin microfilament bundles (*arrowhead*) and central microfilament or "stress fibers" (*single arrow*). Vinculin in confluent monolayer localizes to the tips of stress fibers (*double arrow*).

TABLE 16-1
FUNCTIONS OF ENDOTHELIAL CELLS OF THE BLOOD VESSELS

Permeability barrier
Vasoactive factors: Nitric oxide (EDRF), endothelin
Antithrombotic agent production: Prostacyclin (PGI_2), adenine metabolites
Anticoagulant production: Thrombomodulin, other proteins
Fibrinolytic agent production: Tissue plasminogen activator, urokinase-like factor, tissue factor pathway inhibitor
Procoagulant production: Tissue factor, plasminogen activator/inhibitor, factor V, factor VIIIa (von Willebrand factor)
Inflammatory mediator production: Interleukin-1, cell adhesion molecules
Receptors for factor IX, factor X, low-density lipoproteins, modified low-density lipoproteins, thrombin
Growth factor production: Blood cell colony-stimulating factors, insulin-like growth factors, fibroblast growth factor, platelet-derived growth factor
Growth inhibitor: Heparin

EDRF = endothelium-derived relaxing factor.

at focal contact sites and associate with actin microfilaments and microtubules of the cytoskeleton (Fig. 16-3).

- **Cell–cell adhesion molecules** attach one endothelial cell to its neighbors. Cadherin occurs at intercellular adhesion junctions and occludin at intercellular tight junctions. Cadherins bind to the actin cytoskeleton via catenins.

Endothelial cells carry out a large variety of important metabolic functions (Table 16-1). Many of these are regulated by serum and hemodynamic factors, which activate surface receptors and signal transduction pathways or regulate gene transcription. Endothelial cells do not normally proliferate, but after vascular injury and loss of endothelial cells, they spread, migrate and proliferate rapidly to reestablish the structural integrity of the endothelium and thus protect the wall (Fig. 16-4).

Endothelial cells release a number of biologically potent factors when they are activated. Some of these bioactive

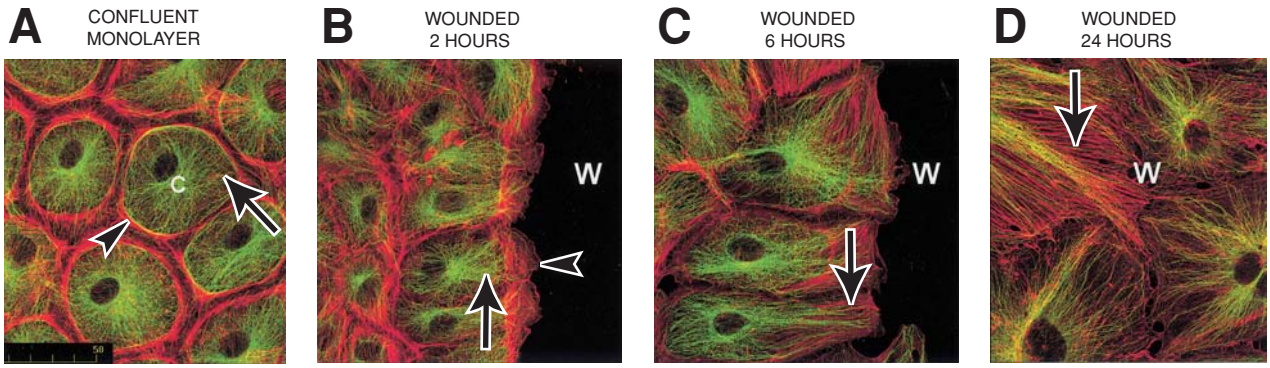

FIGURE 16-4. Remodeling in response to loss of endothelial integrity. Porcine aortic endothelial cells were grown to confluency, and a 1-mm wound was created using a scraper. Cells were fixed and double-stained for actin/tublin at 2, 6 and 24 hours after wounding. **A.** Endothelial cells in confluent monolayers contain a dense peripheral band (DPB) of actin microfilament bundles (*arrowhead*) and centrosomes (C) (*arrow*) toward the cell periphery. **B.** Two hours after wounding, there is formation of lamellipodia (*arrowhead*), and stress fibers (*arrow*) rearrange to become parallel to the wound edge (W). Centrosomes migrate around the nucleus toward the wound edge, and the microtubules begin emanating toward the wound (W). **C.** By 6 hours, changes in microtubules and microfilaments are more prominent, the microtubule/microfilaments are more prominent and the microtubule–microfilament networks (*arrow*) begin to reorganize perpendicular to the wound edge (W) as the cells begin to spread. **D.** Twenty-four hours after wounding, the microtubule–microfilament networks (*arrow*) are aligned perpendicular to the wound edge (W) as the cells migrate into the wound.

molecules are released locally, act at short distances and are rapidly inactivated. For example, prostacyclin (PGI_2), derived from the cyclooxygenase (COX) pathway, relaxes smooth muscle and inhibits platelet aggregation. Endothelial nitric oxide synthase (NOS) converts L-arginine and O_2 to L-citrulline and nitric oxide (NO•) (see below). It also modulates vascular tone and vascular smooth muscle cell proliferation by increasing cyclic guanosine monophosphate (cGMP), in turn activating cGMP-dependent protein kinase. NO• also helps to control the muscular tone of large arteries and resistance vessels. After stimulation of endothelial cell receptors by agonists, prostacyclin and NO• are released and together inhibit platelet aggregation. Compounds that promote NO• release include acetylcholine, bradykinin and adenosine diphosphate (ADP). NO• is even more labile than prostacyclin, with a half-life of 6 seconds.

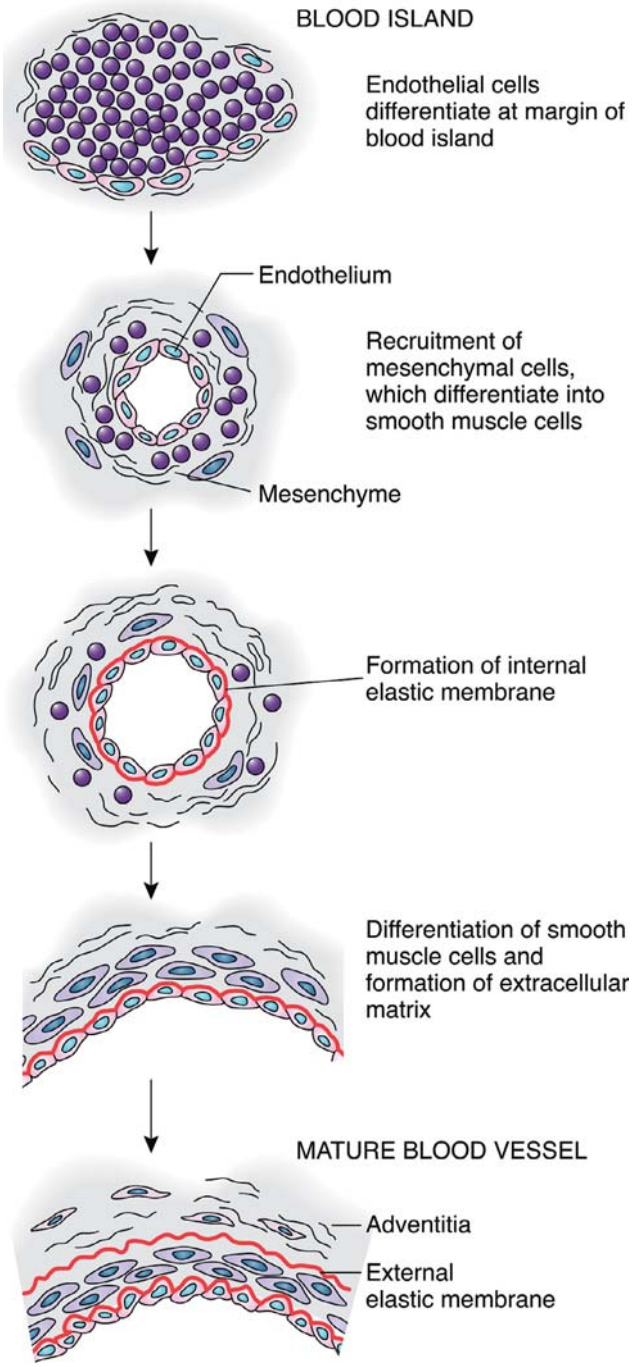
Vascular tone is also affected by several bioactive peptides. **Endothelins** are a family of potent vasoconstrictive proteins made by endothelial cells. They bind two distinct receptors. Both are found on smooth muscle cells, but only one on endothelial cells. Angiotensin-converting enzyme (ACE), an endothelial product, converts angiotensin I to angiotensin II, a potent vasoconstrictor that is important in the pathogenesis of hypertension.

Endothelial cell–derived factors also control some immune responses. Like macrophages, when stimulated, endothelial cells express class II histocompatibility antigens. They may thus work with monocytes—or even replace them—in activating lymphocytes. Immune responses to endothelial cells are a major part of organ rejection following transplantation and play a role in the pathogenesis of graft arteriosclerosis.

Smooth Muscle Cells Maintain Blood Vessel Integrity

Vascular smooth muscle cells are derived from local mesoderm after endothelial tubes are formed (Fig. 16-5). However, the smooth muscle cells of major arteries in the upper part of the body are derived from neural crest. Thus, the structural and functional diversity of vascular smooth muscle cells has a developmental basis and may have pathogenetic implications for diseases of the adult vascular system.

Smooth muscle cells are in the contractile phenotype (differentiated state) and, in association with extracellular matrix, maintain blood vessel integrity and provide support for endothelium. They control blood flow by contracting or dilating in response to specific stimuli. Smooth muscle cells synthesize the connective tissue matrix of the vessel wall, which includes elastin; collagen, especially type I and III collagen; and proteoglycan. They also produce proteolytic enzymes and their inhibitors, which regulate tissue remodeling and repair. In normal arteries, smooth muscle cells rarely divide. Rather, like endothelial cells, they proliferate in response to injury and are important in the pathogenesis of atherosclerotic plaques. In the latter instance, they differentiate to a synthetic phenotype, expressing genes regulating secretion, migration and proliferation. Oxidized low-density lipoprotein (LDL) and platelet-derived growth factor (PDGF) are important stimuli in the switch of smooth muscle cells from a contractile to a synthetic phenotype. Vascular smooth muscle cell phenotype switching is also regulated by microRNA (miRNA). Smooth muscle cells are major producers of the growth factors, cytokines and chemokines involved in atherogenesis.



BLOOD ISLAND

FIGURE 16-5. Differentiation of vessels in early embryos. The course of events from the development of blood islands on the chorioallantoic membrane starts with differentiation of endothelium and proceeds to fully developed arteries and veins.

Inflammatory Cells Enter Vessel Walls and Are Important in Atherosclerosis

Macrophages, dendritic cells and lymphocytes, in particular, promote vascular disease. Atherosclerosis (see below) may be viewed as an inflammatory disease in which monocyte-derived macrophages are very important. T lymphocytes are present in the adventitia in normal arteries and are increased in number in atherosclerotic plaques. Dendritic cells are found in intimal atherosclerotic lesions, and adventitial

leukocytes are organized into clusters similar to lymphoid tissue in areas beneath plaques. Polymorphonuclear leukocytes are important in acute vasculitis, and T cells in acute and chronic vasculitis.

Pericytes Are Modified Smooth Muscle Cells around Capillaries

Pericytes are in close contact with endothelial cells. Both share the same basement membrane. The functions of pericytes are largely unknown. They may be contractile or regulate adjacent endothelial cells' activities and proliferation. The capillary adventitia merges with, and is indistinguishable from, the surrounding connective tissue.

Vascular Progenitor/Stem Cells Regulate Vasculogenesis

The discovery of vascular progenitor/stem cells has aided our understanding of blood vessel injury and repair. Several types of progenitor/stem cells have been identified. **Endothelial progenitor cells** (EPCs) are bone marrow–derived cells arising from perinatal hemangioblasts and are present in adult bone marrow and peripheral circulation. EPCs are identified by their expression of CD133, CD34, c-kit, VEGFR-2, CD144 and Sca-1. They are multipotent immature cells that can proliferate, migrate and differentiate into endothelial cells. Unlike mature endothelial cells, they express CD133, but not endothelial cadherin or von Willebrand factor. The presence of circulating EPCs in adults suggests that new blood vessel growth in adults occurs by **vasculogenesis,** not only by **angiogenesis** as previously thought. Angiogenesis refers to the sprouting of new capillaries from existing blood vessels, whereas vasculogenesis is the differentiation of angioblasts (precursor cells) into endothelial cells that form a vascular network de novo. Vasculogenesis, present in the developing embryo, reappears in adults when EPCs are mobilized and recruited to regions of new blood vessel formation. Embryonic and adult vasculogenesis show many similarities, suggesting that initiating stimuli and regulatory pathways for both are similar.

The number and migratory activity of circulating EPCs are decreased in patients with stable coronary artery disease and are inversely correlated with the number of risk factors in patients with coronary artery disease. EPC proliferation in people with type 2 diabetes mellitus is significantly less than in controls, and EPCs from subjects at high risk for cardiovascular events senesce in culture more readily than do cells from those at low risk. These findings suggest that EPCs may be sensitive indicators of increased risk of vascular disease, especially atherosclerosis.

EPCs have been the subject of intense experimental and clinical investigation, owing to their therapeutic potential in cardiovascular regeneration. EPC transplantation to promote collateral circulation is an innovative therapy to treat tissue ischemia. Blood EPCs from healthy humans can differentiate into endothelial cells and improve blood supply in experimentally injured limbs, and contribute to neovascularization following experimental myocardial infarction. EPC therapy also inhibits left ventricular fibrosis and preserves left ventricular function.

In addition, EPCs help to maintain blood vessel patency after therapeutic stenting. Technologies designed to capture EPCs, such as incorporating anti-CD34 antibody into stents, has shown promise in delaying or preventing restenosis of implanted stents. Therefore, the discovery of adult circulating EPCs may both improve our understanding and contribute to the treatment of vascular injury and repair.

HEMOSTASIS AND THROMBOSIS

Hemostasis is an exquisitely controlled physiologic process initiated to arrest hemorrhage by forming a blood clot. It is a response to vascular injury and involves local vasoconstriction, tissue swelling and platelet adhesion, aggregation and activation. These processes are followed by coagulation and fibrin formation, resulting in a hemostatic plug at sites of injury.

Thrombosis refers to the process that promotes the formation of a blood clot, or thrombus, within the circulation. A thrombus is an aggregate of coagulated blood that contains platelets, fibrin, leukocytes and red blood cells. Its formation involves a balance in favor of factors that promote clotting compared to those that inhibit it. ***Thrombi are formed when antithrombotic systems fail to equal prothrombotic processes.*** Thrombosis involves (1) activation of platelets, (2) activation of coagulation pathways, (3) participation of the monocyte/macrophage system and (4) active involvement of the endothelial cells of the vessel wall.

Coagulation can be induced in vitro in a test tube by activation of the coagulation cascade. In vivo hemostasis involves the coagulation network of activating and inactivating enzymes, and cofactors derived from different cells and tissues, some circulating and some locally produced (Table 16-2). Disorders of hemostasis are discussed in detail in Chapters 7 and 26.

TABLE 16-2
COAGULATION FACTOR DESIGNATIONS

Factor	Standard Name
I	Fibrinogen
II	Prothrombin
III	Tissue factor
IV	Calcium ions
V	Proaccelerin
VII	Proconvertin
VIII	Antihemophilic factor (AHF)
IX	Plasma thromboplastin (PTC)
X	Stuart factor
XI	Plasma thromboplastin antecedent (PTA)
XII	Hageman factor
XIII	Fibrin-stabilizing factor (FSF)
–	Prekallikrein
–	High–molecular-weight kininogen

Blood Coagulates When Fibrinogen Is Converted to Fibrin

The endpoint of blood coagulation is the conversion of soluble plasma fibrinogen to an insoluble fibrillar polymer–fibrin, a reaction catalyzed by the protease enzyme thrombin. This process must be carefully controlled to prevent a massive activation of the system and extensive clotting throughout the entire circulation. A series of finely tuned steps is mediated by a number of coagulation factors (Table 16-2), many of which are restricted by specific inhibitors. This coagulation cascade amplifies an initial signal into the eventual generation of thrombin, production of which is key to progression and stabilization of a thrombus. For example, one molecule of an upstream coagulation factor, factor Xa, generates about 1000 molecules of thrombin.

The coagulation cascade was once divided into the "intrinsic" and "extrinsic" pathways, now called the **contact activation pathway** and the **tissue factor pathway,** respectively. However, this dichotomy does not accurately reflect the main mechanisms of clotting, in which the contact activation pathway actually plays a minor role.

The current view of coagulation (Fig. 16-6) highlights the importance of **tissue factor** (TF), a membrane-bound glycoprotein. The dynamic association of factor VIIa–TF complexes with TF pathway inhibitor (TFPI) is crucial to thrombosis. TFPI inhibits initiation of coagulation by binding TF–FXa–FVIIa complex. A major pool of TFPI on the surface of endothelial cells thus probably regulates coagulation. Hemostasis starts when activated factor VII (VIIa) encounters TF at a site of injury, forming the TF–VIIa complex. This complex activates small amounts of factors IX and X to IXa and Xa. Activation of larger amounts of X to Xa is promoted by factors VIIIa and IXa. Xa converts small amounts of prothrombin to thrombin, and these traces of thrombin catalyze activation of factor XI, which in turn augments conversion of factor IX to IXa. The IXa and VIIIa complex generates more factor Xa from X. In the presence of calcium, this Xa binds Va to form the **prothrombinase complex** on phospholipids from platelet membranes. This complex then catalyzes activation of the inactive zymogen prothrombin to thrombin. Thrombin converts fibrinogen to fibrin monomers, which then form polymers. Thrombin also activates factor XIII to factor XIIIa, forming cross-linked fibrin strands to stabilize the clot.

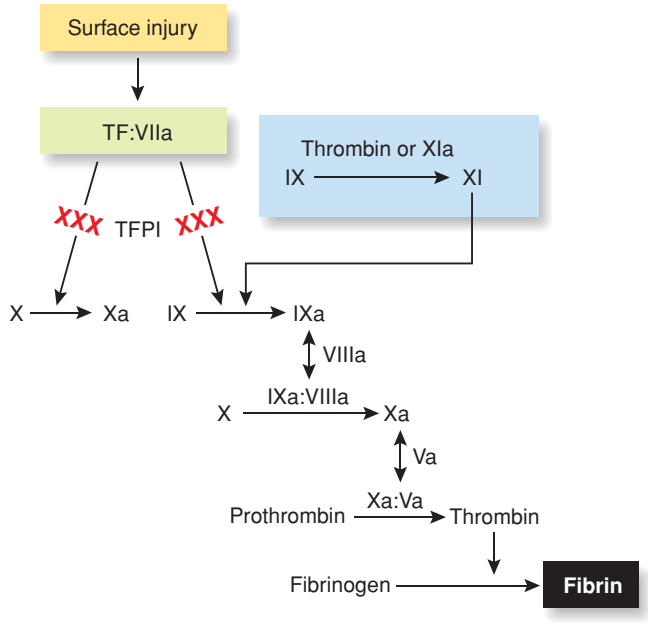

FIGURE 16-6. Coagulation cascade. The coagulation cascade is initiated by endothelial injury, which releases tissue factor (TF). The latter combines with activated factor VII (VIIa) to form a complex that activates small amounts of X to Xa and IX to IXa. The complex of IXa with VIIIa further activates X. The complex of Xa with Va then catalyzes the conversion of prothrombin to thrombin, after which fibrin is formed from fibrinogen. *TFPI* = tissue factor pathway inhibitor.

Besides its important role in coagulation and platelet aggregation, thrombin participates in production of fibrinolytic molecules and regulation of growth factors and leukocyte adhesion molecules. It also mediates the protein C anticoagulant pathway by binding thrombomodulin at the surface of endothelial cells. Factor V, an essential protein coagulation cofactor, also has anticoagulant activity by exerting a cofactor function in the activated protein C system, which then downregulates factor VIIIa activity. Thrombin also increases vessel permeability by promoting alterations in endothelial cell shape and disrupting endothelial cell–cell adhesion junctions.

Injury to Blood Vessels Causes Platelet Adhesion and Aggregation

Normally, circulating platelets are not adherent to each other and to the surface of the vessel wall. However, injury upregulates platelet adhesiveness, after which platelets interact with one another to form a platelet thrombus, that is, an aggregate of activated platelets (Fig. 16-7). This process requires changes in platelet shape that reflect reorganization of actin microfilaments. Several molecules may promote platelet aggregation including thrombin, collagen, ADP, epinephrine, thromboxane A_2, platelet-activating factor (PAF) and vasopressin. Platelet aggregates occlude injured small vessels and prevent leakage of blood.

Once platelets are stimulated to adhere to a vessel wall, their granular contents are released, in part by contraction of the platelet cytoskeleton. These granules promote aggregation of other platelets. Platelet adhesion is enhanced by release of subendothelial von Willebrand factor, which is adhesive for glycoprotein (Gp) Ib platelet membrane protein and for fibrinogen. Activated platelets also release ADP and thromboxane A_2, a product of arachidonic acid metabolism, which recruit additional platelets to the process. The platelet membrane protein complex GpIIb–IIIa binds fibrinogen to form fibrinogen bridges between platelets, enhance aggregation and stabilize the nascent thrombus. Activated platelets in turn release factors that initiate coagulation, thus forming a complex thrombus on the surface of the vessel wall. Thrombin itself stimulates further release of platelet granules and subsequent recruitment of new platelets.

Endothelial Cells Regulate Clotting and Anticoagulation

Endothelium-derived modulators of coagulation are listed in Table 16-3. Endothelial cells synthesize a number of

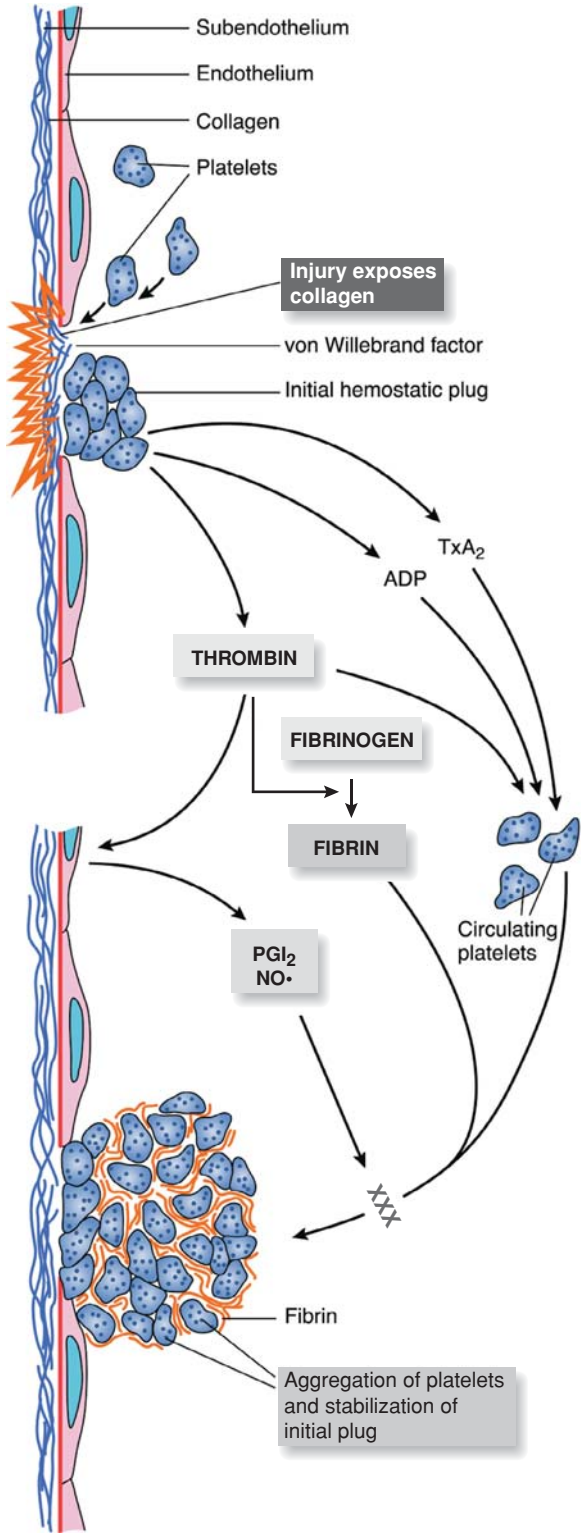

FIGURE 16-7. The role of platelets in thrombosis. Following vessel wall injury and alteration in flow, platelets adhere and then aggregate. Adenosine diphosphate (ADP) and thromboxane A_2 (TxA_2) are released and, along with locally generated thrombin, recruit additional platelets, causing the mass to enlarge. The growing platelet thrombus is stabilized by fibrin. Other elements, including leukocytes and red blood cells, are also incorporated into the thrombus. The release of prostacyclin (PGI_2) and nitric oxide (NO•) by endothelial cells regulates the process by inhibiting platelet aggregation.

TABLE 16-3

REGULATION OF COAGULATION AT THE ENDOTHELIAL CELL SURFACE

Downregulation

1. Thrombin inactivators
   a. Antithrombin III
   b. Thrombomodulin
2. Activated protein C pathway
   a. Synthesis and expression of thrombomodulin
   b. Synthesis and expression of protein S
   c. Thrombomodulin-mediated activation of protein C
   d. Inactivation of factor V_a and factor $VIII_a$ by APC–protein S complex
3. Tissue factor pathway inhibition
4. Fibrinolysis
   a. Synthesis of tissue plasminogen activator, urokinase plasminogen activator and plasminogen activator inhibitor-1
   b. Conversion of Glu-plasminogen to Lys-plasminogen

Procoagulant Pathways

1. Synthesis and expression of:
   a. Tissue factor (thromboplastin)
   b. Factor V
   c. Platelet-activating factor (PAF)
2. Binding of clotting factors IX/IX_a, X (prothrombinase complex)
3. Downregulation of APC pathway
4. Increased synthesis of plasminogen activator inhibitor
5. Synthesis of 15-HPETE

APC = adenomatous polyposis coli; 13-HODE = 13-hydroxy-octadeca-dienoic acid; 15-HPETE = 15-hydroperoxyeicosatetraenoic acid; PGE_2 = prostaglandin E_2; PGI_2 = prostacyclin.

anticoagulant factors. They produce and secrete **PGI_2,** which inhibits platelet aggregation. Endothelial NO• strongly inhibits platelet aggregation and adhesion to the vessel wall. Endothelial cells metabolize ADP, a strong promoter of thrombogenesis, to antithrombogenic metabolites. The luminal surface of the endothelium is coated with heparan sulfate, which binds a number of clotting factors, including the antiprotease β_2-macroglobulin. Endothelial heparan sulfate activates antithrombin, which binds to several coagulation factors, IIa, IXa, Xa, XIa and XIIa, which are free and not bound in complexes or in the clot. Endothelial cells may also lyse some clots as they form through the **plasminogen/plasminogen activator/plasmin system**.

Endothelial cells have several other anticoagulant activities. A cofactor on the endothelial cell surface inactivates thrombin by forming a complex with thrombin and antithrombin III (a plasma antiprotease). Thrombin itself activates protein C by binding its receptor, **thrombomodulin,** at endothelial cell surfaces. Both protein C and thrombomodulin are synthesized by endothelial cells. Activated protein C destroys coagulation factors V and VIII. TFPI generated

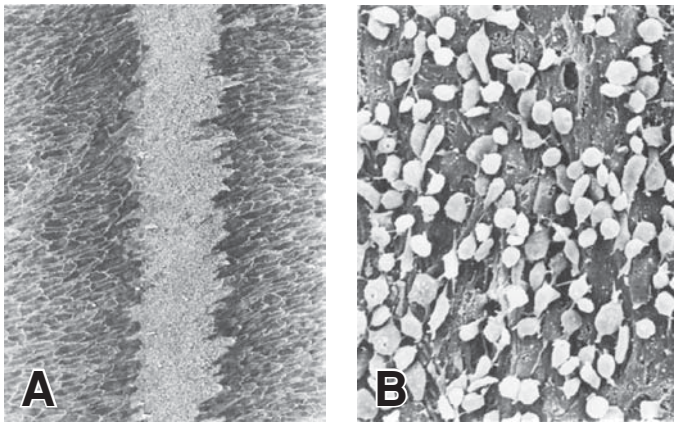

FIGURE 16-8. Scanning electron micrograph of the endothelial surface of a rat aorta 1 hour after the endothelial cells were removed by scraping with a nylon filament. A. Intact endothelium and scratched portion. **B.** Higher-power view of the scratched area shows a pavement of intact platelets that adheres to the underlying connective tissue in the high-velocity arterial stream.

during coagulation is bound to endothelium, where it inhibits the TF–VIIa complex (Fig. 16-6). TF and TFPI are synthesized and secreted by endothelial cells as well as other vascular cells.

In terms of balancing the system, the endothelium is also intimately involved in initiating and propagating thrombosis. The event that triggers most thrombosis is endothelial injury, which imparts a prothrombotic property to endothelium (Fig. 16-7). Endothelial cells synthesize von Willebrand factor, which promotes platelet adherence and activates clotting factor V. Endothelial cells also bind factors IX and X, a process that favors coagulation at the endothelial surface. Finally, inflammatory agents, including cytokines released from monocytes, activate procoagulants on the surface of intact endothelium. Interluekin-1 (IL-1) and tumor necrosis factor (TNF) cause endothelial cells to present thromboplastin to the plasma, thereby potentially triggering the extrinsic coagulation pathway.

Thus, thrombi may form when endothelial function is altered, when endothelial continuity is lost or when blood flow in a vessel becomes abnormal, such as turbulent or static. Simple loss of endothelial cells or injury to a vessel with good flow produces platelet pavementing but not thrombosis (Fig. 16-8).

Endothelial Cells Repair Defects in Damaged Areas

The most common denuding injury to endothelium is progressive disruption by atherosclerotic plaque. Denuding endothelial damage is also described in homocystinuria, hypoxia and endotoxemia, as well as during invasive therapeutic procedures such as harvesting and implantation of saphenous veins for bypass grafts, angioplasty, insertion of intravascular stents and atherectomy. Interactions of a thrombus with subjacent endothelial cells may further disturb endothelial integrity. Both fibrin and thrombin affect the endothelial cytoskeleton and initiate endothelial shape changes to form intercellular gaps that disrupt endothelial integrity.

In that setting, endothelial cells can spread rapidly and migrate into the denuded area to reestablish a thromboresistant barrier (Fig. 16-4). This is followed by endothelial cell proliferation to restore normal cell density. These mechanisms may become dysfunctional at sites of persistent endothelial cell damage and result in focal erosions, ulcers and fissures.

Another hypothesized mechanism of repair is migration of endothelial progenitor cells (EPCs) (see above and Chapter 3). EPCs are thought to proliferate after vascular injury and physiologic stress. They then are released into the peripheral circulation, where they target injured vessel walls, attach to the denuded surface and differentiate to reestablish endothelial integrity.

Clot Lysis Is a Regulatory Mechanism

A thrombus may undergo several fates, including (1) lysis, (2) growth and propagation, (3) embolization and (4) organization and canalization. The combination of aggregated platelets and clotted blood is made unstable by activation of the fibrinolytic enzyme plasmin (Fig. 16-9). During clot formation, plasminogen is bound to fibrin and therefore is an integral part of the forming platelet mass. Endothelial cells make plasminogen activator, but in larger thrombi, circulating plasminogen may also be converted to plasmin by products of the coagulation cascade. Plasminogen activator bound to fibrin activates plasmin. In turn, by digesting fibrin strands into smaller fragments, plasmin lyses clots and disrupts the thrombus. These smaller fragments inhibit thrombin and fibrin formation. Clearance of fibrin also limits its accumulation in atherosclerotic plaques, where it can promote plaque growth and attract inflammatory cells. Endothelial cells also synthesize plasminogen activator inhibitor-1 (PAI-1), and plasmin is inhibited by α_2-antiplasmin. Thus, a regional fibrinolytic state reflects the balance between plasminogen and plasmin activation and inhibition.

Thrombi may undergo organization and become incorporated into vessel walls. The fibrin meshwork contracts to reduce the size of the thrombus. Arterial smooth muscle cells or venous fibroblasts migrate into the thrombus meshwork of cross-linked fibrin and produce extracellular matrix.

Proteolytic enzymes and their inhibitors secreted by smooth muscle cells and macrophages remodel the thrombus, digest the fibrin and form a fibrous structure with its own

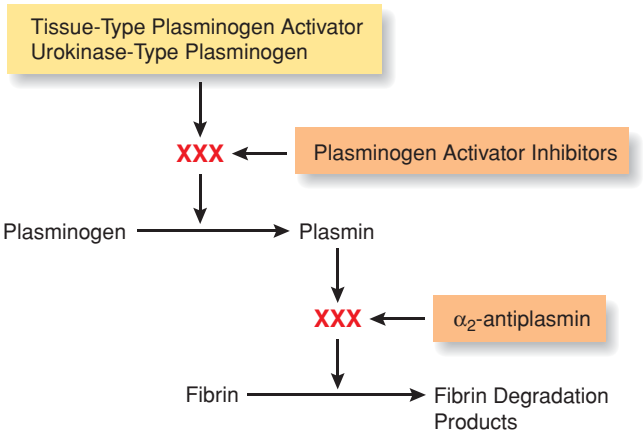

FIGURE 16-9. Mechanisms of fibrinolysis. Plasmin formed from plasminogen lyses fibrin. The conversion of plasminogen to plasmin and the activity of plasmin itself are suppressed by specific inhibitors.

TABLE 16-4
ATHEROGENESIS

- Initiation and growth of fibroinflammatory lipid atheroma is a slowly evolving dynamic process with superimposed acute events.
- Risk factors accelerate progression.
- The pathogenesis is multifactorial and thus the relative importance of specific genetic and environmental factors may vary in individuals.
- Interactions between cellular and matrix components of the vessel wall and serum constituents, leukocytes, platelets and physical forces regulate the formation of the fibroinflammatory lipid atheroma.

new blood vessels formed by angiogenic factors present in the thrombus. This revascularization is called **canalization**. However, blood flow through canalized thrombi is usually limited.

ATHEROSCLEROSIS

Atherosclerosis is characterized by progressive accumulation of inflammatory, immune and smooth muscle cells; lipids; and connective tissue in the intima of large and medium-sized elastic and muscular arteries. The classic atherosclerotic lesion is best described as a fibroinflammatory lipid plaque **(atheroma).** These plaques develop over several decades (Tables 16-4 and 16-5). Their continued growth encroaches on the media of the arterial wall and into the lumen of the vessel, narrowing its caliber. Atherosclerotic lesions are also called atherosclerotic plaques, atheromas, fibrous plaques or fibrofatty lesions.

EPIDEMIOLOGY: The major complications of atherosclerosis, including ischemic heart disease (coronary artery disease), myocardial infarction, stroke and gangrene of the extremities, account for more than half of the annual mortality in the United States, with ischemic heart disease being the leading cause of death. The incidence of death from ischemic heart disease in Western countries peaked in the late 1960s, then declined by more than 30%. There are wide geographic and racial variations in the incidence of the disorder.

TABLE 16-5
IMPORTANT COMPONENTS OF FIBROINFLAMMATORY LIPID ATHEROMA

Cells	– Endothelial cells	Lipids and lipoproteins
	– Foam cells	Serum proteins
	– Giant cells	Platelet and leukocyte products
	– Lymphocytes	Necrotic debris
	– Mast cells	New microvessels
	– Macrophages	Hydroxyapatite crystals
Matrix	– Collagen	Growth factors
	– Elastin	Oxidants/antioxidants
	– Glycoproteins	Proteolytic enzymes
	– Proteoglycans	Procoagulant factors

PATHOPHYSIOLOGY: Over the years, many theories have been proposed to explain the origins of atherosclerotic plaques. With the new knowledge from experimental and clinical observations, a comprehensive description of the pathogenesis of atherosclerosis is now possible, with the caveat that the formation, growth and clinical presentation of the plaques vary from patient to patient.

A Unifying Theory of Atherogenesis

The sequence of events in atherogenesis (Figs. 16-10 to 16-13) may begin in fetal life, with the formation of intimal cell masses, or perhaps shortly after birth, when fatty streaks begin to evolve. However, the typical atherosclerotic lesion, which is initially clinically insignificant, forms over 20–30 years. An exception is homozygous familial hypercholesterolemia, in which lesions develop in the first decade of life.

The life of a plaque can be divided into three stages: (1) initiation and formation, (2) adaptation and (3) clinical. Biologically active molecules regulate several dynamic cellular functions. Identification of a single "master" atherogenic gene responsible for most atherosclerosis is unlikely. Rather, it is probable that multiple gene polymorphisms interact with the environment and with each other.

Initiation and Formation Stage

1. Intimal lesions initially occur at sites that appear to be predisposed to lesion formation due to structural

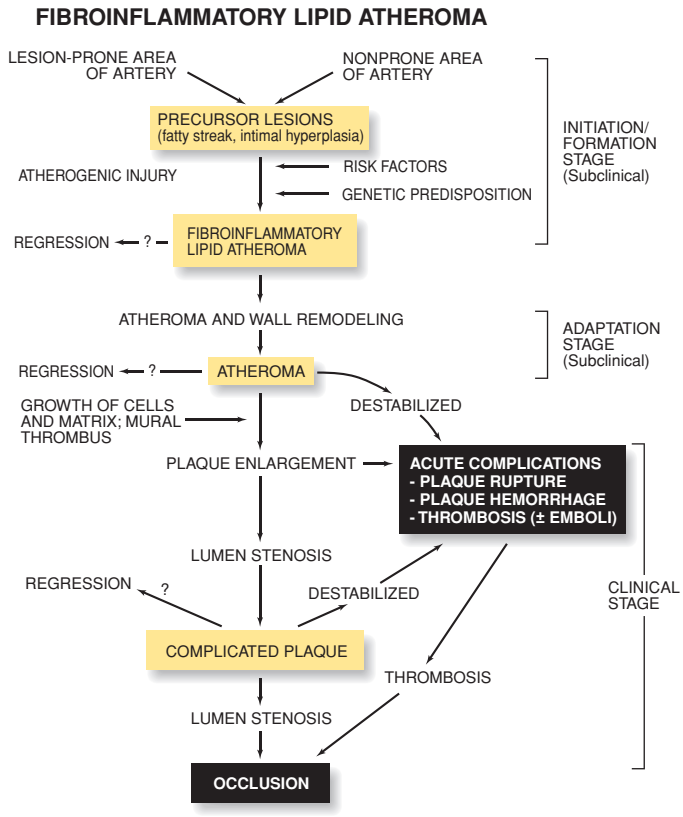

FIGURE 16-10. A unifying hypothesis for the pathogenesis of atherosclerosis.

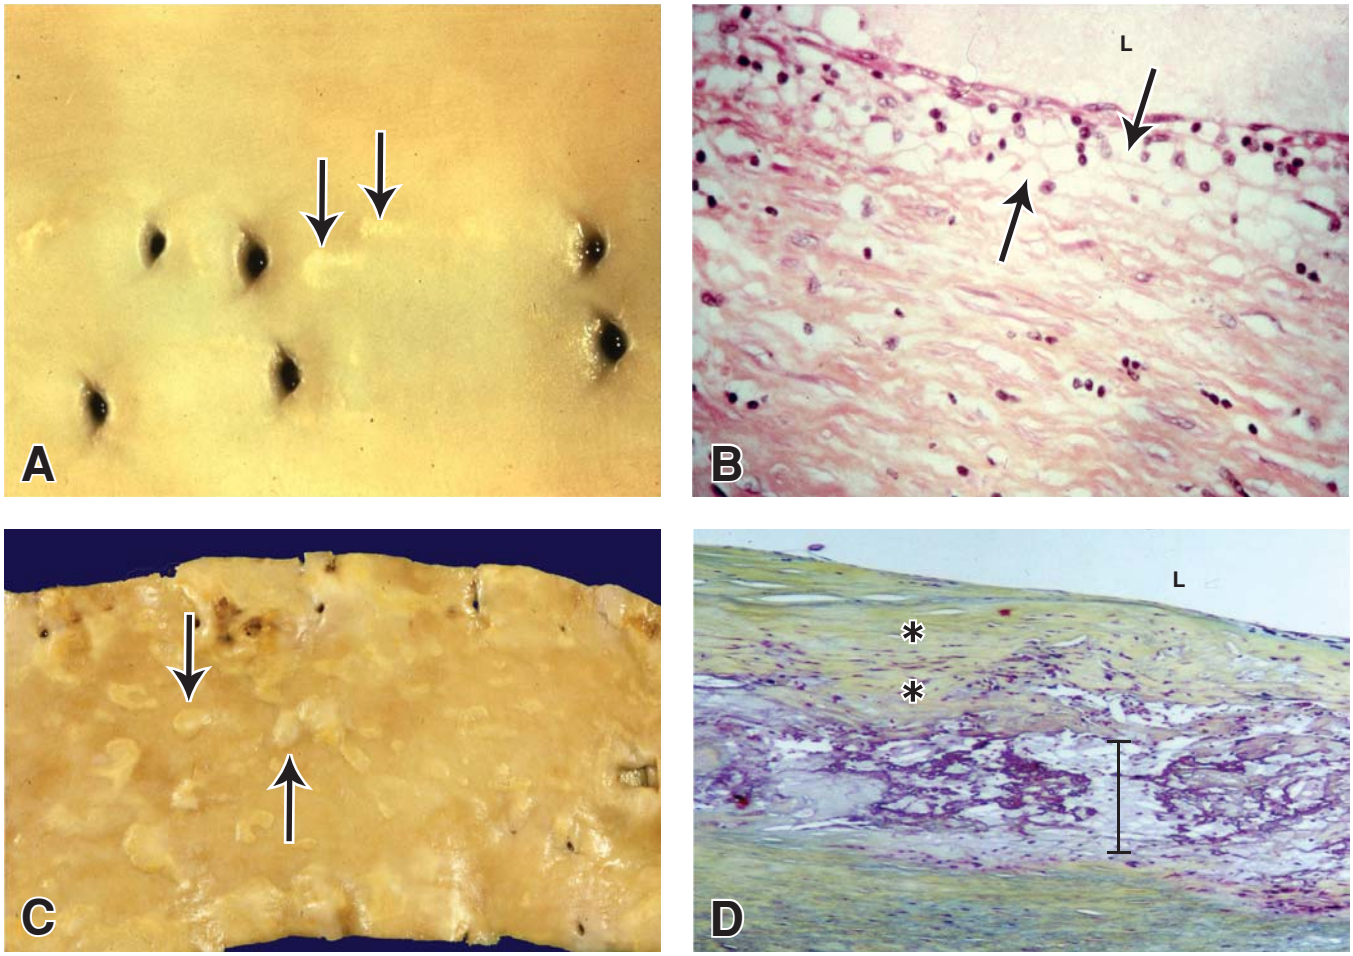

FIGURE 16-11. Fatty streak and atherosclerosis. A. Fatty streak. Gross photo of yellow fatty streaks (*arrows*) in the thoracic aorta. **B.** Fatty streak. Microscopic features of fatty streak in artery wall with intimal foam cells (*arrows*). *L* = lumen. **C.** Fibroinflammatory lipid plaques. features, including intimal cell mass, bifurcations, branch points and curvatures in the artery. Endothelial dysfunction may also be secondary to hemodynamic shear stress or may be constitutive in association with vessel wall structure. Atherosclerotic lesions tend to arise where shear stresses are low but fluctuate rapidly (e.g., branch points and bifurcations). Subendothelial smooth muscle cells accumulate in an intimal cell mass at branch and other points in certain vessels. This cell mass predisposes to plaque formation, particularly in the coronary arteries. Inflammatory cells, including macrophages and dendritic cells, are present in the intima of these atherosclerotic-prone areas.

At sites susceptible to plaque development, expression of proinflammatory genes, vascular cell adhesion molecule-1 (VCAM-1) and intercellular adhesion molecule-1 (ICAM-1) by endothelial cells increases. These molecules recruit monocytes into vessel walls. Monocyte/macrophage recruitment is one of the early events in atherogenesis and is orchestrated through a multistep process involving adhesion and transmigration. Adhesion is regulated by cell surface adhesion molecules including P-selectin, E-selectin, VCAM-1, ICAM-1 and several chemokines. Transmigration involves platelet endothelial cell adhesion molecule-1 (PECAM-1).

The distribution of atherosclerotic lesions in large vessels and differences in location and frequency of lesions in different vascular beds encourage a belief in the role of hemodynamic factors. The fact that hypertension enhances the severity of atherosclerotic lesions further supports a role for hemodynamic factors in atherosclerogenesis. Hemodynamic forces induce unique gene expression patterns, including several factors in endothelial cells that are likely to promote atherosclerosis, for example, fibroblast growth factor 2 (FGF-2), TF, plasminogen activator, endothelin and PECAM. However, shear stress also induces gene expression of agents that may be antiatherogenic, including NOS and PAI-1. In people at increased risk of atherosclerosis, lesions also occur in areas that are not necessarily predisposed to the disease.

2. Lipid accumulation depends on disruption of the integrity of the endothelial barrier through gaps between cells, cell loss or endothelial cell dysfunction. This injury may be due to hypercholesterolemia, abnormal laminar flow, reactive oxygen species, cytokine- induced inflammation, advanced glycation end-products in

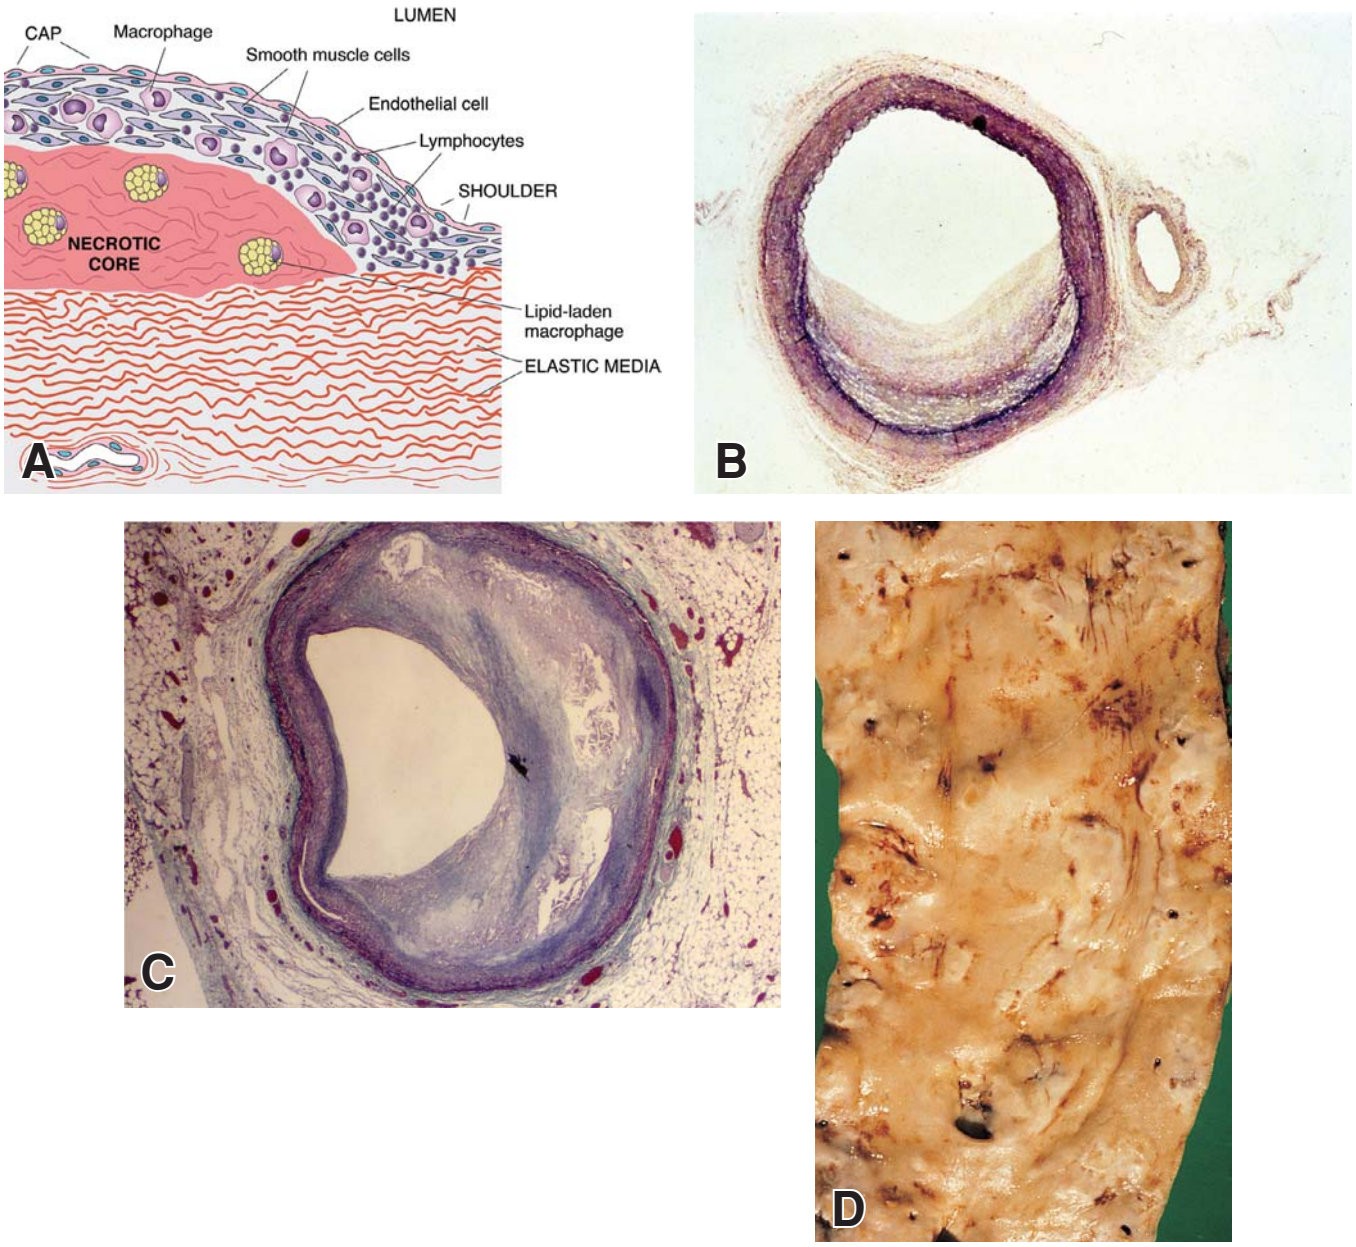

FIGURE 16-12. Fibrofatty plaque of atherosclerosis. A. In this fully developed fibrous plaque, the core contains lipid-filled macrophages and necrotic smooth muscle cell debris. The "fibrous" cap is composed largely of smooth muscle cells, which produce collagen, small amounts of elastin and glycosaminoglycans. Also shown are infiltrating macrophages and lymphocytes. Note that the endothelium over the surface of the fibrous cap frequently appears intact. **B.** Adaptive stage with atherosclerotic plaque and vessel wall dilatation to maintain the normal size of the lumen. Normal artery wall is at the top. **C.** Stenotic coronary artery with atherosclerotic plaque. **D.** The aorta shows discrete, raised, tan plaques. Focal plaque ulcerations are also evident.

diabetes and hyperhomocysteinemia. Hypertension also promotes endothelial dysfunction. Oxidative stress in endothelial cells and macrophages leads to cellular dysfunction and damage. LDLs carry lipids into the intima. Since oxidized LDL activates cell adhesion molecules, macrophages can adhere to activated endothelial cells and transmigrate between endothelial cells into the intima, bringing lipids with them. Some of these "foamy" macrophages undergo necrosis and release lipids. Alterations in types of matrix proteoglycans synthesized by the smooth muscle cells in the intima also render these sites prone to lipid accumulation by binding lipids and trapping them in the intima. ***Reduced egress of lipids out of the artery wall also promotes lipid accumulation.***

3. Mononuclear macrophages, in addition to being central to atherogenesis by participating in lipid accumulation, also release growth factors that stimulate further accumulation of smooth muscle cells. **Oxidized LDL** induces tissue damage and recruits macrophages. It also promotes endothelial and smooth muscle cell release of chemokines, which regulate immune cell recruitment in the plaque. The nuclear factor-κB (NFκB) pathway is an important intracellular signal transduction system that

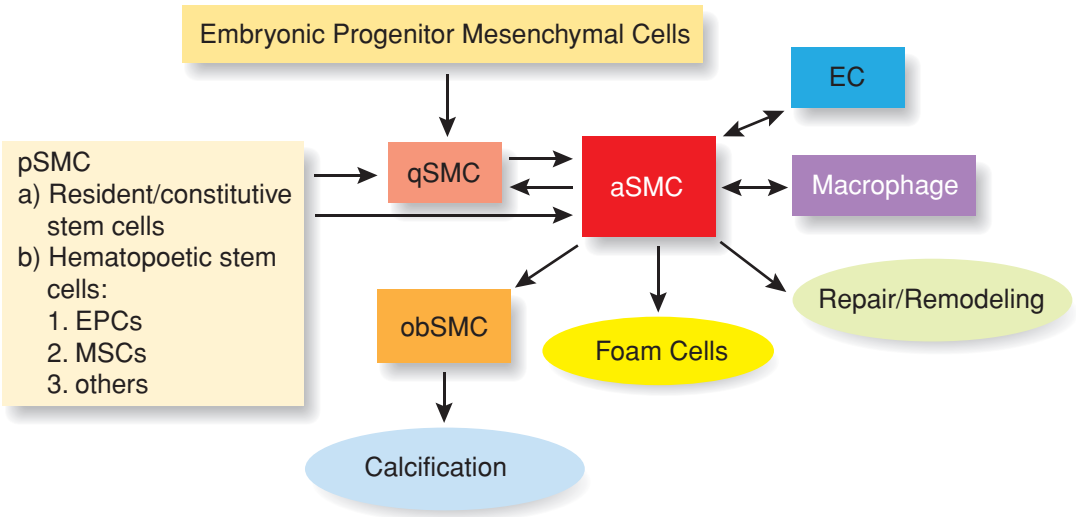

FIGURE 16-13. The hypothesized roles of smooth muscle cells (SMCs) in the pathogenesis of atherosclerosis. SMCs are quiescent (qSMC) in the normal artery wall and are derived embryonically from progenitor mesenchymal cells and neural crest cells. SMCs become activated (aSMC) by lipids and a variety of cytokines, chemokines, other mediators secreted by macrophages and endothelial cells through paracrine pathways in the lesion, and function in repair and remodeling of the lesion. aSMCs migrate, proliferate and secrete prominent extracellular matrix, while qSMCs exhibit a differentiated and contractile phenotype. aSMCs can accumulate lipids and become foam cells in the lesion. aSMCs can also undergo a change in phenotype to show osteoblastic functions (obSMC) promoting calcification in the atherosclerotic lesion. Progenitor SMCs (pSMCs) such as resident stem cells, bone marrow–derived hematopoietic stem cells, endothelial progenitor cells (EPCs) and bone marrow–derived mesenchymal stem cells (MSCs) may replenish SMCs in the vasculature, especially during a response to injury. aSMCs interact with endothelial cells (ECs) and macrophages directly or indirectly to regulate atherosclerotic plaque growth.

is active at several stages of plaque growth and progression. It activates recruitment of leukocytes by endothelial cells, cytokine expression and extracellular matrix remodeling. Monocytes/macrophages synthesize PDGF, FGF, TNF, IL-1, interferon-α and transforming growth factor-β (TGF-β), each of which can stimulate or inhibit growth of smooth muscle or endothelial cells. For example, interferon and TGF limit cell proliferation and could account for the failure of endothelial cells to maintain continuity over the lesion. Alternatively, they could inhibit growth-stimulatory peptides. IL-1 and TNF stimulate endothelial cells to produce PAF, TF and PAI. Thus, the combination of macrophages and endothelial cells may transform the normal anticoagulant vascular surface to a procoagulant one.

4. As a lesion progresses, mural thrombi often form on the damaged intimal surface. This stimulates PDGF release, accelerating smooth muscle proliferation and secretion of matrix components. The thrombus may grow, lyse or become organized and incorporated into the plaque.
5. The deeper parts of the thickened intima are poorly nourished because of a distance limitation for the diffusion of nutrients. This tissue undergoes ischemic necrosis, which is augmented by proteolytic enzymes released by macrophages (i.e., cathepsins) and tissue damage caused by oxidized LDL, reactive oxygen species and other agents. Thus, the central necrotic core is formed. Together with specific platelet- and macrophage-derived angiogenic factors, the necrotic core initiates angiogenesis, with new vasa vasorum forming in the plaque.
6. The fibroinflammatory lipid plaque is formed, with a central necrotic core and a fibrous cap, which separates the core from the blood in the lumen. The core contains tissue debris, apoptotic cells, necrotic foam cells, cholesterol crystals and focal calcification. Cholesterol clefts promote further inflammation. Inflammatory and immune cells infiltrate, mingling with smooth muscle cells, deposited lipids and variably organized matrix. TGF-β, a key regulator of extracellular matrix deposition, induces formation of several types of collagen, fibronectin and proteoglycans. It also enhances expression of proteolytic enzyme inhibitors that promote matrix degradation. TGF-β also has anti-inflammatory properties and has been reported to promote growth of smooth muscle cells. Since its effects depend on the environment, TGF-β may be both atherogenic and antiatherogenic.
7. The immune system participates in atherogenesis. Expression of human leukocyte antigen (HLA)-DR antigens on the endothelial and smooth muscle cells of plaques implies that these cells may have undergone immunologic activation, perhaps in response to interferon released by activated T cells in the plaque. In this scenario, the presence of T cells reflects an autoimmune response (e.g., against oxidized LDL). Dendritic cells are present in early lesions, and T lymphocytes also increase in the plaque.

Adaptation Stage

As the plaque protrudes into the lumen (e.g., in coronary arteries), the wall of the artery remodels to maintain lumen size. When a plaque occupies about half of the lumen, such remodeling can no longer compensate, and

the arterial lumen becomes narrowed **(stenosis)**. Hemodynamic shear stress, an important regulator of vessel wall remodeling, acts through the mechanotransduction properties of endothelial cells. These include the cell cytoskeleton, ion channels in the cell membrane and the cell coat. Smooth muscle cell turnover, proliferation, apoptosis and matrix synthesis and degradation modulate remodeling of the vessel and the atherosclerotic plaque. Matrix metalloproteinases (MMPs) and their inhibitors (TIMPs) are important in this process (see Chapter 3). Just as remodeling maintains vessel patency, it also allows a plaque to be "clinically silent." Even a small plaque at this stage can rupture, with catastrophic results, as noted below.

Clinical Stage

1. As a plaque encroaches on the lumen, hemorrhage into it may increase its size without rupture. This hemorrhage occurs when fragile new vessels are formed in the plaques, which may rupture locally. Macrophages clean up the hemorrhagic material. Circulating blood may undermine the plaque, in which case the raised plaque, hemorrhage and thrombosis combine to obstruct the vessel.
2. Complications develop in the plaque, including surface ulceration, fissure formation, calcification and aneurysm formation. Activated mast cells at sites of erosion may release proinflammatory mediators and cytokines. Continued plaque growth leads to severe stenosis or occlusion of the lumen. Plaque rupture, involving the fibrous cap, and ensuing thrombosis and occlusion may precipitate catastrophic events in these advanced plaques (e.g., acute myocardial infarction). However, recent angiographic studies suggest that even plaques causing less than 50% stenosis may suddenly rupture. There are several conditions that appear to favor rupture, as noted in Fig. 16-10. These include hemodynamic shear stress, fissure formation, a thin fibrous cap, reduced number of smooth muscle cells, increased matrix metalloproteinase activity, inflammation, foam cell accumulation and focal nodular calcification.

Fig. 16-10 shows how these mechanisms may operate in atherogenesis.

The Initial Lesion of Atherosclerosis

PATHOLOGY: Two distinct lesions precede atherosclerotic plaques.

FATTY STREAK: Fatty streaks are flat or slightly elevated lesions in the intima in which intracellular and extracellular lipids accumulate. They are seen in young children as well as in adults. Cells filled with lipid droplets ("foam cells") congregate (Fig. 16-11). Macrophages contain the most lipid, but smooth muscle cells contain fat as well.

In children who die accidentally, significant fatty streaks may be evident in many parts of the arterial tree, but they do not reflect the distribution of atherosclerotic lesions in adults. Fatty streaks are common in the thoracic aorta in children, but atherosclerosis in adults is far more prominent in the abdominal aorta. Nonetheless, many believe that fatty infiltration is a precursor lesion of atherosclerosis and that other factors control the transition from fatty streak to clinically significant atherosclerotic plaque.

INTIMAL CELL MASS: The intimal cell mass is another candidate for a precursor lesion of atherosclerosis. Intimal cell masses are white, thickened areas at branch points in the arterial tree. Microscopically, they contain smooth muscle cells and connective tissue but no lipid. The location of these lesions, also known as "cushions," at arterial branch sites correlates well with the locations of later atherosclerotic lesions.

THE CHARACTERISTIC LESION OF ATHEROSCLEROSIS: The characteristic lesion of atherosclerosis is the fibroinflammatory lipid plaque. Simple plaques are focal, elevated, pale yellow, smooth-surfaced lesions, irregular in shape but with well-defined borders. Fibrofatty plaques (Fig. 16-12) represent more-advanced lesions and tend to be oval, with diameters of up to 12 cm. In smaller vessels, such as the coronary or cerebral arteries, a plaque is often eccentric; that is, it occupies only part of the circumference of the lumen. In later stages, fusion of plaques in muscular arteries can give rise to larger lesions, which occupy several square centimeters.

Atherosclerotic plaques are initially covered by endothelium and tend to involve the intima and very little of the upper media (Fig. 16-12B). The area between the lumen and the necrotic core—the **fibrous cap**—contains smooth muscle cells, macrophages, lymphocytes, lipid-laden cells (foam cells) and connective tissue components. The central core contains necrotic debris. Cholesterol crystals and foreign body giant cells may be present within the fibrous tissue and necrotic areas. Foam cells are both macrophages and smooth muscle cells that have taken up lipids. Numerous inflammatory and immune cells, especially T cells, are present within a plaque.

Neovascularization is an important contributor to plaque growth and its subsequent complications (Fig. 16-13). It is postulated that vessels grow inward from the vasa vasorum. They are rare in healthy coronary arteries but plentiful in atherosclerotic plaques.

COMPLICATED ATHEROSCLEROTIC PLAQUES: A **complicated** plaque may reflect erosion, ulceration or fissuring of the plaque surface; plaque hemorrhage; mural thrombosis; calcification; and aneurysm (Figs. 16-12C, D; 16-14; and 16-15). Progression from a simple fibrofatty atherosclerotic plaque to a complicated lesion may occur as early as the third decade of life, but most affected people are 50 or 60 years of age.

Cellular interactions in atherogenesis are summarized in Fig. 16-16.

- **Calcification** involving osteochondrocytic differentiation occurs in areas of necrosis and elsewhere in the plaque. Oxidized lipids and inflammatory cytokines promote vascular calcification. Calcification in the artery is thought to depend on mineral deposition and resorption, which are regulated by osteoblast-like and osteoclast-like cells in the vessel wall. These cells are considered to be rare precursor cells in the artery wall, derived from smooth muscle–type cells that have undergone a phenotypic transformation or possibly circulating stem/precursor cells derived from bone marrow. Several transcription factors (including Msx2, Runx2, Osterix and Sox9) promote cell osteoblast development. Calcification may also reflect changes in the physical-chemical properties of a diseased vessel wall that provoke formation of hydroxyapatite crystals.
- **Mural thrombosis** results from abnormal blood flow around the plaque, where it protrudes into the lumen

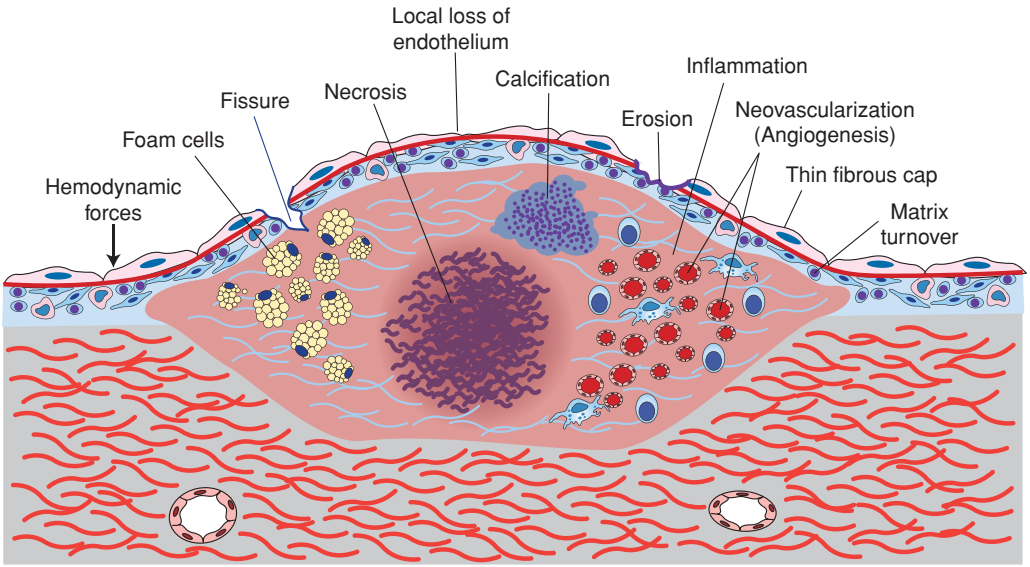

FIGURE 16-14. Complicated atherosclerotic plaque. The surface shows endothelial denudation, erosion and fissure formation. The plaque shows a thin fibrous cap, a central necrotic core, inflammation, lipids, calcification and neovascularization.

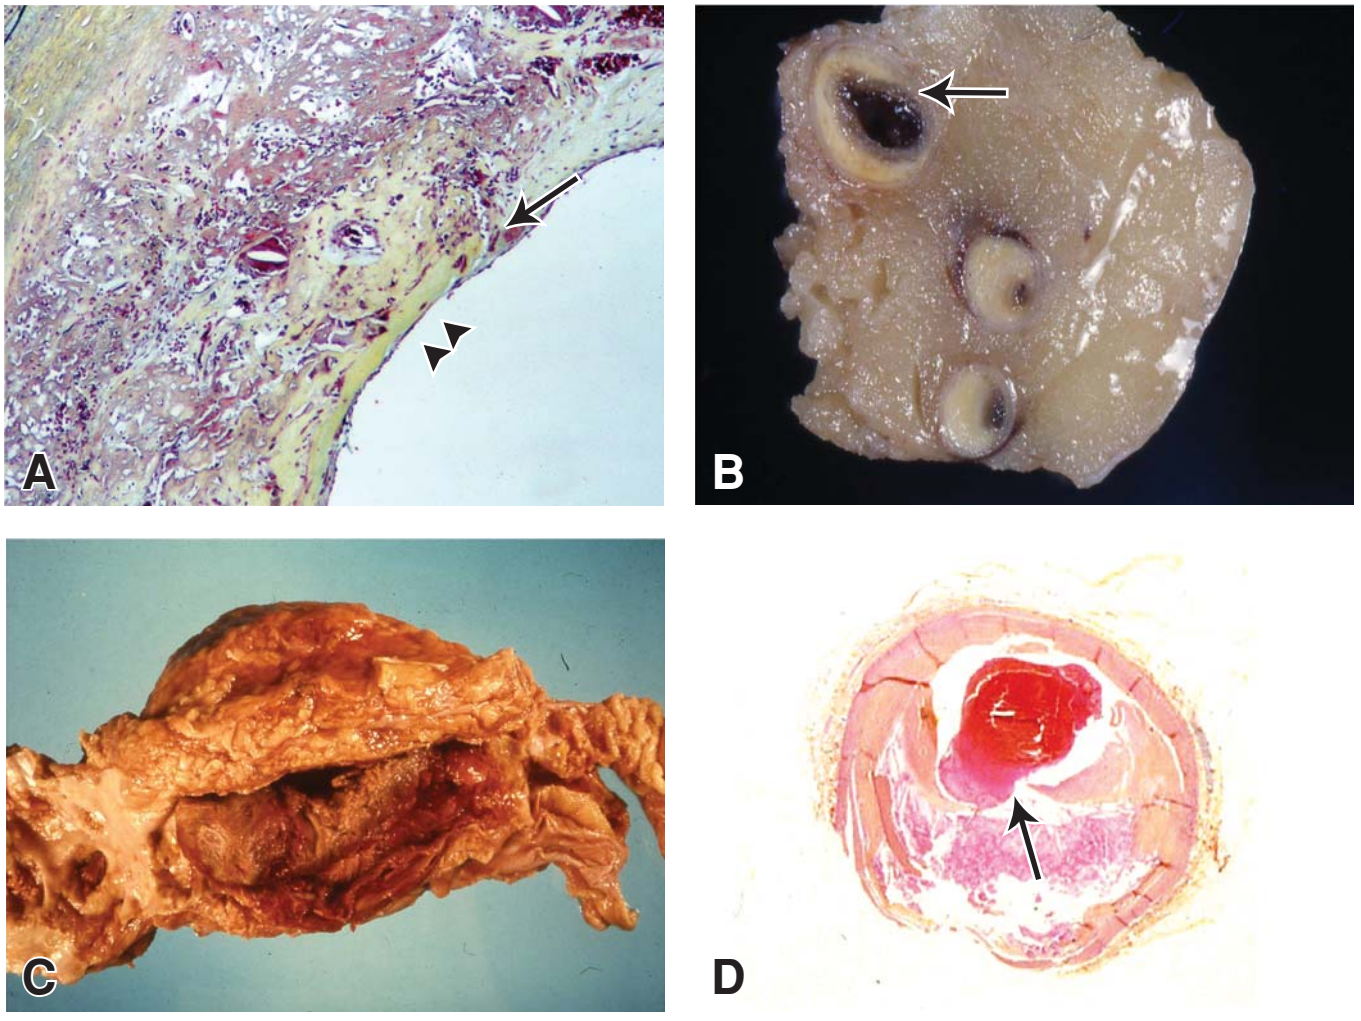

FIGURE 16-15. Complications of atherosclerosis. A. Fibroinflammatory lipid plaque. Microscopic features of plaque erosion (*arrowheads*) and fissure formation (*arrow*). **B. and creates turbulence, reduced luminal flow or stasis. The disturbance in flow also causes damage to the endothelial lining, which may become dysfunctional or locally denuded, in which case it no longer presents a thromboresistant surface. Thrombi often form at sites of erosion and fissuring on the surface of the fibrous cap. Mural thrombi in the proximal region of a coronary artery may embolize to more distal sites in the vessel.

- **The vulnerable atheroma** has structural and functional alterations that predispose to plaque destabilization.
- **Atheroma destabilization** often results in acute coronary syndromes. It may occur whenever the dynamic balance of opposing biological and physical processes is disrupted, leading to mural thrombosis, fibrous cap rupture or intraplaque hemorrhage. Some ruptures are clinically silent and can heal. In a ruptured plaque, the necrotic material that comes in contact with the blood contains TF and is highly thrombogenic. The adjacent endothelium has reduced inhibitor (TFPI) levels and lower antiplatelet and fibrinolytic activities, all favoring coagulation. The presence of circulating markers of inflammation suggests that procoagulant inflammatory mediators may also participate.

Once a plaque **ruptures,** the exposed thrombogenic material promotes clot formation in the lumen, causing an occlusive thrombus. Plaque hemorrhage due to rupture of thin, newly formed vessels may occur within a plaque, with or without a subsequent rupture of the fibrous cap. In the latter case, hemorrhage may expand the plaque and so narrow the lumen further. The hemorrhage will be resorbed over time within the plaque, leaving telltale residual hemosiderin-laden macrophages.

Most plaques that rupture show less than 50% luminal stenosis, and over 95% are less than 70% stenosed. Plaque rupture often occurs at the shoulder of the plaque, suggesting that hemodynamic shear stress weakens and tears the fibrous cap. If not repaired, endothelial loss leads to plaque erosion, weakening the fibrous cap and exposing the plaque to blood constituents. Plaque rupture has been associated with (1) areas of inflammation, (2) large lipid core size, (3) thin fibrous cap, (4) decreased smooth muscle cells owing to apoptosis, (5) imbalance of proteolytic enzymes and their inhibitors in the fibrous cap, (6) calcification in the plaque and (7) intraplaque hemorrhage, leading to inside-out rupture of the fibrous cap.

Several circulating markers have been associated with plaque burden, including C-reactive protein (CRP), fibrinogen, soluble VCAM, IL-1, IL-6 and TNF.

Complications of Atherosclerosis

The complications of atherosclerosis depend on the location and size of the affected vessel (Fig. 16-17) and the chronicity of the process.

- **Acute occlusion:** Thrombosis on an atherosclerotic plaque may abruptly occlude a muscular artery (Fig. 16-18). The result is ischemic necrosis (infarction) of the tissue supplied by that vessel, manifested clinically as myocardial infarction, stroke or gangrene of the intestine or lower extremities. Some occlusive thrombi can be dissolved therapeutically by enzymes that activate plasma fibrinolytic activity, including streptokinase and tissue plasminogen activator.
- **Chronic narrowing of the vessel lumen:** As an atherosclerotic plaque grows, it may narrow the lumen, progressively reducing blood flow to tissue served by that artery.

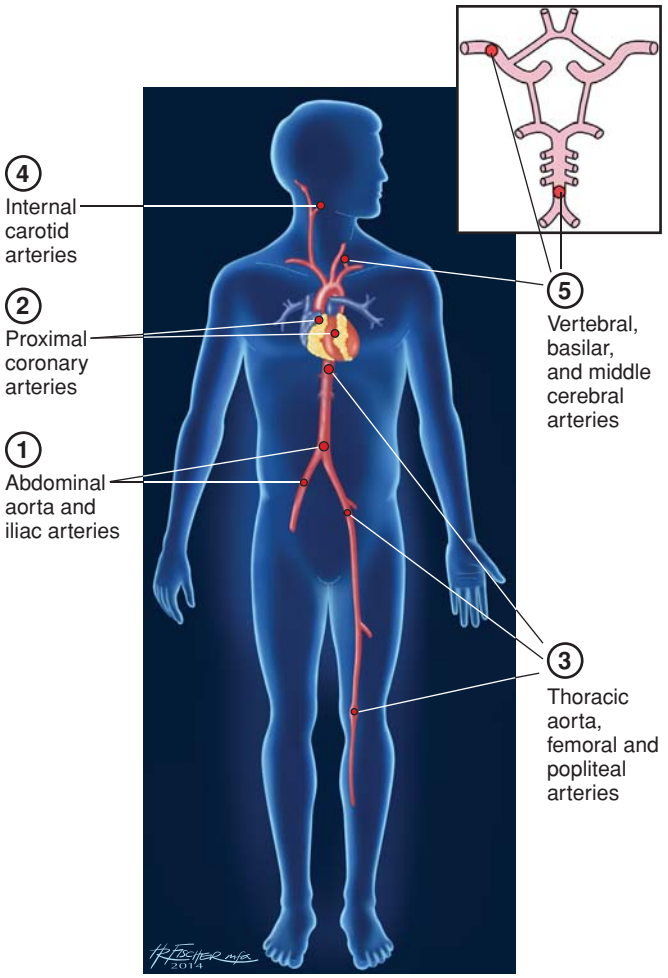

FIGURE 16-17. Sites of severe atherosclerosis in order of frequency.

Chronic ischemia of the affected tissue causes atrophy of the organ, for example, (1) unilateral renal artery stenosis giving rise to renal atrophy, (2) mesenteric artery atherosclerosis causing intestinal stricture or (3) ischemic atrophy of the skin occurring in a diabetic with severe peripheral vascular disease.

- **Aneurysm formation:** The complicated lesions of atherosclerosis may extend into the media of elastic arteries and weaken their walls, so as to allow aneurysm formation, typically in the abdominal aorta. The reduced elastin promotes thinning and ballooning of the wall, while matrix metalloproteinases secreted by smooth muscle cells and macrophages break down collagen. Such aneurysms often contain thrombi, which may embolize. Sudden rupture of these aneurysms, especially in the aorta and cerebrum, may precipitate a vascular catastrophe.
- **Embolism:** A thrombus formed over an atherosclerotic plaque may detach and lodge in a distal vessel. Thus, embolization from a thrombus in an abdominal aortic aneurysm may acutely occlude the popliteal artery, causing gangrene of the leg. Ulceration of an atherosclerotic plaque may also dislodge atheromatous debris and produce so-called cholesterol crystal emboli, which appear as needle-shaped spaces in affected tissues (Fig. 16-19), most often the kidney.

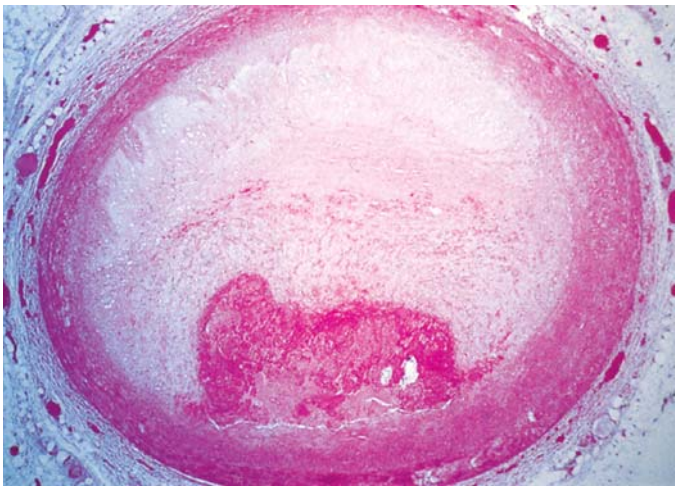

FIGURE 16-18. Coronary artery thrombosis. A microscopic section of a coronary artery shows severe atherosclerosis and a recent thrombus in the narrowed lumen.

Restenosis

Percutaneous transluminal coronary angioplasty (PTCA) is an important treatment for stenotic atherosclerotic vascular disease, especially for the epicardial coronary arteries. With a catheter-based approach, coronary arteries are revascularized by inflating a balloon catheter to dilate the stenotic portion of the artery. However, the balloon causes endothelial damage and tears in the plaque and the media. In 30%–40% of cases in which the vessel lumen is satisfactorily dilated, restenosis occurs within 3–6 months.

Intimal hyperplasia due to smooth muscle cell proliferation and matrix deposition, with or without an organized mural thrombus on the luminal surface, leads to restenosis. In addition, vascular wall remodeling, induced in part by trauma to the vessel wall and involving the adventitia, also results in luminal narrowing through contraction of the arterial wall.

Restenosis is reduced when a stent, a tubular scaffold device, is deployed by a catheter to keep the diseased

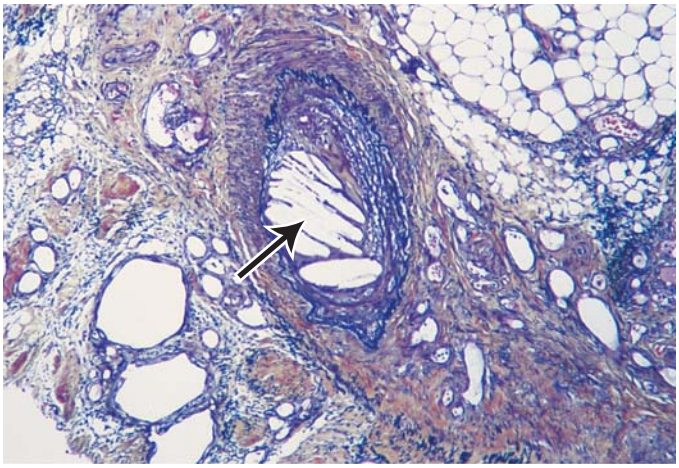

FIGURE 16-19. Cholesterol crystal embolus. Needle-shaped clefts (*arrow*) are seen in an atherosclerotic embolus that has occluded a small artery.

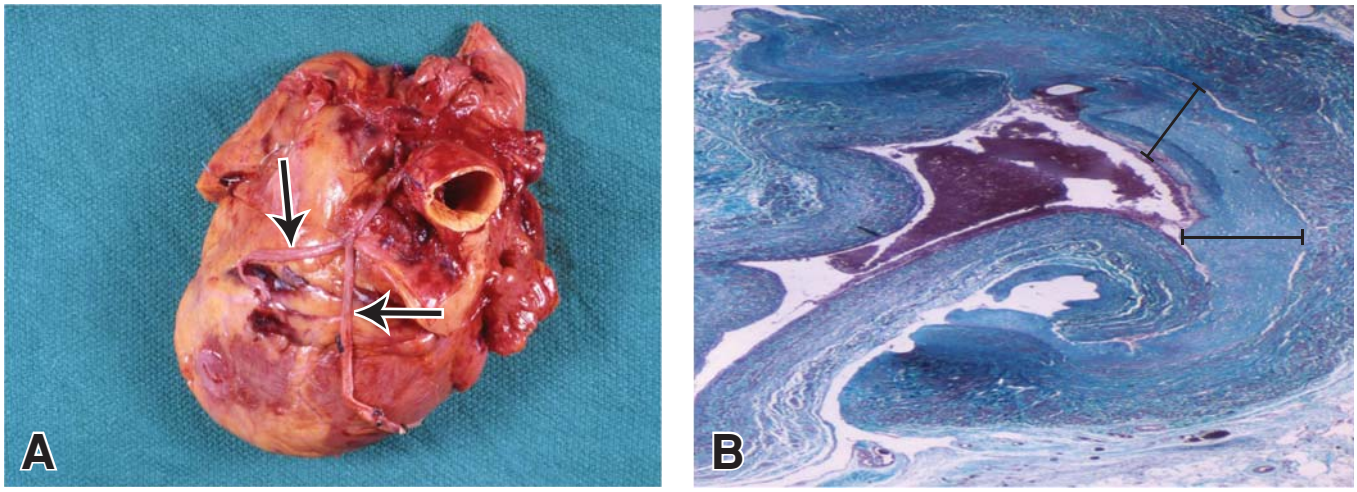

FIGURE 16-20. Saphenous vein aortocoronary bypass. A. Saphenous vein aortocoronary bypass on the surface of the heart (epicardium) (*arrows*). **B.** Distal anastomosis site with atherosclerotic coronary artery (*brackets*).

atherosclerotic artery open. Originally, bare metal stents were used, but because of frequent restenosis, these have been replaced by stents coated with biocompatible polymers and biologically active agents, with much less restenosis. For example, drug-eluting stents with antiproliferative agents block cell cycle progression and thus inhibit overgrowth of smooth muscle cells in the vessel wall. Although long-term complications are not fully known, especially as they relate to thrombosis, drug-eluting stents are used extensively.

Transplanted saphenous veins are used as autografts in coronary artery bypass operations and undergo a series of adaptive and reparative changes. These include (1) intimal thickening associated with phlebosclerosis, (2) occasional medial calcification, (3) focal muscle cell hypertrophy and, eventually, (4) adventitial scarring. Venous grafts in place for a few years develop atherosclerotic plaques indistinguishable from those found in native coronary arteries (Fig. 16-20). Half of bypass grafts occlude within 5–10 years as a result of neointimal hyperplasia and atherosclerosis.

Risk Factors for Atherosclerosis

Factors associated with a twofold or greater risk of ischemic heart disease include:

- **Hypertension:** High blood pressure increases the risk of myocardial infarction. Recent evidence indicates that both diastolic and systolic hypertension contribute equally to this increased risk. Men with systolic blood pressures over 160 mm Hg have almost triple the incidence of myocardial infarction compared to those with systolic pressures under 120 mm Hg. The use of antihypertensive drugs has significantly reduced myocardial infarction and stroke.
- **Blood cholesterol level:** Serum cholesterol levels correlate with development of ischemic heart disease and account for much of the geographic variation in the incidence of this condition. Absent genetic disorders of lipid metabolism (see below), blood cholesterol correlates strongly with dietary intake of saturated fat. Use of cholesterol-lowering drugs lowers the risk of myocardial infarction. Total serum cholesterol does not necessarily predict risk of ischemic heart disease, since cholesterol is transported by atherogenic and antiatherogenic lipoproteins. Thus, therapeutic decisions are mainly based on LDL cholesterol levels.
- **Cigarette smoking:** Coronary and aortic atherosclerosis are more severe and extensive in cigarette smokers than in nonsmokers, and the effect is dose related (see Chapter 8). Thus, smoking markedly increases the risk of myocardial infarction, ischemic stroke and abdominal aortic aneurysms.
- **Diabetes:** Diabetics are at increased risk for occlusive atherosclerotic vascular disease in many organs. However, the relative contribution of carbohydrate intolerance alone, as opposed to the hypertension and hyperlipidemias common in diabetics, is not well defined (see Chapter 13).
- **Increasing age and male sex:** Both correlate strongly with the risk of myocardial infarction, but probably as reflections of accumulated effects of other risk factors.
- **Physical inactivity and stressful life patterns:** These factors correlate with increased risk of ischemic heart disease, but their role in the evolution of atherosclerosis is not clear.
- **Homocysteine:** Homocystinuria is a rare autosomal recessive disease caused by mutations in the gene encoding cystathionine synthase. The disorder causes premature and severe atherosclerosis. Mild elevations of plasma homocysteine are common and are an independent risk factor for atherosclerosis of the coronary arteries and other large vessels. The increased risk is similar in magnitude to those of smoking and hyperlipidemia. Homocysteine is toxic to endothelial cells and impairs several anticoagulant mechanisms in endothelial cells. It inhibits thrombomodulin on the endothelial cell surface, antithrombin III–binding activity of heparan sulfate proteoglycan, binding of tissue plasminogen activator and ecto-ADPase activity on the endothelial cell surface, the last of which promotes platelet aggregation. In addition, oxidative interactions between homocysteine, lipoproteins and cholesterol further complicate the situation.

Low dietary folate intake may aggravate genetic predispositions to hyperhomocysteinemia, but it is not known whether folic acid treatment protects from atherosclerotic vascular disease.

- **C-reactive protein:** CRP is an acute phase reactant mainly produced by hepatocytes. It is a serum marker for systemic inflammation and has been linked to an increased risk of myocardial infarction and ischemic stroke. This observation, together with the presence of CRP in atherosclerotic plaques, suggests that systemic inflammation may contribute to atherogenesis.

Infection and Atherosclerosis

Seroepidemiologic studies suggest that some infectious agents may contribute to atherosclerosis. *Chlamydia pneumoniae* and cytomegalovirus have been the most studied, although there is also interest in *Helicobacter pylori*, herpesvirus and others. DNA from these agents has been found in human atherosclerotic lesions, but the nature of this association is obscure.

Lipid Metabolism

Since Rudolf Virchow in the 19th century first identified cholesterol crystals in atherosclerotic lesions, considerable information has accumulated on lipoproteins and their roles in lipid transport and metabolism in atherosclerosis. Cholesterol and other lipids (mainly triglycerides) are insoluble, and lipoprotein particles function as special transporters (Table 16-6; Fig. 16-21). These particles differ in protein and lipid composition, size and density. They are categorized according to density:

- Chylomicrons
- Very-low-density lipoproteins (VLDLs)
- LDLs
- High-density lipoproteins (HDLs)

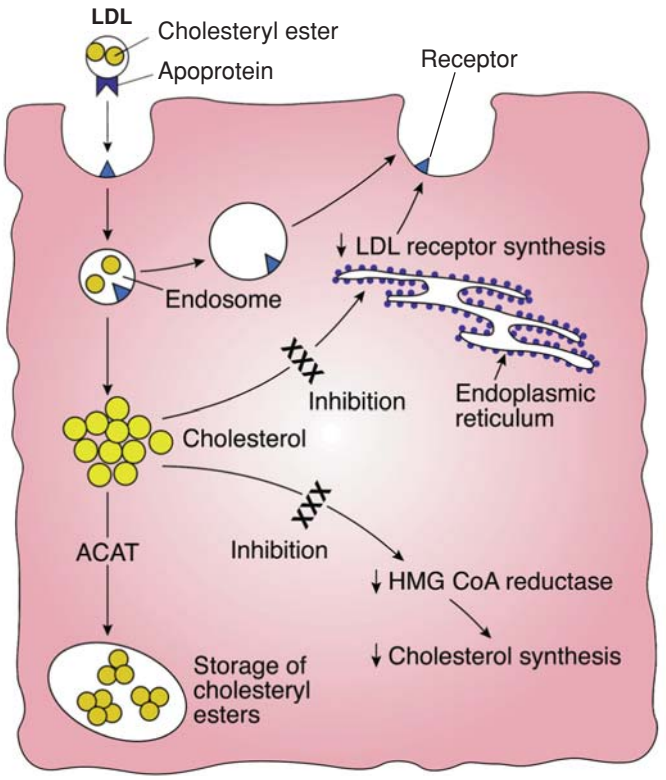

FIGURE 16-21. The relationship between circulating low-density lipoprotein (LDL) cholesterol, LDL receptors and the synthesis of cholesterol. LDL, which contains cholesteryl esters, is taken up by cells into vesicles by a receptor-mediated pathway to form an endosome. The receptor and lipids are dissociated, and the receptor is returned to the cell surface. The exogenous cholesterol, now in the cytoplasm, causes a reduction in receptor synthesis in the endoplasmic reticulum and inhibits the activity of hydroxymethylglutaryl–coenzyme A (HMG–CoA) reductase in the cholesterol-synthesizing pathway. Excess cholesterol in the cell is esterified to cholesteryl esters and stored in vacuoles. *ACAT* = acyl-CoA: cholesterol acyltransferase.

TABLE 16-6
THE APOLIPOPROTEINS

Apolipoprotein	Approximate Molecular Weight	Major Density Class	Major Sites of Synthesis in Humans	Major Function in Lipoprotein Metabolism
AI	28,000	HDL	Liver, intestine	Activates lecithin:cholesterol acyltransferase
AII	18,000	HDL	Liver, intestine	
AIV	45,000	Chylomicrons	Intestine	
B-100	250,000	VLDL, IDL, LDL	Liver	Binds to LDL receptor
B-48	125,000	Chylomicrons, VLDL, IDL	Intestine	
CI	6500	Chylomicrons, VLDL, HDL	Liver	Activates lecithin:cholesterol acyltransferase
CII	10,000	Chylomicrons, VLDL, HDL	Liver	Activates lipoprotein lipase
CIII	10,000	Chylomicrons	Liver	Inhibits lipoprotein uptake by the liver
D	20,000	HDL		Cholesteryl ester exchange protein
E	40,000	Chylomicrons, VLDL, HDL	Liver, macrophage	Binds to E receptor system

HDL = high-density lipoprotein; IDL = intermediate-density lipoprotein; LDL = low-density lipoprotein; VLDL = very-low-density lipoprotein.

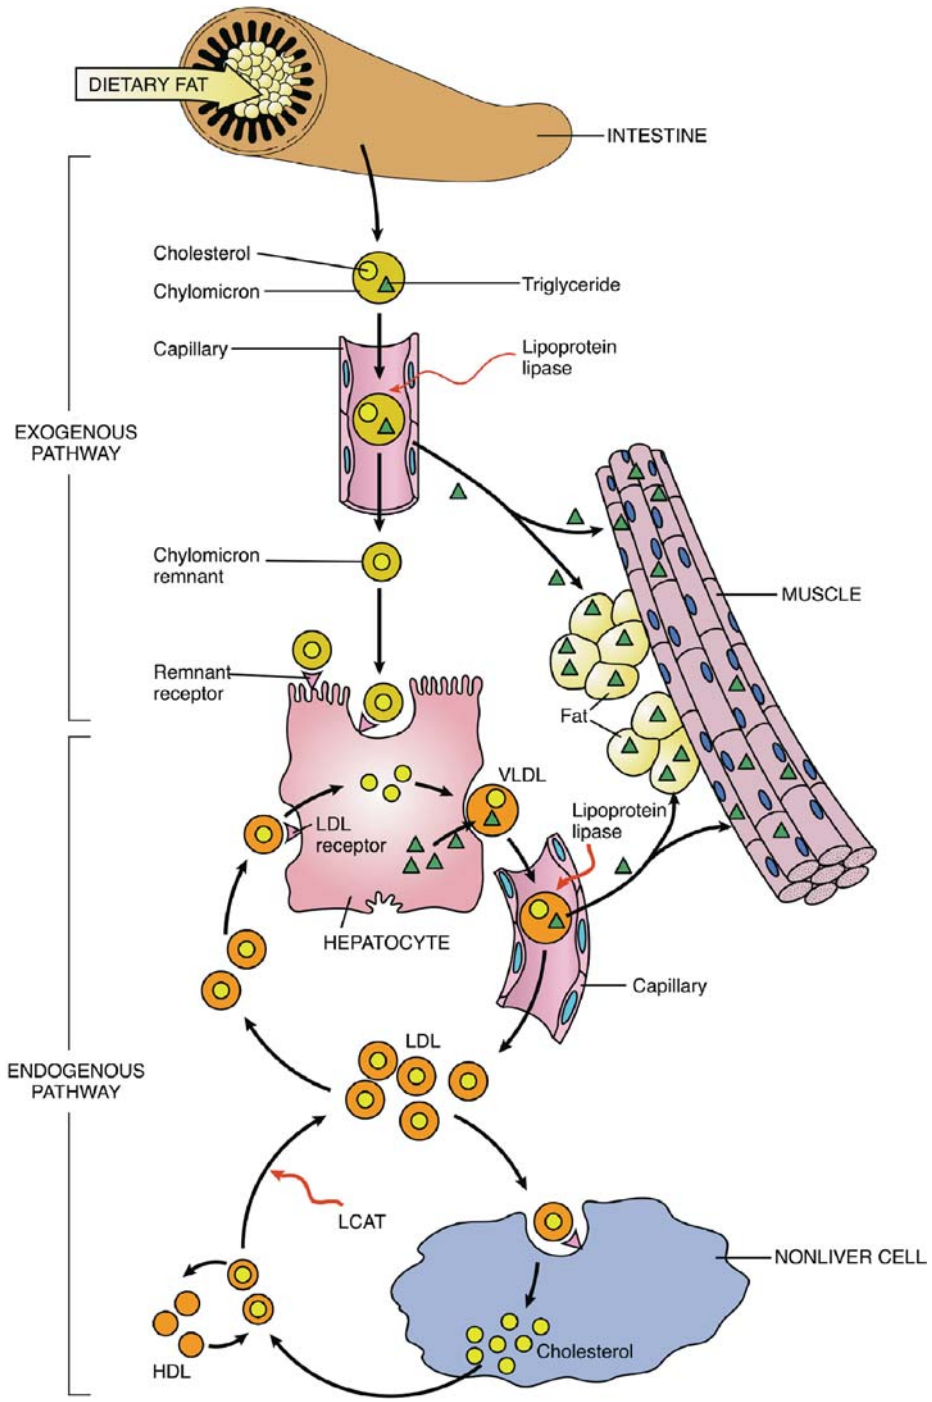

FIGURE 16-22. Exogenous and endogenous cholesterol transport pathway. In the exogenous pathway, cholesterol and fatty acids from food are absorbed through the intestinal mucosa. Fatty acid chains are linked to glycerol to form triglycerides. Triglycerides and cholesterol are packaged into chylomicrons that are returned via the lymph to the blood. The lipids are coupled to proteins by enzymes such as the microsomal transfer protein complex. In the capillaries (mainly of fat tissue and muscle, but also other tissues), the ester bonds holding the fatty acids in triglycerides are split by lipoprotein lipase. Fatty acids are removed, leaving cholesterol-rich lipoprotein remnants. These bind to special remnant receptors and are taken up by liver cells. The cholesterol of the remnant is either secreted into the intestine, largely as bile acids, or packaged as very-low-density lipoprotein (VLDL) particles, which are then secreted into the circulation. This is the first step in the endogenous cycle. In fat or muscle tissue, the triglyceride is removed from the VLDLs with the aid of lipoprotein lipase. The intermediate-density lipoprotein (IDL) particles (not shown) remain in the circulation. Some IDLs are immediately taken up by the liver via the mediation of low-density lipoprotein (LDL) receptors for apoB/E. The remaining IDLs in the circulation are either taken up by nonliver cells or converted to LDLs. Most of the LDLs in the circulation bind to hepatocytes or other cells and are removed from the circulation. High-density lipoproteins (HDLs) take up cholesterol from cells. This cholesterol is esterified by the enzyme lecithin:cholesterol acyltransferase (LCAT), after which the esters are transferred to LDLs and taken up by cells.

Each of these has a lipid core with associated proteins (apolipoproteins) (Table 16-6). The metabolic pathways for lipoproteins containing B apolipoproteins (apoB) are two major cascades, one from the intestine and the other from the liver (Fig. 16-22).

EXOGENOUS PATHWAY: This metabolic route involves chylomicrons containing the protein apoB-48, secreted by the intestine. After secretion, chylomicrons rapidly acquire apoCII and apoE from HDL. These triglyceride-rich lipoproteins mainly transport lipid from intestine to liver. The triglycerides in chylomicrons are hydrolyzed by lipoprotein lipase at the surface of capillary endothelial cells. ApoCII activates lipoprotein lipase, which removes triglycerides and converts chylomicrons to "remnants," and finally to intermediate-density lipoproteins (IDLs). Hepatocytes take up chylomicron remnants through an apoE-mediated (remnant) receptor process.

ENDOGENOUS PATHWAY: This network of reactions involves triglyceride-rich lipoproteins containing apoB-100 secreted by the liver. Liver VLDL particles acquire apoCII and apoE from HDL shortly after their secretion. The triglycerides on VLDL are hydrolyzed by lipoprotein lipase. The particles containing apoB-100 are initially converted to IDLs, and then to LDLs. Hepatic lipoprotein lipase converts IDL to LDL, at least in part, at which point most apoCII and apoE dissociates from the particles and reassociates with HDL.

Lipoprotein lipase acts both as a triglyceride hydrolase and, more importantly, as a phospholipase. LDL, which contains apoB-100, interacts with high-affinity receptors on hepatocytes and other cells, including smooth muscle cells, fibroblasts and adrenal cells (Fig. 16-22). Interaction of LDL with its receptor initiates receptor-mediated endocytosis, leading to catabolism of LDL.

HIGH-DENSITY LIPOPROTEIN: HDL containing apoAI and apoAII is synthesized by several pathways. These include direct secretion of HDL by intestine and liver, and transfer of lipid and apolipoprotein constituents released during lipolysis of lipoproteins that contain apoB. Two major functions have been proposed for HDL: (1) a reservoir for apolipoproteins, mainly apoCII and apoE, and (2) interaction with cells in the transport system to carry extrahepatic cholesterol, including that in the arterial wall, to the liver for elimination. The latter function has been called **reverse cholesterol transport**. The cholesterol removed from cells is principally free cholesterol, which is rapidly esterified to cholesteryl esters. The latter are transferred to the cores of lipoprotein particles or are exchanged to VLDL and LDL. These transfers are mediated by specific transfer proteins (e.g., cholesterol ester transfer protein [CETP]). Defects in cholesteryl ester transfer and exchange lead to dyslipoproteinemia, increased intracellular cholesteryl ester concentrations and premature atherosclerosis.

HDL is referred to as "good" cholesterol. ***An inverse correlation between ischemic heart disease and HDL cholesterol levels has been established.*** Factors that increase HDL levels include female gender, estrogens, vigorous exercise and moderate alcohol consumption. Decreased HDL occurs with diets low in fat or high in polyunsaturated fats, truncal obesity, diabetes, smoking and androgen administration.

LOW-DENSITY LIPOPROTEIN: LDL contains apoB-100 and cholesterol esters as its main lipid entity. LDLs are heterogeneous in particle density, a characteristic that correlates with differences in atherogenicity. Macrophages, endothelial cells and smooth muscle cells in atherosclerotic lesions can oxidize LDL, thereby increasing LDL atherogenicity, facilitating LDL recognition by the macrophage scavenger receptor and leading to massive cholesterol uptake by macrophages. **Oxidized lipoproteins** also affect other processes that may contribute to atherogenesis, including regulation of vascular tone, activation of inflammatory and immune responses and coagulation. Autoantibodies to oxidized LDL are detected in both plasma and plaques in patients with atherosclerosis, and may be important in plaque development. Oxidized LDLs are toxic to vascular wall cells, may disrupt endothelial integrity and promote the accumulation of cell debris within atheromas. They are also chemotactic for macrophages, thereby increasing their accumulation in atheromas even more. Nonetheless, clinical trials of antioxidants to

TABLE 16-7
MOLECULAR DEFECTS IN DYSLIPOPROTEINEMIAS

Disease	Genetic Defect	Clinical Features
Apolipoprotein Defects		
ApoAI deficiency	ApoA1 truncations or rearrangements (11q23)	Absent HDL, severe atherosclerosis
ApoAI variants	ApoA1 point mutations (11q23)	Reduced HDL, variable atherosclerosis
Abetalipoproteinemia (absence of both apoB-100 defects, absence of atherosclerosis and apoB-48)	Microsomal triglyceride protein mutations (4q22–24)	Ataxia, malabsorption, hemolytic anemia, visual
ApoB-100 absence	Unknown (2p24)	Mild ataxia, malabsorption, absence of atherosclerosis
ApoCII deficiency	ApoCII mutations (19q13.2)	Type I hyperlipidemia: severe hypertriglyceridemia, variable atherosclerosis
ApoE variants	ApoE mutations (19q13.2)	Type III hyperlipidemia: elevated triglycerides, premature atherosclerosis
Enzyme Defects		
Lipoprotein lipase deficiency	Lipoprotein lipase mutations (8p22)	Type I hyperlipidemia: hypertriglyceridemia; minimal atherosclerosis
Hepatic lipase deficiency	Hepatic lipase mutations (15q21–23)	Elevations of IDL and HDL; severe atherosclerosis
Lecithin:cholesterol acyltransferase (LCAT) deficiency	LCAT mutations (16q22.1)	Mild hypertriglyceridemia; reduced HDL; corneal opacities; variable atherosclerosis
Receptor Defect		
Familial hypercholesterolemia	LDL receptor mutations (19p13.2)	Type II hyperlipidemia: severe elevation of LDL; premature atherosclerosis

Apo = apoprotein; HDL = high-density lipoprotein; IDL = intermediate-density lipoprotein; LDL = low-density lipoprotein.

prevent ischemic heart disease have not demonstrated any protection. An interesting therapeutic strategy is related to the inhibition of proprotein convertase subtilisin kexin type 9 (PCSK9), an enzyme that promotes degradation of the LDL receptor and thus impairs clearance of LDL.

Heritable Dyslipoproteinemias

Familial clustering of ischemic heart diseases is well documented (Table 16-7).

FAMILIAL HYPERCHOLESTEROLEMIA: The 1985 Nobel Prize was awarded to Brown and Goldstein for discovering the LDL receptor. They identified the pathways regulating cholesterol homeostasis (Fig. 16-21) and facilitated our understanding of receptor-mediated endocytosis and regulation of cell membrane receptors. The LDL receptor is a cell surface glycoprotein that regulates plasma cholesterol by mediating endocytosis and recycling of apoE, the major plasma cholesterol transport protein. Mutations in the LDL receptor gene, on the short arm of chromosome 19, give rise to familial hypercholesterolemia (FH), an autosomal dominant disease for which about 1 in 500 people are heterozygotes and 1 in a million are homozygotes.

Most untreated homozygotes die from coronary artery disease before the age of 20. Among people under 60 years of age who have suffered a myocardial infarction, 5% are heterozygous for familial hypercholesterolemia. Such heterozygotes have plasma LDL levels that are twice normal, whereas homozygotes exhibit a 6- to 10-fold increase in plasma LDL. Heterozygote patients also suffer from premature myocardial infarction but at a later age than do homozygotes (40–45 years of age in men).

More than 400 mutant alleles for familial hypercholesterolemia are known, including point mutations, insertions and deletions. These mutations fall into five main classes, based on their effects on receptor protein function (Fig. 16-23). Genetic issues in familial hypercholesterolemia are discussed more fully in Chapter 6.

In addition to accelerated accumulation of cholesterol in arteries (premature atherosclerosis), LDL cholesterol also deposits in skin and tendons to form xanthomas (Fig. 16-24). In some cases (before age 10 in homozygotes), an *arcus lipoides* is present in the cornea.

APOLIPOPROTEIN E: Genetic variations in various apoproteins are also accompanied by alterations in LDL levels. Polymorphisms in apoE and variants of apolipoprotein AI and AII have been observed. Apolipoprotein E is one of the main protein constituents of VLDL and of a subclass of HDL. The gene locus that codes for apoE is polymorphic; three common alleles, E2, E3 and E4, code for three major apoE isoforms and determine the six apoE phenotypes. Some 20% of the variability in serum cholesterol has been attributed to apoE polymorphism. In men, the apoE 3/2 phenotype is associated with a 20% lower LDL level than the most common phenotype, apoE 3/3. By contrast, the E4 allele is associated with elevated serum cholesterol. Interestingly, the E2 allele is increased and E4 decreased among male octogenarians. The E4 allele is also a major risk factor for late-onset Alzheimer disease. Patients who display E2/2 clear chylomicron remnants and IDLs poorly and have familial type III hyperlipoproteinemia, with premature atherosclerosis.

HIGH-DENSITY LIPOPROTEIN: The genes for apolipoproteins AI and CIII are on chromosome 11 and are physically linked, whereas the gene for AII is on chromosome 1.

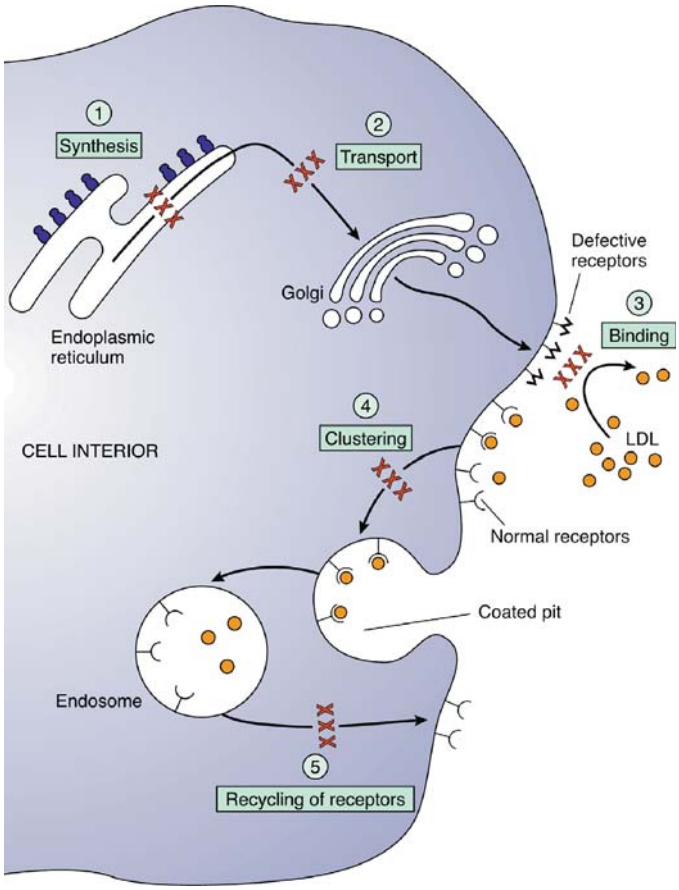

FIGURE 16-23. Mutations of the low-density lipoprotein (LDL) receptor in familial hypercholesterolemia.

Polymorphisms of apoAI are associated with premature atherosclerosis, as are rare cases of hereditary apoAI deficiency. Hypertriglyceridemia is often associated with low HDL cholesterol.

LIPOPROTEIN (a) (Lp[a]): Lp(a) is an LDL-like particle to which the glycoprotein apo(a) is attached through a disulfide bridge with apoB-100. High circulating levels of Lp(a) are associated with an increased risk of atherosclerosis of the coronary arteries and larger cerebral vessels in both sexes. Plasma levels of this cholesterol-rich lipoprotein vary greatly (<1 to >140 mg/dL) and appear to be independent of LDL levels. The Lp(a)-specific protein, apo(a), has been detected in atherosclerotic lesions, and high Lp(a) levels correlate with target organ damage in hypertensive patients.

Apo(a) is encoded by a gene on chromosome 6 (6q2.7), close to the gene for plasminogen, to which apo(a) is highly homologous. Apo(a) and plasminogen display similar domains that mediate interactions with fibrin and cell surface receptors. Lp(a) enhances cholesterol delivery to injured blood vessels, suppresses generation of plasmin and promotes smooth muscle proliferation. Thus, it may be an important link between atherosclerosis and thrombosis.

Lp(a) plasma levels are heritable and not altered by most cholesterol-lowering drugs, although they are reduced by nicotinic acid. Taken together, this information distinguishes a risk factor that appears superficially to be related to serum cholesterol but the effect of which may actually be linked to an alteration in clot lysis.

HYPERTENSIVE VASCULAR DISEASE

There has been a significant increase in the prevalence of hypertension worldwide, with dramatic increases since the beginning of the 20th century. Hypertension affects over 30% of the population of the United States. It is present in more than half of cases of myocardial infarction, stroke and chronic renal disease. It is included in the "metabolic syndrome" (see Chapter 13), along with hyperglycemia, insulin resistance, dyslipidemia and obesity. Hypertension is present in 95% or greater of ascending aortic dissections or rupture. At least 3/4 of patients with dissecting aortic aneurysm, intracerebral hemorrhage or myocardial wall rupture also have elevated blood pressure. Blacks are particularly plagued by hypertension and are more likely than are whites to experience severe complications.

In 95% of patients, hypertension occurs without an identifiable cause, a condition referred to as **primary** hypertension. A number of diseases contribute to the development of hypertension, including renal artery stenosis, most forms of chronic renal disease, diabetes mellitus, primary elevation of aldosterone levels, Cushing syndrome, pheochromocytoma, hyperthyroidism, coarctation of the aorta and renin-secreting tumors. In addition, people with severe atherosclerosis may have high systolic pressure because a sclerotic aorta cannot properly absorb the kinetic energy of the pulse wave. Whatever the etiology, effective treatment of hypertension prolongs life.

The definition of hypertension depends on a statistical estimate of the distribution of systolic and diastolic blood pressures in the general population. Both systolic and diastolic pressures are important in determining the risk of cardiovascular disease, especially that due to atherosclerosis. Over the course of the day, blood pressure varies widely, depending on exertion, emotional state and other poorly understood factors. It also exhibits a circadian rhythm, falling at night or during sleep, as sympathetic nervous system tone declines. The mean systolic blood pressure in 20-year-old men is about 130 mm Hg, but 95% confidence limits range from 105 to 150 mm Hg. Average systolic blood pressure increases with age, so that in 80-year-olds, it reaches 170 mm Hg, with 95% confidence limits from 125 to 220. The World Health Organization (WHO) defines hypertension as systolic pressure above 160 mm Hg or diastolic pressure above 90.

ETIOLOGIC FACTORS: Blood pressure is the product of cardiac output and systemic vascular resistance to blood flow. The most widespread hypothesis holds that primary hypertension results from an imbalance in the interactions between these mechanisms (Fig. 16-25). However, both of these functions are critically influenced by renal function and sodium homeostasis. Frequency of hypertension increases as the glomerular filtration rate (GFR) falls even with mild renal dysfunction. Reduced GFR causes sodium retention and volume expansion, which should be compensated by a decrease in tubular sodium reabsorption. Impaired renal tubular sodium handling and reduced GFR are likely to be important in hypertension that afflicts patients with chronic kidney disease due to diabetes or aging.

A complex endocrine axis centers on the renin–angiotensin system (RAS), which is both hormonal and tissue based, the latter present in many organs, including the brain. The RAS is important in regulation of normal blood pressure, and dysregulation of RAS is implicated in over 2/3 of the cases of hypertension. Renal artery occlusion or dietary salt restriction leads to increased renal secretion of renin. Renin is a protease that cleaves angiotensinogen to a decapeptide, angiotensin I. In turn, angiotensin I is converted to angiotensin II by ACE on the endothelial surface. Angiotensin II causes vasoconstriction and also affects centers in the brain

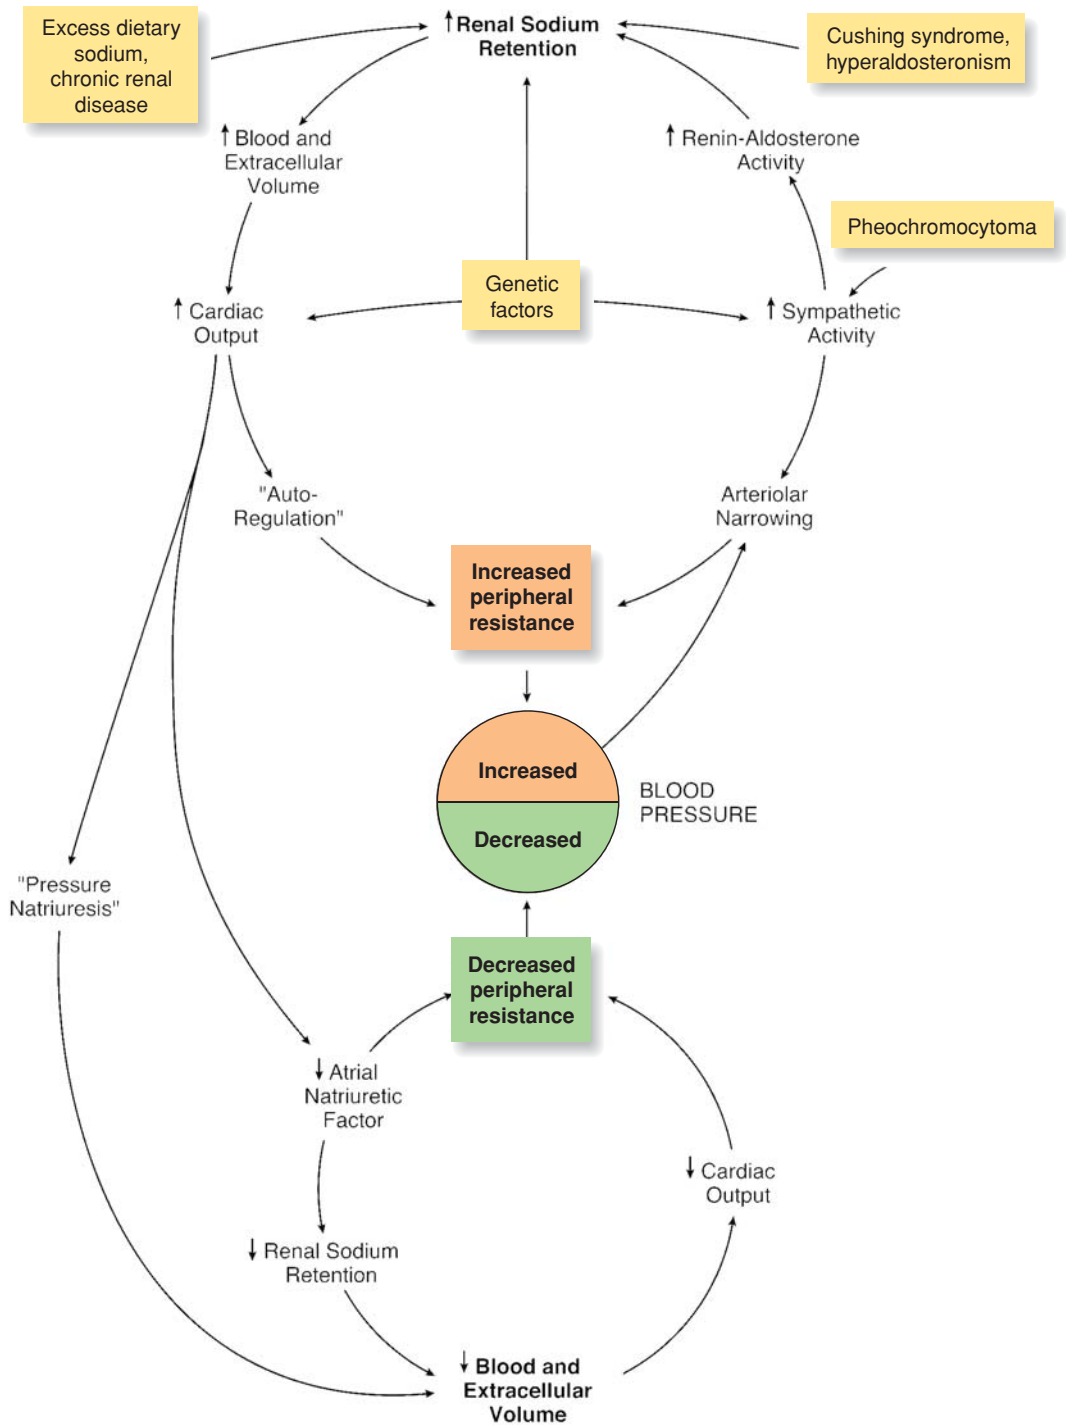

FIGURE 16-25. Factors contributing to hypertension and the counterregulatory factors that lower blood pressure. An imbalance in these factors results in the increased peripheral resistance that is responsible for most cases of essential (primary) hypertension. Note the central role of peripheral resistance.

that control sympathetic outflow and stimulate adrenal aldosterone release. Aldosterone increases sodium reabsorption by the renal tubules. The net effect of all these actions is increased total body fluid. Thus, the **renin–angiotensin** system elevates blood pressure by three mechanisms:

- Increased sympathetic output
- Increased mineralocorticoid secretion
- Direct vasoconstriction

This axis is antagonized by atrial natriuretic factor (ANF), a polypeptide hormone secreted by specialized cells in the cardiac atria. ANF binds specific receptors in the kidney and increases urinary sodium excretion, thereby opposing angiotensin II–induced vasoconstriction. Secretion of ANF may be controlled by stretch–secretion coupling after atrial distention, a consequence of increased volume, or by as-yet undefined endocrine interactions, possibly involving endothelin-1.

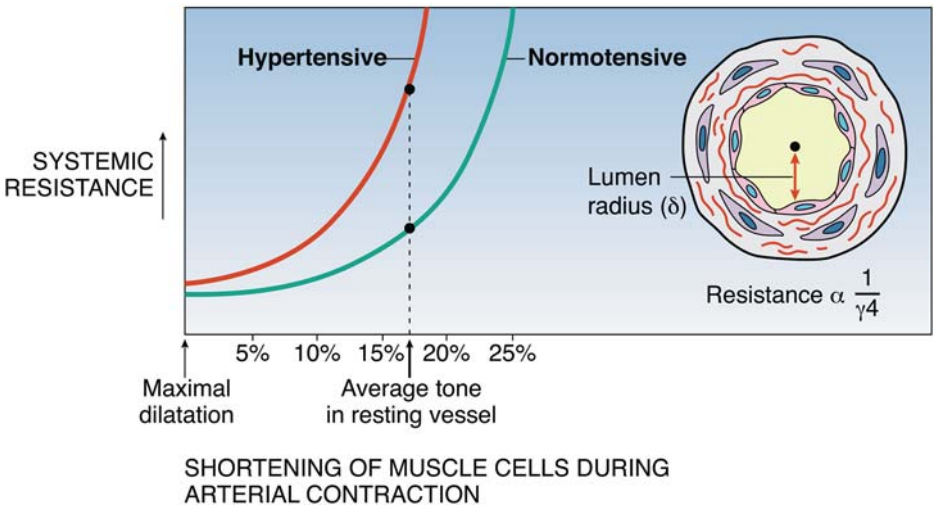

FIGURE 16-26. Structural autoregulation of blood pressure. Hypertension, regardless of its primary cause, increases the ability of the resistance vessel walls to respond to vasoactive stimuli. Resistance is increased even in maximally dilated vessels because the lumen size is decreased in the hypertensive vascular bed. As the smooth muscle cells contract, the increase in vessel wall thickness increases the resistance, which is inversely proportional to the fourth power of the radius of the lumen. Note that at the average resting muscular tone, the resistance in hypertensive patients is considerably higher than normal.

The importance of this hormonal axis in regulating blood pressure in hypertension is demonstrated by the therapeutic success of sympathetic antagonists (β-adrenergic blockers), diuretics and inhibitors of ACE. Nonetheless, no central defect in the renin–angiotensin axis has been identified, in part because the vasculature responds quickly to hemodynamic changes in the tissues by autoregulation (Fig. 16-26).

Extensive mechanisms regulate renal sodium excretion. Renal collecting ducts are important in maintaining sodium balance when alterations in more proximal parts of the nephron occur. Thus, dysregulation of sodium transport at the collecting duct can lead to the greatest deficit in sodium handling. Genetic mutations involving sodium reabsorption at this final segment are strongly associated with hypertension. Defects in the epithelial sodium channel in the renal distal tubule and collecting duct, or defects in signaling pathways regulating its expression, are responsible for several rare genetic forms of hypertension. These include mutations in WNK protein kinases and increased expression of epithelial sodium channels.

In the case of hypertension, the end result of autoregulation is always increased peripheral resistance. For example, hypertension can be induced experimentally by surgically removing large amounts of renal tissue, followed by administering excess sodium and water. Cardiac output, and therefore blood pressure, increases rapidly as a result of the rapid change in blood volume. However, within a few days, pressure-induced diuresis restores near-normal cardiac output and plasma volume. At that point, blood pressure is maintained by increased peripheral resistance. Thus, although the blood pressure elevation is initially due to increased volume, compensatory mechanisms successfully mask the volume changes and cause apparent primary hypertension. Many cases of human hypertension may also result from a process that begins with altered cardiac output, salt metabolism or ANF release.

The Prothrombotic Paradox

Hypertension exposes the arterial tree to increased pulsatile stress. Paradoxically, most major complications of chronic hypertension, such as myocardial infarction and stroke, are thrombotic, rather than hemorrhagic. This is known as the *prothrombotic paradox of hypertension.* This state can result from chronic shear stress and low-grade inflammation. Endothelial dysfunction may be multifactorial and includes decreased activity of vasodilator agents and increased activity of, or increased sensitivity to, vasoconstrictor agents. Enhanced activity of the renin–angiotensin system and kallikrein–kinin system has opposite effects via angiotensin II–converting enzyme, causing vasoconstriction and vasodilation, respectively. Importantly, increased activity of these systems also leads to a hypercoagulable state. Thus, there is an increased load on the myocardium, which gives rise to left ventricular hypertrophy and ventricular and atrial arrhythmias and impairs coronary circulation.

Acquired Causes of Hypertension

Causes of hypertension are identifiable only in a small proportion of cases. These include renal artery stenosis, most forms of chronic renal disease, diabetes mellitus, primary elevation of aldosterone levels (Conn syndrome), Cushing syndrome, pheochromocytoma, hyperthyroidism, coarctation of the aorta and renin-secreting tumors. In addition, people with severe atherosclerosis may have high systolic pressure because a sclerotic aorta cannot properly absorb the kinetic energy of pulse waves, and because they often have renovascular hypertension.

PATHOPHYSIOLOGY: It is likely that many genes contribute small effects to individual cases of hypertension. Environmental factors play a role as well. However, a number of monogenic forms of hypertension have been defined:

- **Glucocorticoid-remediable aldosteronism (GRA):** GRA is an autosomal dominant trait, in which congenital hypertension is mediated by the renal mineralocorticoid receptor. Excess aldosterone production is caused by adrenocorticotropic hormone (ACTH) (see Chapter 27), rather than by the normal secretagogue for aldosterone, angiotensin II. The aldosterone synthase gene on chromosome 8 is normally expressed in the adrenal cortical zona glomerulosa, where the enzyme catalyzes aldosterone biosynthesis. This gene is 95% homologous with the steroid 11β-hydroxylase

gene, which regulates adrenal cortisol biosynthesis. Nearby, on the same chromosome, mutations in aldosterone synthase and 11β-hydroxylase genes create a hybrid gene, with ectopic production of aldosterone in the zona fasciculate, under the control of ACTH. In turn, unrestrained secretion of mineralocorticoids leads to prolonged volume expansion and hypertension.

- **Syndrome of apparent mineralocorticoid excess (AME):** In this autosomal recessive form of early-onset hypertension, the mineralocorticoid receptor is stimulated, despite very low levels of aldosterone. Normally, the mineralocorticoid receptor responds both to aldosterone and to cortisol, albeit much more weakly to the latter. The aldosterone-like activity of cortisol is suppressed when 11β-hydroxysteroid dehydrogenase in renal tubular epithelial cells converts it to cortisone. In AME, inactivating mutations in the gene for this enzyme allow cortisol to accumulate and constitutively stimulate the mineralocorticoid receptor. Interestingly, consumption of large quantities of licorice can produce a similar syndrome, because glycyrrhetinic acid in licorice inhibits 11β-hydroxysteroid dehydrogenase.
- **Liddle syndrome:** This rare autosomal dominant form of hypertension stems from a gain-of-function mutation in a gene on chromosome 16 that codes for the amiloride-sensitive, epithelial sodium channel. Patients have constitutively activated renal tubule sodium channels but low mineralocorticoid levels. Sustained channel activation is due to lack of the repressor activity that normally promotes internalization and degradation of the cell surface channel. This effect causes kidneys to resorb too much salt and water, independently of mineralocorticoids, thereby leading to volume expansion and hypertension.

All mutations that cause hereditary hypertension constitutively increase renal sodium reabsorption. Conversely, diseases, such as pseudohypoaldosteronism type I and Gitelman syndrome (with inactivating mutations in *SLC12A3* encoding the thiazide-sensitive sodium chloride cotransporter), that result in sodium-losing syndromes are associated with profound hypotension. ***Thus, these Mendelian disorders illustrate the central role of sodium homeostasis in determining blood pressure.***

Large genome-wide association studies have reported some loci associated with primary hypertension, including a susceptibility locus in the promoter region of endothelial NOS. Increasing evidence using targeted gene approaches indicates that common polymorphisms of the angiotensinogen gene contribute to primary hypertension: (1) the angiotensinogen locus is linked to elevated blood pressure in sibling pairs, (2) specific angiotensinogen variants have been tied to hypertension in case-control studies and (3) the same variants are associated with increased plasma angiotensinogen.

PATHOLOGY: In most cases of hypertension, the critical lesions are in resistance vessels that control blood flow through the capillary beds and in the kidney. The lumens of these small muscular arteries and arterioles may be restricted by active contraction of the vessel wall or increased vessel wall mass. Thicker vessel walls narrow vascular lumens more than do normal, thinner walls. Over time, chronic hypertension leads to reactive changes in smaller arteries (arteriosclerosis) and arterioles (arteriolosclerosis) throughout the body. Kidneys affected with chronic hypertension have a contracted and granular gross appearance, and microscopically often show tubular and glomerular changes.

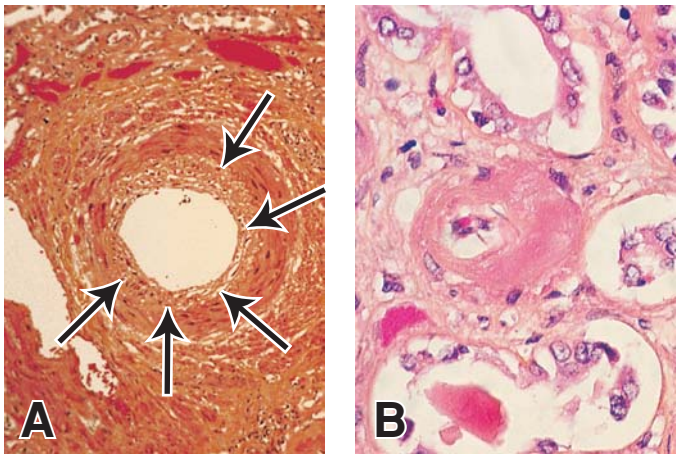

FIGURE 16-27. Benign arteriosclerosis. A. A cross-section of a renal intralobular artery shows irregular thickening of the intima (*arrows*). **B.** A renal arteriole exhibits hyaline arteriolosclerosis (*center*).

Benign arteriosclerosis reflects mild chronic hypertension, the major change being a variable increase in arterial wall thickness (Fig. 16-27A). In the smallest arteries and arterioles, these lesions are referred to as **hyaline arteriosclerosis** and **arteriolosclerosis**. "Hyaline" refers to the glassy scarred appearance of the blood vessel walls by light microscopy. Thickened arterioles reflect deposition of basement membrane material and accumulation of plasma proteins (Fig. 16-27B). The small muscular arteries have new layers of elastin, which manifest as reduplication of the intimal elastic lamina and increased connective tissue. The vascular lesions of benign arteriosclerosis are particularly evident where they result in loss of renal parenchyma, termed **benign nephrosclerosis**. The presence of benign arteriosclerosis is not diagnostic of hypertension, since similar morphologic alterations are common with aging. Hyaline arteriosclerosis may also be present in diabetes.

In **malignant hypertension,** blood pressure is very high, leading to rapidly progressive vascular compromise with the onset of symptomatic disease of the brain, heart or kidney. Blood pressures usually exceed 160/110 mm Hg, but modern antihypertensive therapy has made malignant hypertension a rare disorder. Malignant hypertension produces dramatic microvascular pathologic changes. Segmental constriction and dilation of retinal arterioles in severely hypertensive patients are sufficiently prominent to allow one to make the diagnosis by ophthalmoscopy (see Chapter 33). If blood pressure rises rapidly, retinal arterioles show microaneurysms, focal hemorrhages and retinal scarring. Ischemic necrosis and edema of the retina appear as "cotton wool spots" with the ophthalmoscope. These retinal changes are typical of those in other resistance vessels when pressure rises rapidly.

In malignant hypertension, small muscular arteries show segmental dilation due to necrosis of smooth muscle

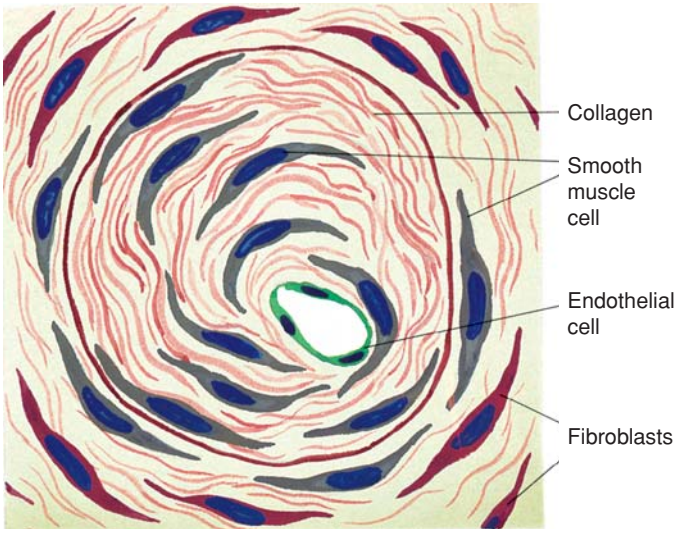

FIGURE 16-28. Arteriolosclerosis. In cases of hypertension, the arterioles exhibit smooth muscle cell proliferation and increased amounts of intercellular collagen and glycosaminoglycans, resulting in an "onion-skin" appearance. The mass of smooth muscle and associated elements tends to fix the size of the lumen and restrict the arteriole's capacity to dilate.

cells. Endothelial integrity is lost in these regions, and increased vascular permeability leads to entry of plasma proteins into the vessel wall, deposition of fibrin and an appearance called **fibrinoid necrosis** (see Chapter 1). Acute injury is rapidly followed by smooth muscle proliferation and a striking concentric increase in the number of layers of smooth muscle cells, producing an "onion-skin" appearance (Fig. 16-28). This form of smooth muscle proliferation may be a response to release of growth factors from platelets and other cells at sites of vascular injury. Together, these changes are labeled **malignant arteriosclerosis** or **arteriolosclerosis,** depending on the size of the vessels affected. In the kidney, lesions of malignant hypertension are known as **malignant nephrosclerosis.**

MÖNCKEBERG MEDIAL SCLEROSIS

Mönckeberg medial sclerosis refers to degenerative calcification of the media of large and medium-sized muscular arteries. The disorder occurs principally in older people and most often involves arteries of the upper and lower extremities. It is also common in advanced chronic renal disease.

PATHOLOGY: Involved arteries are hard and dilated. Microscopically, the smooth muscle of the media is focally replaced by pale-staining, acellular, hyalinized fibrous tissue, with concentric dystrophic calcification. In most cases the internal elastic lamina shows focal calcification. Osseous metaplasia in calcified areas is occasionally observed. Mönckeberg medial sclerosis is distinct from atherosclerosis and ordinarily does not entail any clinically significant impairment. Some assert that in patients with chronic renal disease, the features of Mönckeberg medial sclerosis in arteries should be considered a form of accelerated atherosclerosis.

FIGURE 16-29. Raynaud phenomenon. The tips of the fingers show marked pallor.

RAYNAUD PHENOMENON

Raynaud phenomenon refers to intermittent bilateral attacks of ischemia of the fingers or toes, and sometimes the ears or nose. It is characterized by severe pallor (Fig. 16-29) and is often accompanied by paresthesias and pain. Symptoms are precipitated by cold or emotional stimuli and relieved by heat. Primary cold sensitivity of the Raynaud type is more common in women, and it often starts in the late teens. It is bilateral and symmetric and, on rare occasions, may lead to ulcers or gangrene of the tips of digits. The hands are more commonly affected than feet.

Raynaud phenomenon may occur as an isolated disorder or as part of systemic diseases of connective tissue (collagen vascular disorders), particularly scleroderma and systemic lupus erythematosus. It includes primary and secondary cold sensitivity, livedo reticularis and acrocyanosis. Whatever its cause, Raynaud phenomenon reflects vasospasm of the arteries and arterioles in the skin. Dysregulation of vascular tone by sympathetic nerve activity and by neurohumoral factors may play a role in its pathogenesis. Phosphodiesterase type 5 inhibitors induce vasodilation and have shown some therapeutic value.

FIBROMUSCULAR DYSPLASIA

Fibromuscular dysplasia is a rare noninflammatory thickening of large and medium-sized muscular arteries, which is distinct from atherosclerosis and arteriosclerosis. The cause is unknown; however, it may be developmental in nature. Renal artery stenosis due to this condition is an important cause of renovascular hypertension, although fibromuscular dysplasia may affect almost any other vessel, including carotid, vertebral and splanchnic arteries. It is typically a disease of women during their reproductive years but may appear at any age, even in childhood.

PATHOLOGY: In most cases, the distal 2/3 of the renal artery and its primary branches have several segmental stenoses, which represent fibrous and muscular ridges that project into the lumen. Microscopically,

these segments show disorderly arrangement and proliferation of the cellular elements of the vessel wall, without necrosis or inflammation. Smooth muscle is replaced by fibrous tissue and myofibroblasts, and the media may be thinned. In some cases, intimal fibroplasia predominates, and in unusual instances, connective tissue encircles the adventitia. Other than renal hypertension, the major complication of fibromuscular dysplasia is dissecting aneurysm owing to thinning of the media of affected arteries.

VASCULITIS

Vasculitis is inflammation and necrosis of blood vessels. It may affect arteries, veins and capillaries (Table 16-8). Vessels may be damaged by immune mechanisms (see Chapter 4), infectious agents, mechanical trauma, radiation or toxins. However, in many cases, no specific cause is determined.

ETIOLOGIC FACTORS: Vasculitic syndromes are thought to involve immune mechanisms, including (1) **deposition of immune complexes,** (2) **direct attack on vessels by circulating antibodies** and (3) **various forms of cell-mediated immunity.** Agents that incite these reactions are largely unknown, although in some instances vasculitis is associated with viral infection.

Serum sickness was one of the first human immunologic disorders to be linked with vasculitis. In animal models of serum sickness, immune complexes and complement are found in local tissue reaction (see Chapter 4). However, in most human cases, immune complexes are only sometimes present, and firm evidence for them in most cases of vasculitis is lacking.

Viral antigens may cause vasculitis. Thus, chronic infection with hepatitis B virus is associated with some cases of polyarteritis nodosa (see below). In this case, viral antigen–antibody complexes circulate and are deposited in the vascular lesions. Human vasculitis has also been associated with other viral infections, including herpes simplex, cytomegalovirus and parvovirus, as well as with several bacterial antigens.

Small vessel vasculitides (e.g., polyangiitis with granulomatosis; see below) are associated with circulating **antineutrophil cytoplasmic antibodies (ANCAs),** but why these autoantibodies appear and how they lead to vasculitis are not known. Infection may play a role in the development of ANCAs. ANCA may cause endothelial damage by activating neutrophils, and antibody titers correlate with disease activity in some cases. ANCA is detected by indirect immunofluorescence assays using patients' sera and ethanol-fixed neutrophils. Common patterns include **perinuclear immunofluorescence (P-ANCA),** mostly against myeloperoxidase, and a more general **cytoplasmic immunofluorescence (C-ANCA),** mainly against proteinase 3.

Neutrophils activated by, for example, TNF degranulate and express myeloperoxidase and proteinase 3 at their surfaces. ANCA, which is present as a response to infection, can then bind and activate the neutrophils. Other autoantibodies that activate neutrophils and injure endothelial cells also occur in vasculitides (Fig. 16-30).

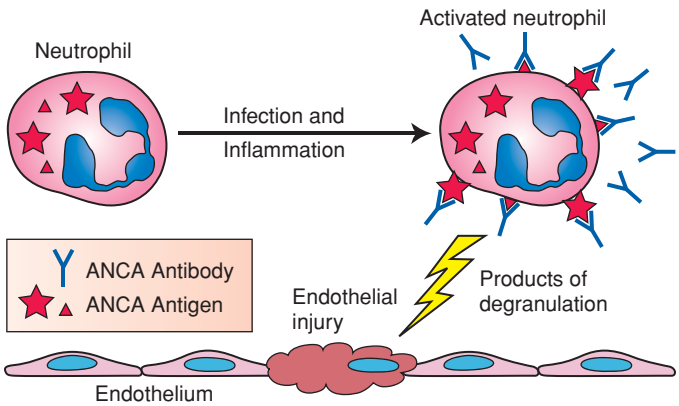

FIGURE 16-30. Model of the pathogenesis of antineutrophil cytoplasmic antibody (ANCA) vasculitis. ANCA antigens are normally found in the neutrophil cytoplasm with very little surface expression. In inflammation and infection, increased cell surface expression of ANCA antigens is induced in the neutrophils. ANCA present in the circulation owing to previous formation through unknown mechanisms binds to these ANCA antigens on the surface, leading to neutrophil activation and interaction with endothelial cells. Neutrophil degranulation releases toxic factors including reactive oxygen species, proteinase 3 (PR3) and myeloperoxidase, and other granule enzymes cause endothelial cell apoptosis and necrosis, leading to endothelial injury.

Polyarteritis Nodosa Is an Acute, Necrotizing Vasculitis

Polyarteritis nodosa affects medium-sized and smaller muscular arteries and, occasionally, larger arteries. It is more common in men than in women. The disease was rare until the 1940s, when there was a striking rise in its incidence. The increased frequency of polyarteritis nodosa at that time seemed to be associated with the widespread use of antisera to bacteria and toxins produced in animals, and with use of sulfonamides. The incidence of polyarteritis nodosa now seems to be subsiding.

PATHOLOGY: The characteristic lesions of polyarteritis nodosa occur patchily in small to medium-sized muscular arteries. However, on occasion they extend into larger arteries, such as renal, splenic or coronary arteries. Each lesion is no more than 1 mm long and may involve part or all of the circumference of the vessel. Fibrinoid necrosis is the most prominent morphologic feature. The medial muscle and adjacent tissues are fused into a structureless eosinophilic mass that stains for fibrin. A vigorous acute inflammatory response envelops the area of necrosis, usually involving the entire adventitia (periarteritis), and extends through the other coats of the vessel (Fig. 16-31). Neutrophils, lymphocytes, plasma cells and macrophages are present in varying proportions, and eosinophils are often conspicuous.

Infarcts are common in involved organs and are caused by thrombosis in affected segments of arteries. Injury to larger arteries may cause small aneurysms (<0.5 cm), especially in branches of the renal, coronary and cerebral arteries. An aneurysm may rupture and, if located in a critical area, has resulted in fatal hemorrhage.

Over time, many vascular lesions start to heal, especially if corticosteroids have been given. Necrotic tissue and inflammatory exudate are resorbed, and the vessel is left with fibrosis of the media and conspicuous gaps in the elastic laminae.

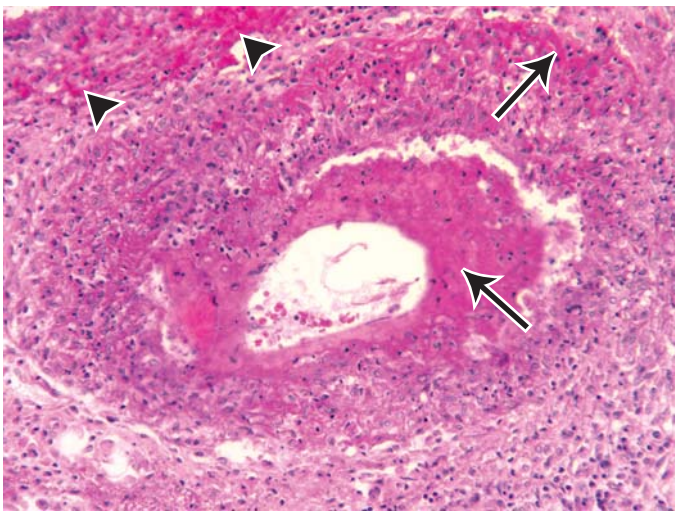

FIGURE 16-31. Polyarteritis nodosa. The intense inflammatory cell infiltrate in the arterial wall and surrounding connective tissue is associated with fibrinoid necrosis (*arrows*) and disruption of the vessel wall with hemorrhage into surrounding tissues (*arrowheads*).

CLINICAL FEATURES: Clinical manifestations of polyarteritis nodosa are variable and depend on the organs affected by the lesions. Kidneys, heart, skeletal muscle, skin and mesentery are most often involved, but lesions may occur in almost any organ, including the bowel, pancreas, lungs, liver and brain. Constitutional symptoms such as fever and weight loss are common. Polyarteritis nodosa–like lesions may occur in viral infections including hepatitis B and C and HIV infection.

Without treatment, polyarteritis nodosa is usually fatal, but anti-inflammatory and immunosuppressive therapy, in the form of corticosteroids and cyclophosphamide, leads to remissions or cures in most patients.

Hypersensitivity Angiitis Is a Response to Exogenous Substances

Hypersensitivity angiitis refers to a broad category of inflammatory vascular lesions that are thought to represent a reaction to foreign materials (e.g., bacterial products or drugs). In the case of vascular lesions confined predominantly to skin, the terms **leukocytoclastic vasculitis** (referring to nuclear debris from disintegrating neutrophils), **cutaneous vasculitis** or **cutaneous necrotizing venulitis** (emphasizing the predominant involvement of the venules) are applied. **Systemic hypersensitivity angiitis,** also referred to as **microscopic polyangiitis,** affects many of the same organs as polyarteritis nodosa but is restricted to the smallest arteries and arterioles.

CLINICAL FEATURES: Cutaneous vasculitis may follow administration of many drugs, including aspirin, penicillin and thiazide diuretics. It is also commonly related to such disparate infections as streptococcal and staphylococcal illnesses, viral hepatitis, tuberculosis and bacterial endocarditis. The disease typically presents as palpable purpura, principally on the lower extremities. Microscopically, superficial cutaneous venules show fibrinoid necrosis with acute inflammation. Cutaneous vasculitis is generally self-limited (see Chapter 28).

Systemic hypersensitivity angiitis may be an isolated entity or a feature of other conditions, including collagen vascular diseases (lupus erythematosus, rheumatoid arthritis, Sjögren syndrome), Henoch-Schönlein purpura, dysproteinemias and several malignancies. Patients with systemic hypersensitivity angiitis may also have cutaneous purpuric lesions. The most feared complication of microscopic polyangiitis is renal involvement, characterized by rapidly progressive glomerulonephritis and renal failure (see Chapter 22). ***Microscopic polyarteritis is strongly associated with P-ANCA.***

Giant Cell Arteritis Mainly Affects the Temporal Arteries

Although it most often affects the temporal artery, granulomatous arteritis (temporal arteritis) may also involve other cranial arteries, the aorta (giant cell aortitis) and its branches and occasionally other arteries. Aortic aneurysms and dissection occur. The average age at onset is 70 years, and it is rare before age 50. Giant cell arteritis is the most common vasculitis; its incidence rises with age and may reach 1% by 80 years of age. Women are slightly more often affected than men. The age at onset helps differentiate it from other vasculitides that may involve the same vessels in younger people, such as Takayasu disease.

PATHOPHYSIOLOGY: The etiology of giant cell arteritis is obscure. Its association with HLA-DR4 and its occurrence in first-degree relatives support a genetic component in its pathogenesis. The morphologic alterations, including activated $CD4^+$ T-helper cells and macrophages, and the association of the disease with a specific polymorphism of ICAM-1 suggest an immune reaction. B lymphocytes are lacking. Macrophages at the border of the intima and media produce matrix metalloproteinases that digest extracellular matrix. ANCA is absent in giant cell arteritis. Generalized muscle aching and widespread distribution of its manifestations are consistent with a relationship to rheumatoid diseases.

PATHOLOGY: Affected vessels are cord-like with nodular thickening. Lumens are reduced to slits or may be obliterated by a thrombus (Fig. 16-32A). Microscopically, the media and intima show granulomatous inflammation; aggregates of macrophages, lymphocytes and plasma cells are admixed with variable numbers of eosinophils and neutrophils. Giant cells tend to be distributed at the internal elastic lamina (Fig. 16-32B) but vary widely in number. Foreign body giant cells and Langhans giant cells are both seen. Foci of necrosis are characterized by changes in the internal elastica, which becomes swollen, irregular and fragmented, and in advanced lesions may completely disappear. Fragments of the elastica occasionally appear in the giant cells. In the late stages, the intima is conspicuously thickened and the media is fibrotic. Thrombi may obliterate the lumen, after which organization and canalization occur.

CLINICAL FEATURES: Giant cell arteritis tends to be benign and self-limited, and symptoms subside in 6–12 months. Patients present with headache and throbbing temporal pain. In some instances, there are early constitutional symptoms, including malaise, fever and weight loss, plus generalized muscular aching or stiffness in the shoulders and hips. Throbbing and pain over the temporal artery are accompanied by swelling, tenderness and redness in overlying skin. Almost half of patients have visual symptoms, which may proceed from transient to permanent blindness in one or both eyes, sometimes rapidly. Occasionally, the disease causes myocardial, central nervous system (CNS) or gastrointestinal infarcts, which may be fatal. Because the inflammatory process is patchy, biopsy of the temporal artery may not be diagnostic in as many as 40% of patients with otherwise classic manifestations. Response to corticosteroids is usually dramatic, and symptoms subside within days.

Granulomatosis with Polyangiitis Is a Vasculitis That Affects the Respiratory Tract and Kidney

Granulomatosis with polyangiitis (GPA, formerly Wegener granulomatosis) is a systemic necrotizing vasculitis of unknown etiology, with granulomatous lesions of the nose, sinuses and lungs and renal glomerular disease. Men are affected more than women, usually in their fifth and sixth decades. Over 90% of patients with GPA are positive for ANCA, of whom 75% have C-ANCA. It has been suggested that these antibodies activate circulating neutrophils to attack blood vessels. The response to immunosuppressive therapy supports an immunologic basis for the disease.

PATHOLOGY: Lesions of GPA feature parenchymal necrosis, vasculitis and granulomatous inflammation composed of neutrophils, lymphocytes, plasma cells, macrophages and eosinophils. Individual lesions in the lung may be as large as 5 cm across and must be distinguished from tuberculosis. Vasculitis involving small arteries and veins may be seen anywhere but occurs most frequently in the respiratory tract (Fig. 16-33), kidney and spleen. Arteritis is characterized principally by chronic inflammation, although acute inflammation, necrotizing and nonnecrotizing granulomas and fibrinoid necrosis are often present. Medial thickening and intimal proliferation are common and often cause narrowing or obliteration of the lumen.

The most prominent pulmonary feature is persistent bilateral pneumonitis, with nodular infiltrates that undergo cavitation similar to tuberculous lesions (although the mechanisms are clearly different). Chronic sinusitis and nasopharyngeal mucosal ulcers are frequent. The kidney at first shows focal necrotizing glomerulonephritis, which progresses to crescentic glomerulonephritis (see Chapter 23).

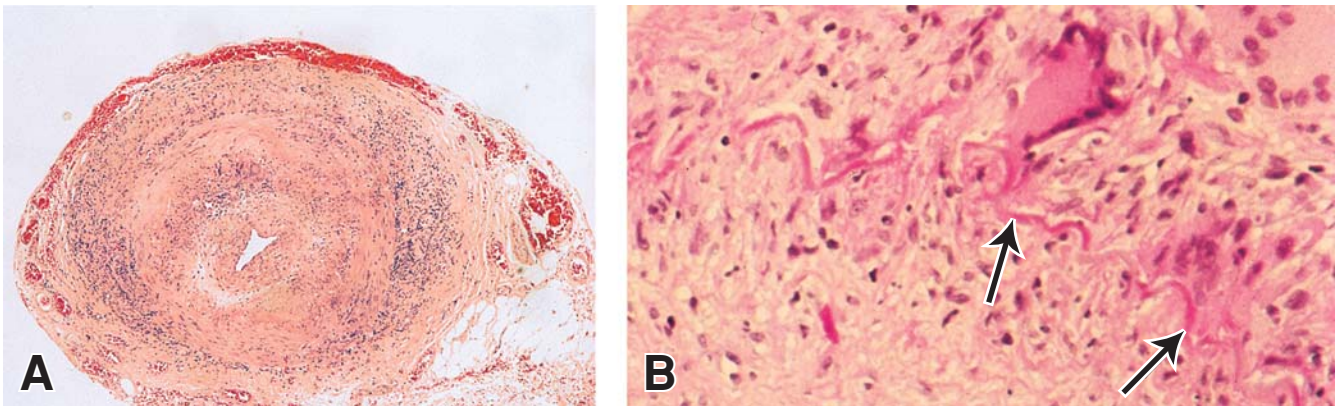

FIGURE 16-32. Temporal arteritis. A. A photomicrograph of a temporal artery shows chronic inflammation throughout the wall and a lumen severely narrowed by intimal thickening. **B.** A high-power view shows giant cells adjacent to the fragmented internal elastic lamina (*arrows*).

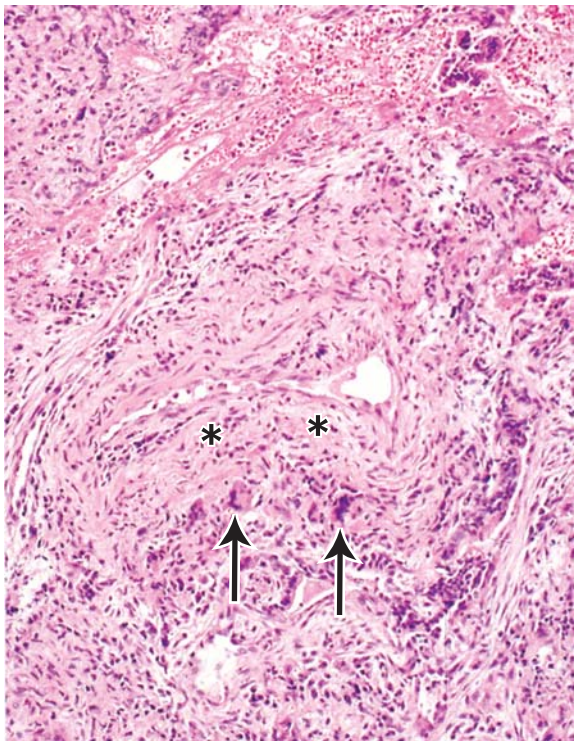

FIGURE 16-33. Granulomatosis with polyangiitis (GPA). A photomicrograph of the lung shows vasculitis of a pulmonary artery. There are chronic inflammatory cells and Langerhans giant cells (*arrows*) in the wall, together with thickening of the intima (*asterisks*).

CLINICAL FEATURES: Most patients present with symptoms referable to the respiratory tract, particularly pneumonitis and sinusitis. In fact, the lung is eventually involved in over 90% of patients. Radiologically, multiple pulmonary infiltrates are prominent, which are often cavitary. Hematuria and proteinuria are common, and glomerular disease can progress to renal failure. Rash, muscular pains, joint involvement and neurologic symptoms occur. Most patients (80%) die within a year if untreated, with a mean survival of 5–6 months. Treatment with cyclophosphamide produces both complete remissions and substantial disease-free intervals in most patients. Interestingly, antimicrobial sulfa drugs significantly reduce the incidence of relapses, suggesting a relationship of the disease to bacterial infection.

Allergic Granulomatosis and Angiitis (Churg-Strauss Syndrome) Occurs in Young People with Asthma

PATHOLOGY: Two thirds of patients with Churg-Strauss syndrome have P-ANCA. Widespread necrotizing lesions of small and medium-sized arteries (Fig. 16-34), arterioles and veins are found in the lungs, spleen, kidney, heart, liver, CNS and other organs. These lesions are granulomas and intense eosinophilic infiltrates in and around blood vessels. The resulting fibrinoid necrosis, thrombosis and aneurysm formation may simulate polyarteritis nodosa, although Churg-Strauss syndrome seems to be a distinct entity. It must also be distinguished from other eosinophilic syndromes, such as parasitic and fungal infestations, polyangiitis with granulomatosis, eosinophilic pneumonia (Loeffler syndrome) and drug vasculitis.

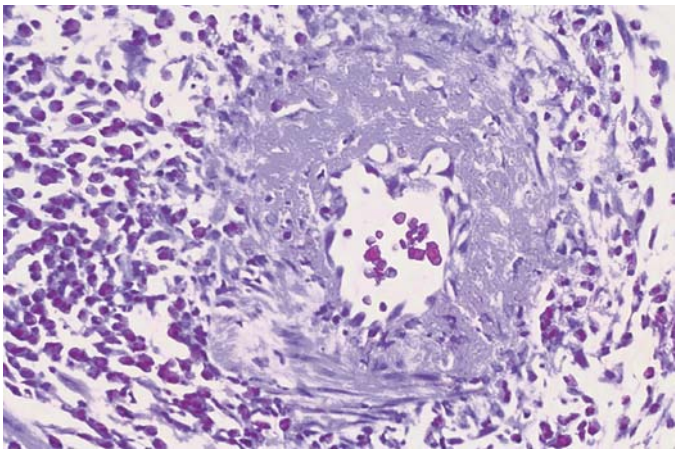

FIGURE 16-34. Churg-Strauss syndrome. A medium-sized artery shows fibrinoid necrosis and a surrounding eosinophilic infiltrate.

Untreated, these patients have a poor prognosis, but corticosteroid therapy is almost always effective.

Takayasu Arteritis Affects the Aorta and Its Branches

This form of arteritis is seen worldwide. It mainly affects women (90%), most of whom are under 30 years of age. The cause of Takayasu arteritis is unknown, but an autoimmune basis has been proposed.

PATHOLOGY: Takayasu arteritis is classified according to the extent of aortic involvement: (1) disease restricted to the aortic arch and its branches, (2) arteritis only affecting the descending thoracic and abdominal aorta and its branches and (3) combined involvement of the arch and descending aorta. The pulmonary artery is also occasionally affected and the retinal vasculature is frequently involved.

The aorta wall is thickened, and the intima shows focal, raised plaques. Branches of the aorta often have localized stenosis or occlusion, which interferes with blood flow. If the subclavian arteries are affected, the synonym **pulseless disease** is used. The aorta, particularly the distal thoracic and abdominal segments, commonly shows variably sized aneurysms. Early lesions of the aorta and its main branches consist of an acute panarteritis, with infiltrates of neutrophils, mononuclear cells and occasional Langhans giant cells. Inflammation of vasa vasorum in Takayasu arteritis resembles that observed in syphilitic aortitis. Late lesions display fibrosis and severe intimal proliferation. Secondary atherosclerotic changes may obscure the basic disease.

CLINICAL FEATURES: Patients with early Takayasu arteritis complain of constitutional symptoms, dizziness, visual disturbances, dyspnea and, occasionally, syncope. As the disease progresses, cardiac symptoms become more severe, with intermittent claudication of the arms or legs. Asymmetric differences in blood pressure may develop, and pulses in one extremity may sometimes actually disappear. Hypertension may reflect coarctation of the aorta or renal artery stenosis. Most patients eventually develop congestive heart failure. Loss of visual

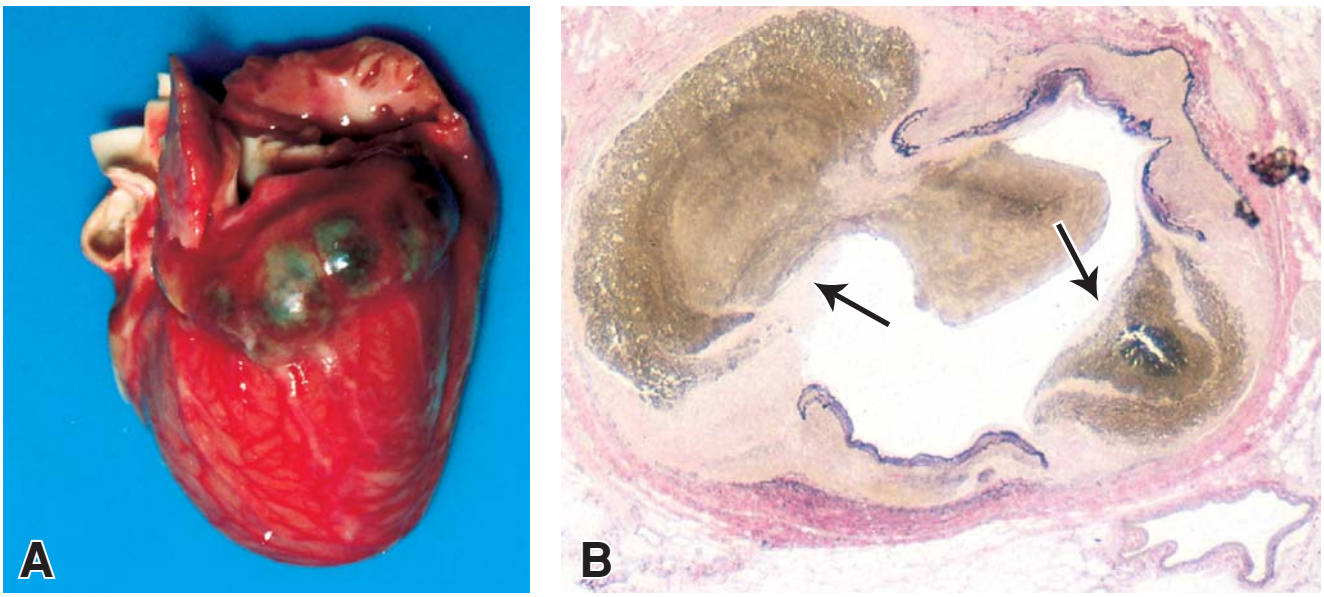

FIGURE 16-35. Kawasaki disease. A. The heart of a child who died from Kawasaki disease shows conspicuous coronary artery aneurysms. **B.** A microscopic section of a coronary artery from the same patient shows two large defects (*arrows*) in the internal elastic lamina, with two small aneurysms filled with thrombus.

acuity ranges from field defects to total blindness. Early Takayasu arteritis responds to corticosteroids, but the later lesions require surgical reconstruction.

Kawasaki Disease Mainly Targets Coronary Arteries in Children

Kawasaki disease (mucocutaneous lymph node syndrome) is an acute necrotizing vasculitis of infancy and early childhood, with high fever, rash, conjunctival and oral lesions and lymphadenitis. In 70% of patients, vasculitis of the coronary arteries leads to coronary artery aneurysms (Fig. 16-35), 1%–2% of which are lethal.

ETIOLOGIC FACTORS: Kawasaki disease is usually self-limited. Although an infectious cause has been sought, none has been conclusively demonstrated. Infection with *parvovirus B19* or with *New Haven coronavirus* has been implicated in some cases, and there is evidence for various bacterial infections, including *Staphylococcus, Streptococcus* and *Chlamydia* in others. The common theme seems to be viral or bacterial production of superantigens. These are molecules that bind to major histocompatibility complex (MHC) class II receptors and the V-beta region of the T-cell receptor, thereby massively activating immune responses. Autoantibodies to endothelial and smooth muscle cells have been identified in some patients.

Buerger Disease Is a Peripheral Vascular Disease of Smokers

Buerger disease (thromboangiitis obliterans) is an occlusive inflammatory disease of medium and small arteries in the distal arms and legs. It once occurred almost only in young and middle-aged men who smoked heavily, but it is now also described in women. It is more common in the Mediterranean area, Middle East and Asia.

ETIOLOGIC FACTORS: The etiologic role of smoking in Buerger disease is underscored by the fact that cessation of smoking may lead to remission, and resumption of smoking to exacerbation. Yet, how tobacco smoke produces the malady is obscure. Certain polyphenols from tobacco elicit antibodies and can induce inflammation. Smokers show a higher incidence of such sensitivity to tobacco than do nonsmokers. Cell-mediated hypersensitivity to collagen types II and III has also been observed. Endothelium-dependent vasodilatory responses in disease-free blood vessels are dysfunctional in some patients, suggesting that there may be a generalized impairment of endothelial function. HLA-A9 and HLA-B5 haplotypes are more common among Buerger patients, further suggesting that a genetically controlled hypersensitivity to tobacco is involved in the pathogenesis of disease.

PATHOLOGY: The earliest change in Buerger disease is acute inflammation of medium-sized and small arteries. Neutrophilic infiltrates extend to involve neighboring veins and nerves. Involvement of the endothelium in inflamed areas gives rise to thrombosis and obliteration of the lumen (Fig. 16-36A). Small microabscesses of the vessel wall, with a central area of neutrophils surrounded by fibroblasts and Langhans giant cells, distinguish this process from thrombosis associated with atherosclerosis. Early lesions often become severe enough to cause gangrene of the extremity, leading to amputation. Late in the course of the disease, thrombi are completely organized and partly canalized.

CLINICAL FEATURES: Symptoms of Buerger disease usually start between the ages of 25 and 40 years as intermittent claudication (cramping pains in muscles after exercise, quickly relieved by rest). Patients often present with painful ulceration of a digit, which progresses to destruction of the tips of the involved digits (Fig. 16-36B).

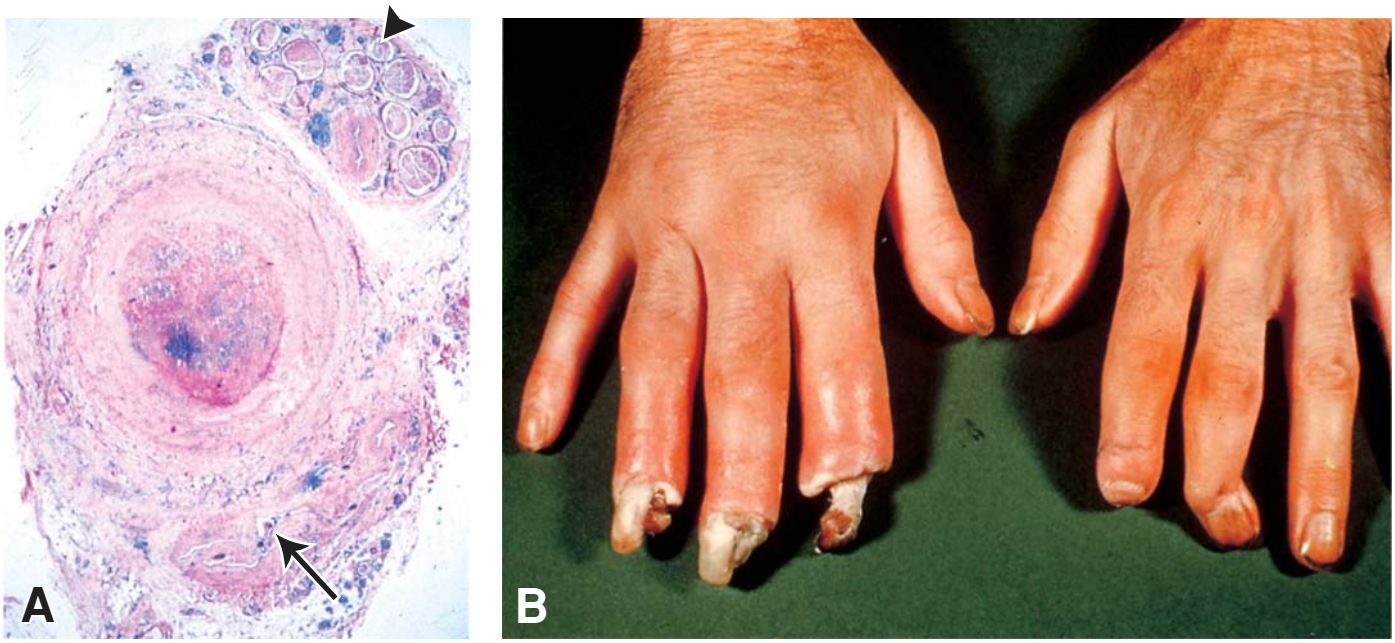

FIGURE 16-36. Buerger disease. A. Section of the upper extremity shows an organized arterial thrombus that has occluded the lumen. Some inflammatory cells are evident in the adventitial fat. In this instance, the vein (*arrow*) and the adjacent nerve (*arrowhead*) show foci of chronic inflammation. **B.** The hand shows necrosis of the tips of the fingers.

Those who continue to smoke may slowly lose both hands and feet.

Behçet Disease Is a Vasculitis of Many Mucous Membranes

Behçet disease is a systemic vasculitis characterized by oral aphthous ulcers, genital ulcers and ocular inflammation. Occasionally, there are lesions in the CNS, gastrointestinal tract and cardiovascular system. Both large and small vessels show vasculitis. The mucocutaneous lesions exhibit nonspecific vasculitis of arterioles, capillaries and venules, with infiltration of vessel walls and perivascular tissue by lymphocytes and plasma cells. Occasional endothelial cells are proliferated and swollen. Medium and large arteries show destructive arteritis, characterized by fibrinoid necrosis, mononuclear infiltration, thrombosis, aneurysms and hemorrhage. The cause is unknown, but the effectiveness of corticosteroid treatment and an association with specific HLA subtypes suggest an immune basis.

Radiation Vasculitis Has Acute and Chronic Phases

The acute phase of radiation vasculitis shows endothelial injury and denudation, ballooning degeneration of intimal smooth muscle cells, the presence of macrophages and smooth muscle cell necrosis of the media, which may appear fibrinoid. Thrombi may be seen in small arteries and arterioles. In the chronic phase, intimal hyperplasia and fibrosis of the vessel wall are noted. Occasionally, vessels display complete fibrous occlusion. Radiation damage predisposes to accelerated atherosclerosis.

Rickettsial Vasculitis Is Caused by Intracellular Parasites

Rickettsiae are obligate intracellular parasites that produce a characteristic vasculitis (see Chapter 9). Each different rickettsial disease affects different types of small vessels, and its extent and severity vary. The organisms usually disseminate from the entry site into the blood and invade endothelial cells, smooth muscle cells of the media of small vessels and capillaries.

ANEURYSMS

Arterial aneurysms are localized dilations of blood vessels caused by a congenital or acquired weakness of the media. They are not rare, and their incidence tends to rise with age. Aneurysms of the aorta and other arteries are found in as many as 10% of unselected autopsies. The wall of an aneurysm is formed by stretched remnants of the arterial wall.

Aneurysms are classified by location, configuration and etiology (Fig. 16-37). The location refers to the type of vessel involved—artery or vein—and the specific vessel affected, such as the aorta or popliteal artery. There are several categories of aneurysms:

- **Fusiform aneurysms** are ovoid swellings parallel to the long axis of the vessel.
- **Saccular aneurysms** are bubble-like arterial wall outpouchings at a site of weakened media.
- **Dissecting aneurysms** are actually dissecting hematomas, in which blood from hemorrhage into the media separates the layers of the vascular wall.
- **Arteriovenous aneurysms** are direct conduits between an artery and a vein.

Abdominal Aortic Aneurysms Complicate Atherosclerosis

Abdominal aortic aneurysms are dilations that increase vessel wall diameter by at least 50%. They are the most frequent aneurysms, usually developing after the age of

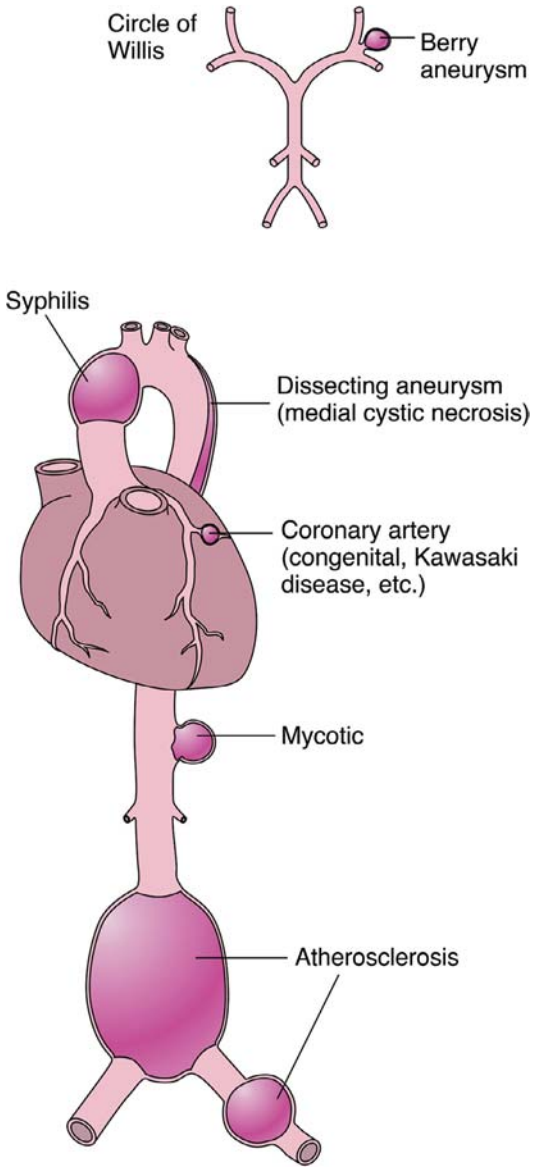

FIGURE 16-37. The locations of aneurysms. Syphilitic aneurysms are the common variety in the ascending aorta, which is usually spared by the atherosclerotic process. Atherosclerotic aneurysms can occur in the abdominal aorta or muscular arteries, including the coronary and popliteal arteries and other vessels. Berry aneurysms are seen in the circle of Willis, mainly at branch points; their rupture leads to subarachnoid hemorrhage. Mycotic aneurysms occur almost anywhere that bacteria can deposit on vessel walls.

50 years, and are associated with severe atherosclerosis of the artery. The prevalence rises to 6% after age 80. They occur much more often in men than in women, and half of patients are hypertensive. Occasionally, aneurysms may be found in all parts of the thoracic aorta and in iliac and popliteal arteries.

PATHOPHYSIOLOGY: Abdominal aortic aneurysms (AAAs) invariably occur in the context of atherosclerosis. However, it is thought that the disease is actually multifactorial, involving inflammation and dysregulation of matrix remodeling and repair. The growth of the aneurysm is regulated in part by hemodynamic forces that occur in the aneurysm; as the radius of the vessel increases, so does the circumferential wall stress. Enzymes important in the proteolysis of medial and adventitial type I/III fibrillar collagen promote the growth of abdominal aneurysms. These include matrix metalloproteinases; cysteine protease cathepsins K, L and S; and osteoclastic proton pump vH^+-adenosine triphosphatase (ATPase). Proinflammatory cytokines, such as IL-1β, TNF-α, monocyte chemotactin protein-1 (MCP-1) and IL-8, have also been linked to the pathogenesis of abdominal aneurysms. The walls of AAAs contain chemokines and growth factors that regulate remodeling. Examples are granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor (M-CSF), IL-13, IGF-1, TGF-β and macrophage inflammatory protein (MIP)-1α and -1β. Familial clustering suggests a genetic predisposition, although this is poorly understood.

PATHOLOGY: Most abdominal aortic aneurysms occur distal to the renal arteries and proximal to the aortic bifurcation (Fig. 16-38). They are usually fusiform, but saccular varieties are occasionally seen. Although most of the symptomatic lesions are over 5–6 cm in diameter, they may be of almost any size. Some extend into the iliac arteries, which occasionally exhibit distinct

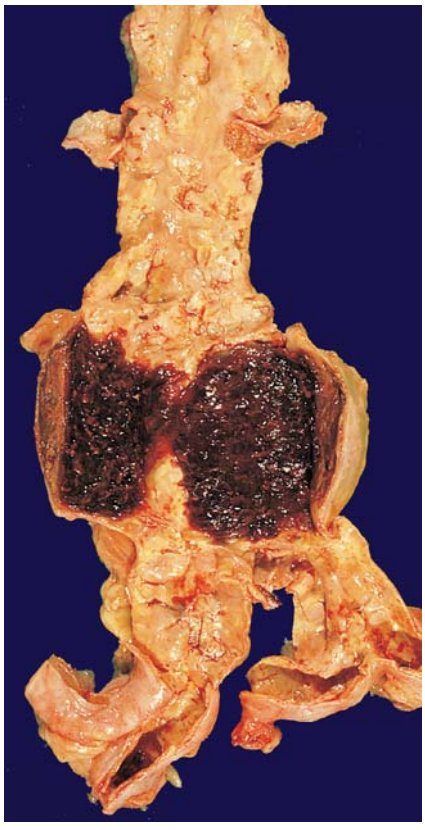

FIGURE 16-38. Atherosclerotic aneurysm of the abdominal aorta. The aneurysm has been opened longitudinally to reveal a large mural thrombus in the lumen. The aorta and common iliac arteries display complicated lesions of atherosclerosis.

aneurysms distal to the one in the aorta. Aneurysms that extend above the renal arteries may occlude the origin of the superior mesenteric artery and the celiac axis.

Most abdominal aortic aneurysms are lined by raised, ulcerated and calcified (complicated) atherosclerotic lesions. The majority contain mural thrombi of varying degrees of organization, portions of which may embolize to peripheral arteries. Infrequently, a thrombus itself enlarges enough to compromise the lumen of the aorta.

Microscopically, walls of AAAs complicated by atherosclerotic lesions are destroyed and replaced by fibrous tissue. Remnants of normal media are seen focally, and atheromatous lesions extend to variable depths. The adventitia is thickened and focally inflamed as a response to severe atherosclerosis.

CLINICAL FEATURES: Many abdominal aortic aneurysms are asymptomatic and are discovered only after palpation of a mass in the abdomen or on radiologic examination for some other reason. In some cases the condition is brought to medical attention by the onset of abdominal pain, which often reflects expansion of the aneurysm. Abrupt occlusion of a peripheral artery by an embolus from a mural thrombus presents as sudden ischemia of a lower limb. The most dreaded complication of aortic aneurysms is rupture and exsanguination into the retroperitoneum (or chest), in which case the patient presents with pain, shock and a pulsatile mass in the abdomen. This is an acute emergency, and half of patients die, even with prompt surgical intervention. Therefore, even asymptomatic large aneurysms are often replaced by or bypassed with prosthetic grafts.

The risk of rupture of an abdominal aortic aneurysm is a function of its size. Aneurysms under 4 cm in diameter rarely rupture (2%), and 25%–40% of those larger than 5 cm rupture within 5 years of their discovery.

Aneurysms of Cerebral Arteries Cause Subarachnoid Hemorrhage

The most common type of cerebral aneurysm is a saccular structure known as **berry aneurysm,** because it resembles a berry attached to a twig of the arterial tree. Berry aneurysms occur due to congenital defects in arterial walls and tend to arise at branches in the circle of Willis or one of the arterial junctions. The most common sites are between the anterior cerebral and anterior communicating arteries; the internal carotid and posterior communicating arteries; and the first main divisions of the middle cerebral artery and the bifurcation of the internal carotid artery. These aneurysms are also discussed Chapter 32.

Dissecting Aneurysm Features Blood in the Arterial Wall

The dissection occurs on a path along the length of the vessel (Fig. 16-39) and essentially represents a false lumen within the wall of the artery. Although the lesion is usually designated an aneurysm, it is actually a form of hematoma. Dissecting aneurysms most often affect the aorta, especially the ascending portion, and its major branches. Thoracic dissections may involve the ascending aorta alone (type A) or only the distal aorta (type B). Their frequency has been estimated to be as high as 1 in 400 autopsies, with men affected three times as frequently as women. They may occur at almost any age but are most common in the sixth and seventh decades. Almost all patients have a history of hypertension, and associated conditions include atherosclerosis, bicuspid aortic valve and idiopathic aortic root dilation.

PATHOPHYSIOLOGY: The basis of dissecting aneurysms is usually weakening of the aortic media. The changes were originally described as **cystic medial necrosis (of Erdheim),** because focal loss of elastic and muscle fibers in the media leads to "cystic" spaces filled with a metachromatic myxoid material. These spaces are not true cysts but are rather pools of matrix collected between the cells and tissues of the media. The mechanisms of medial degeneration are not well understood. However, genetic studies have linked some cases to specific disorders, including Marfan, Ehlers-Danlos and Loeys-Dietz syndromes, and to filamin mutations. In Marfan syndrome, a systemic connective tissue abnormality, specific mutations in the gene encoding fibrillin (an extracellular matrix protein) have been identified (see Chapter 6). In some patients, mutations have been identified in other genes, including TGF-β receptors 1 and 2, smooth muscle cell–specific β-myosin (MYH11) and α-actin (ACTA2). Aging also results in mild degenerative changes in the aorta, with focal elastin loss and medial fibrosis. Patients with dissection of the thoracic aorta show decreased expression of fibulin-5, an extracellular protein that regulates elastic fiber assembly. Abnormal release of MMP-2 and its inhibitor by smooth muscle cells has also been implicated in aortic aneurysms. In animals, defective cross-linking of collagen induced by a copper-deficient diet (lysyl oxidase is a copper-dependent enzyme) causes dissecting aneurysm of the aorta. The same lesion is produced by feeding β-aminopropionitrile, an inhibitor of lysyl oxidase. People with Wilson disease who are treated with penicillamine, a copper chelator, also may develop medial necrosis of the aorta. Taken together, these data suggest that the common factor in these several situations is a molecular defect that brings on weakness of aortic connective tissue.

PATHOLOGY: The initial event that triggers medial dissection is controversial. Over 95% of cases have a transverse tear in the intima and internal media, and it is widely held that spontaneous laceration of the intima allows blood from the lumen to enter and dissect the media. Alternatively, it has been proposed that hemorrhage from vasa vasorum into a media weakened by cystic medial necrosis initiates stress on the intima, which in turn leads to the ubiquitous intimal tear.

Most intimal tears are in the ascending aorta, 1 or 2 cm above the aortic ring. Dissection in the media occurs within seconds and separates the inner 2/3 of the aorta from the outer third. It can also involve coronary arteries, great vessels of the neck and renal, mesenteric or iliac arteries. Since the outer wall of the false channel of the dissecting aneurysm is thin, hemorrhage into the extravascular space—including the pericardium, mediastinum, pleural space and

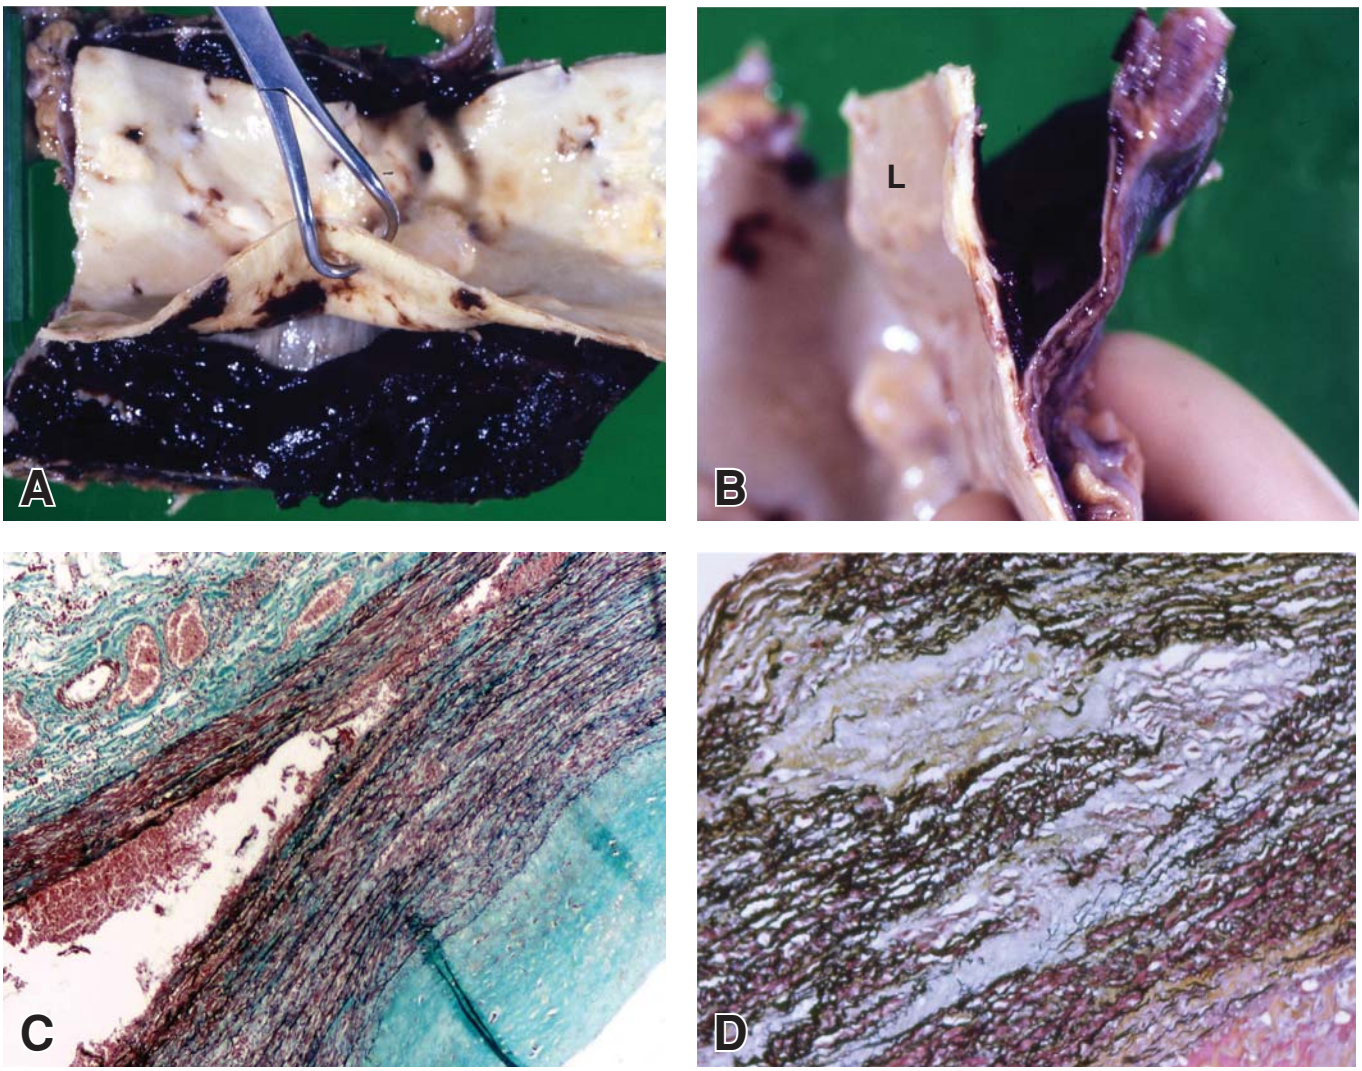

FIGURE 16-39. Dissecting aortic aneurysm. A. Thoracic aorta with metal clamps revealing the dissection and hematoma in the wall with old blood clot. **B.** The thoracic aorta has been opened longitudinally and reveals clotted blood dissecting the media of the vessel. *L* = lumen. **C.** Atherosclerotic aorta with dissection along the outer third of the media (elastic stain). **D.** A section of the aortic wall stained with aldehyde fuchsin shows pools of metachromatic material characteristic of the degenerative process known as cystic medial necrosis.

retroperitoneum—frequently causes death. In 5%–10% of cases, the blood within the dissection reenters the lumen via a second distal tear to form a "double-barreled aorta." In a comparable proportion, a reentry site produces communication of the aorta with a major artery, most often the iliac artery.

CLINICAL FEATURES: Patients typically present with acute onset of severe, "tearing" pain in the anterior chest, which is sometimes misdiagnosed as myocardial infarction. Loss of one or more arterial pulses is common, as is a murmur of aortic regurgitation. Whereas hypertension is a frequent finding in patients with dissecting aneurysms, hypotension is an ominous sign and suggests aortic rupture. Cardiac tamponade or congestive heart failure is diagnosed by the usual criteria.

Before antihypertensive and surgical treatment became available, more than a third of patients with aortic dissection died within 24 hours, and 80% succumbed by 2 weeks. Of the survivors, half died within 3 months. Prompt surgical intervention and control of hypertension have reduced overall mortality to less than 20%.

Inflammation of Aortic Vasa Vasorum Causes Syphilitic Aneurysms

Syphilis was once the most common cause of aortic aneurysms, but as the infection has become less common, so has syphilitic vascular disease, including aortitis and aneurysms. Syphilitic aneurysms mainly affect the ascending aorta, which shows endarteritis and periarteritis of vasa vasorum. These vessels ramify in the adventitia and penetrate the outer and middle thirds of the aorta, where they become encircled by lymphocytes, plasma cells and macrophages. Obliterative changes in the vasa vasorum cause focal medial necrosis and scarring, and disruption and disorganization of elastic lamellae. The depressed medial scars create a roughened intimal surface, a "tree bark" appearance (Fig. 16-40). The relentless pressure of the blood eventually forces the weakened wall of the

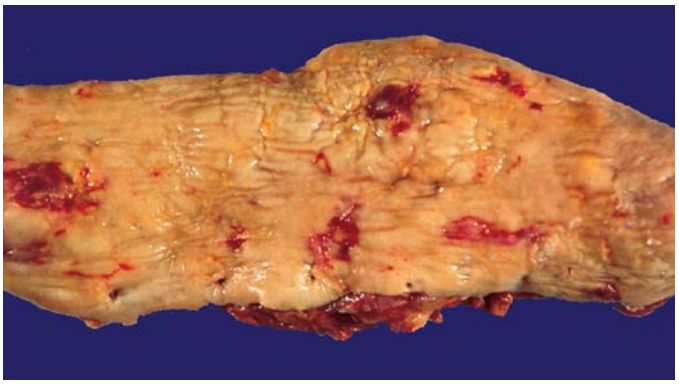

FIGURE 16-40. Syphilitic aortitis. The thoracic aorta is dilated, and its inner surface shows the typical "tree bark" appearance.

ascending aorta and aortic arch to form a fusiform aneurysm, which may rupture.

Mycotic Aneurysms Are Microbial Infections of a Vessel Wall

Mycotic (infectious) aneurysms tend to rupture and bleed. They may develop in the aortic wall or in cerebral vessels during septicemia, most commonly due to bacterial endocarditis. Mesenteric, splenic or renal arteries are also commonly affected. Mycotic aneurysms may also occur adjacent to a focus of tuberculous or a bacterial abscess.

VEINS

Varicose Veins Are Enlarged and Tortuous

Superficial varicosities of leg veins, usually in the saphenous system, are very common. They vary from a trivial knot of dilated veins to painful and disabling distention of the whole venous system of the leg, with secondary trophic disturbances. It is estimated that as much as 10%–20% of the population has some varicosities in the leg veins, but only a fraction of these develop symptoms.

ETIOLOGIC FACTORS: There are several risk factors for varicose veins:

- **Age:** Varicose veins increase in frequency with age and may reach 50% in people over 50 years. This increased incidence may reflect age-related degenerative changes in connective tissues of venous walls, loss of supporting fat and connective tissues, more flaccid muscle tone and inactivity.
- **Sex:** Among 30- to 50-year-olds, women are more often affected by varicose veins than men, particularly those who have experienced increased venous pressure on the iliac veins from a pregnant uterus.
- **Heredity:** There is a strong familial predisposition to varicose veins, possibly owing to inherited configurations or structural weaknesses of the walls or valves of these vessels.
- **Posture:** Leg vein pressure is 5–10 times higher when a person is erect rather than recumbent. As a result, the incidence of varicose veins and its complications are greater in those whose occupations require them to stand in one place for long periods.
- **Obesity:** Excessive body weight increases the incidence of varicose veins, possibly because of increased intra-abdominal pressure or poor support to vessel walls provided by subcutaneous fat.

Other factors that raise venous pressure in the legs can cause varicose veins, including pelvic tumors, congestive heart failure and thrombotic obstruction of the main venous trunks of the thigh or pelvis.

In the pathogenesis of varicose veins, it is not clear whether incompetence of the valves or dilation of the vessels comes first. Whatever the case, the two reinforce each other. As the vein increases in length and diameter, tortuousities develop. Once the process begins, the varicosity extends progressively throughout the length of the affected vein. As each valve becomes incompetent, increasing strain is put on the vessel and valve below. The role of inflammation is not well studied, although elevated expression of leukocyte-endothelial adhesion molecules is reported in affected veins.

PATHOLOGY: Microscopically, varicose veins show variations in wall thickness. Some areas are thin, owing to dilation, while others are thickened by smooth muscle hypertrophy, subintimal fibrosis and incorporation of mural thrombi into the wall. Patchy calcification is frequently seen. Valvular deformities consist of thickening, shortening and rolling of the cusps.

CLINICAL FEATURES: Visual inspection makes the diagnosis of varicose veins of the leg. Most affected vessels and veins have little clinical effect and are mainly cosmetic problems. The principal symptoms are aching in the legs, aggravated by standing and relieved by elevation. Severe varicosities (Fig. 16-41) may give rise to trophic changes in the skin drained by the

FIGURE 16-41. Varicose veins of the legs. Severe varicosities of the superficial leg veins have led to stasis dermatitis and secondary ulcerations.

affected veins, called **stasis dermatitis**. Surgery is mandated if the overlying skin has ulcerated or if spontaneous bleeding or extensive thrombosis (which may lead to pulmonary embolism) occurs.

Varicose Veins also Occur at Other Sites

HEMORRHOIDS: These are dilations of the veins of the rectum and anal canal and may occur inside or outside the anal sphincter (see Chapter 19). Although there may be a hereditary predisposition, the condition is aggravated by factors that increase intra-abdominal pressure. These include constipation, pregnancy and venous obstruction by rectal tumors. Hemorrhoids often bleed, an occurrence that may be confused with bleeding rectal cancers. Thrombosed hemorrhoids are exquisitely painful.

ESOPHAGEAL VARICES: This complication of portal hypertension is caused mainly by cirrhosis of the liver (see Chapter 20). High portal pressure distends the anastomoses between portal and systemic venous circulations at the lower end of the esophagus. Although they may be prominent radiologically, esophageal varices are usually unimpressive at autopsy. After their collapse at death, bluish streaks in the esophageal mucosa may be all that is evident. Hemorrhage from esophageal varices is a common cause of death in patients with cirrhosis.

VARICOCELE: This palpable scrotal mass represents varicosities of the pampiniform plexus (see Chapter 23).

Deep Venous Thrombosis Principally Affects Leg Veins

- **Thrombophlebitis** is inflammation and secondary thrombosis of small veins and sometimes larger ones, commonly as part of a local reaction to bacterial infection.
- **Phlebothrombosis** is the term for venous thrombosis that occurs without an initiating infection or inflammation.
- **Deep venous thrombosis** now refers to both phlebothrombosis and thrombophlebitis. Since most cases of venous thrombosis are not associated with inflammation or infection, the condition is currently associated with prolonged bed rest or reduced cardiac output. It is most frequent in deep leg veins and can be a major threat to life because of pulmonary embolization (witness the well-known phenomenon of sudden death with ambulation after surgery). Deficiencies of anticoagulants, such as protein C and antithrombin, increase the incidence of venous thromboembolism. Deep venous thrombosis is discussed more fully in Chapter 7.

LYMPHATIC VESSELS

Lymphatic vessels are thin-walled low-pressure channels. They are important for normal tissue fluid balance, providing drainage of plasma filtrates, cells and foreign material from the interstitial spaces. They are also important in fat digestion, through lacteals in the intestinal villi, and in immune surveillance. Lymphatic vessels are more permeable than blood vessels, in part because the former have fewer tight junctions. NO• may act as a mediator of several growth factors that are lymphangiogenic and may be important in lymphatic function. For example, NO• may inhibit pumping in collecting lymphatics. Inflammation and tumors frequently spread via lymphatics.

MOLECULAR PATHOGENESIS: Fox2, the forkhead transcription factor, regulates lymphatic valve morphogenesis and maintains the lymphatic capillary phenotype late in development. The VEGF-C/VEGFR-3 pathway mediates lymphatic endothelial cell migration, proliferation and survival. Missense mutations in VEGFR-3 result in lymphedema and lymphatic hypoplasia. PROX-1 is essential for early steps in lymphatic formation, such as budding from the anterior cardinal vein and forming lymph sacs. Along with podoplanin, VEGFR-3 and neuropilin-2, it also contributes to primary lymphatic plexus development. In inflammatory conditions, VEGF-C is upregulated by cytokines, and macrophages express VEGFR-3 and secrete VEGF-C. In experimental studies, tumor metastasis and lymphangiogenesis can be blocked by inhibiting VEGF-C/VEGFR-3. In some patients, primary lymphedema is associated with mutations in VEGFR-3, FOXC2, SOX18 and germline GATA2.

Lymphangitis Reflects Infection in Lymphatic Vessels

Transport of infectious material to regional lymph nodes incites **lymphadenitis**. The periphery of a focus of inflammation reveals dilated lymphatics filled with fluid exudate, cells, cellular debris and bacteria. When tissues are expanded by exudate, there is comparable distention of lymphatic channels and an opening of intercellular channels between endothelial cells.

Almost any pathogen can cause acute lymphangitis, but β-hemolytic streptococci (pyogenes) are particularly notorious offenders. The process may extend beyond these channels into surrounding tissues. Draining lymph nodes are regularly enlarged and inflamed. Painful subcutaneous red streaks, often accompanied by similarly painful regional lymph nodes, characterize acute lymphangitis.

Lymphatic Obstruction Causes Lymphedema

Lymphatics may be obstructed by scar tissue, intraluminal tumor cells, pressure from surrounding tumor tissue or plugging with parasites. As collateral lymphatic routes are abundant, lymphedema (distention of tissue by lymph) usually occurs only when major trunks are obstructed, especially in the axilla or groin. For example, when radical mastectomy for breast cancer was routine, axillary lymph node dissection frequently disrupted lymphatic channels and led to lymphedema of the arm. Prolonged lymphatic obstruction causes progressive dilation of lymphatic vessels, or **lymphangiectasia,** and overgrowth of fibrous tissue. The term **elephantiasis** describes a lymphedematous limb that is grossly enlarged. In the tropics, filariasis, in which a parasitic worm invades lymphatics, is a common cause of elephantiasis (see Chapter 9).

Milroy disease is an inherited type of lymphedema that is present at birth. It is associated with mutations in VEGF3 receptor, which is normally activated by VEGF-C and VEGF-D in lymphatic embryogenesis. It usually affects only one limb, but it may be more extensive and involve the eyelids and lips. Affected tissues show hugely dilated lymphatic

channels, and the entire area appears honeycombed or spongy. This lesion is more properly considered lymphangiectasia rather than simply lymphedema.

BENIGN TUMORS OF BLOOD VESSELS

Tumors of the vascular system are common. Many are hamartomas rather than true neoplasms. Some mutations have been linked to vascular anomalies. For example, endoglin and ALK-1 mutations have been identified in hereditary hemorrhagic telangiectasia, and several gene mutations have been identified in familial cerebral cavernous malformation.

Hemangiomas Are Common Benign Tumors of Vascular Channels

Hemangiomas usually occur in the skin but may also be found in internal organs.

PATHOLOGY:

CAPILLARY HEMANGIOMA: ***This lesion is composed of vascular channels with the size and structure of normal capillaries.*** Capillary hemangiomas may occur in any tissue. The most common sites are skin; subcutaneous tissues; mucous membranes of the lips and mouth; and internal viscera, including spleen, kidneys and liver. Capillary hemangiomas vary from a few millimeters to several centimeters in diameter. They are bright red to blue, depending on the degree of oxygenation of the blood. In the skin, capillary hemangiomas are known as **birthmarks** or **ruby spots**. The only disability is cosmetic disfiguration.

JUVENILE HEMANGIOMA: Also called **strawberry hemangiomas,** these lesions are found on the skin of newborns. They grow rapidly in the first months of life, begin to fade at 1–3 years of age and completely regress in most (80%) cases by 5 years of age. Juvenile hemangiomas contain packed masses of capillaries separated by connective tissue stroma (Fig. 16-42). The endothelial-lined channels are usually filled with blood. Thromboses, sometimes organized, are common. Occasionally, the vascular channels rupture, causing scarring and accumulation of hemosiderin. Juvenile hemangiomas are usually well demarcated despite lacking capsules. Although finger-like projections of the vascular tissue may give the impression of invasion, these growths are benign; they do not invade or metastasize.

CAVERNOUS HEMANGIOMA: ***This term is reserved for lesions made of large vascular channels, often interspersed with small, capillary-type vessels.*** When cavernous hemangiomas occur in the skin (Fig. 16-43), they are called **port wine stains**. They also appear on mucosal surfaces and visceral organs, including the spleen, liver and pancreas. If they occur in the brain, they may enlarge slowly and cause neurologic symptoms after long quiescent periods.

A cavernous hemangioma is a red-blue, soft, spongy mass, with a diameter of up to several centimeters. Unlike capillary hemangiomas, cavernous hemangiomas do not regress spontaneously. Although the lesion is demarcated by a sharp border, it is not encapsulated. Large endothelial-lined, blood-containing spaces are separated by sparse connective tissue. Cavernous hemangiomas can undergo a variety of changes, including thrombosis, fibrosis, cystic cavitation and intracystic hemorrhage.

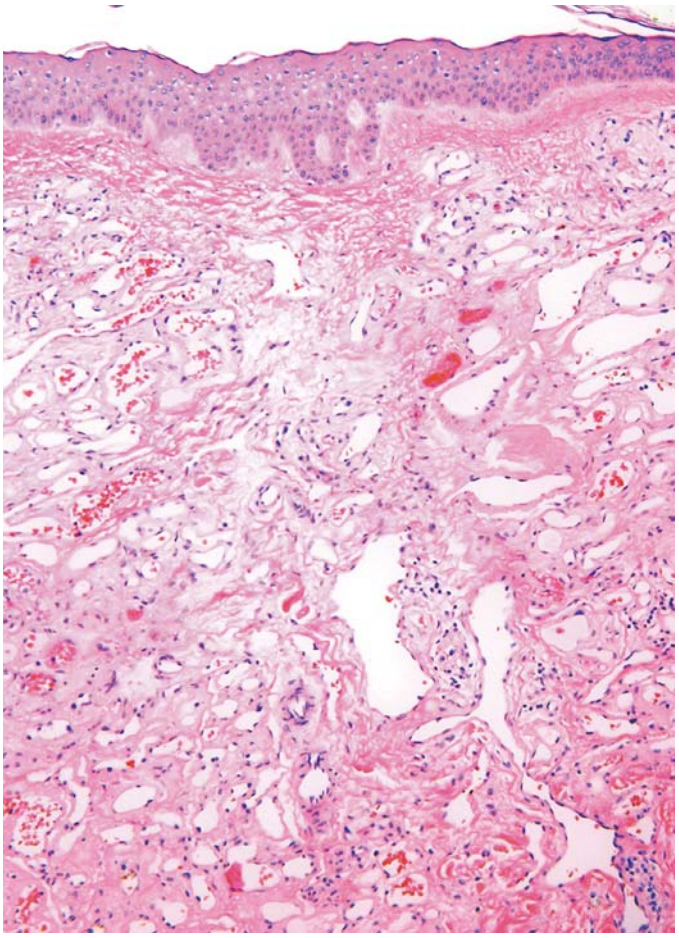

FIGURE 16-42. Juvenile hemangioma. A network of delicate, anastomosing vessels is present subcutaneously.

MULTIPLE HEMANGIOMATOUS SYNDROMES: More than one hemangioma may occur in a single tissue. Two or more tissues may be involved, such as skin and nervous system or spleen and liver. **von Hippel-Lindau syndrome** is a rare entity in which cavernous hemangiomas occur in the cerebellum or brainstem and the retina. **Sturge-Weber**

FIGURE 16-43. Congenital cavernous hemangioma of the skin.

syndrome involves a developmental disturbance of blood vessels in the brain and skin. Other closely related lesions are plexiform or racemose angiomas, cirsoid aneurysms and angiomatous dilation of vessels of the brain and elsewhere.

ETIOLOGIC FACTORS: Although hemangiomas are clearly benign, their origin is uncertain; they may be true neoplasms or they may be hamartomas. The evidence favoring hamartoma includes (1) the lesion is present at birth; (2) it grows only as the rest of the body grows and remains limited in size; and (3) after growth ceases, it usually remains unchanged indefinitely absent trauma, thrombosis or hemorrhage.

The development of these vascular malformations recalls the embryology of the vascular system. A network of endothelial channels undergoes remodeling, acquiring a muscular coat and adventitia. In this view, vascular malformations reflect the persistence of the original or modified channels and mixtures of connective tissue elements derived from the mesenchyme. At present, hemangiomas are classified by histologic type and location, although molecular characterization will likely lead to new classifications and better understanding of the prognosis of given lesions.

Glomus Tumor Is a Painful Tumor of the Glomus Body

Glomus bodies are normal neuromyoarterial receptors that are sensitive to temperature and regulate arteriolar flow. Glomus bodies are widely distributed in the skin, mostly in distal parts of fingers and toes. This parallels the sites of glomus tumors (glomangiomas), typically under the nails. The lesions tend to be unusually painful.

PATHOLOGY: Glomus tumors are usually under 1 cm in diameter; many are smaller than a few millimeters. In the skin, they are slightly elevated, rounded, red-blue and firm (Fig. 16-44). The two main histologic components are branching vascular channels in a connective tissue stroma and aggregates or nests of specialized glomus cells. The latter are regular, round to cuboidal cells that reveal typical smooth muscle cell features by electron microscopy.

Hemangioendothelioma Is Intermediate between Hemangiomas and Angiosarcomas

The epithelioid or histiocytoid hemangioendothelioma displays endothelial cells with considerable eosinophilic, often vacuolated, cytoplasm. Vascular lumina are evident, as are a few mitoses. These tumors occur in almost all locations. Although the lesion may recur locally, surgical removal is generally curative. However, about 1/5 of patients develop metastases.

Spindle cell hemangioendothelioma occurs principally in males of any age, usually in the dermis and subcutaneous tissue of distal extremities. It features vascular, endothelial-lined spaces into which papillary projections extend.

MALIGNANT TUMORS OF BLOOD VESSELS

Malignant vascular neoplasms are rare, and only rarely do they arise in preexisting benign tumors.

Angiosarcoma Is a Rare Malignant Tumor of Endothelial Cells

These tumors occur in either sex and at any age. They begin as small, painless, sharply demarcated, red nodules. The most common locations are skin, soft tissue, breast, bone, liver and spleen. Eventually, most enlarge to become pale gray, fleshy masses without a capsule. These tumors often undergo central necrosis, with softening and hemorrhage.

PATHOLOGY: Angiosarcomas exhibit varying degrees of differentiation, ranging from those composed mainly of distinct vascular elements to undifferentiated tumors with few recognizable blood channels (Fig. 16-45). The latter display frequent mitoses, pleomorphism and giant cells and tend to be more malignant. Almost half of patients with angiosarcoma die of the disease.

Angiosarcoma of the liver is of special interest; it is associated with environmental carcinogens, particularly arsenic (a component of pesticides) and vinyl chloride (used in production of plastics). Hepatic angiosarcoma was observed after administration of thorium dioxide, a radioactive contrast

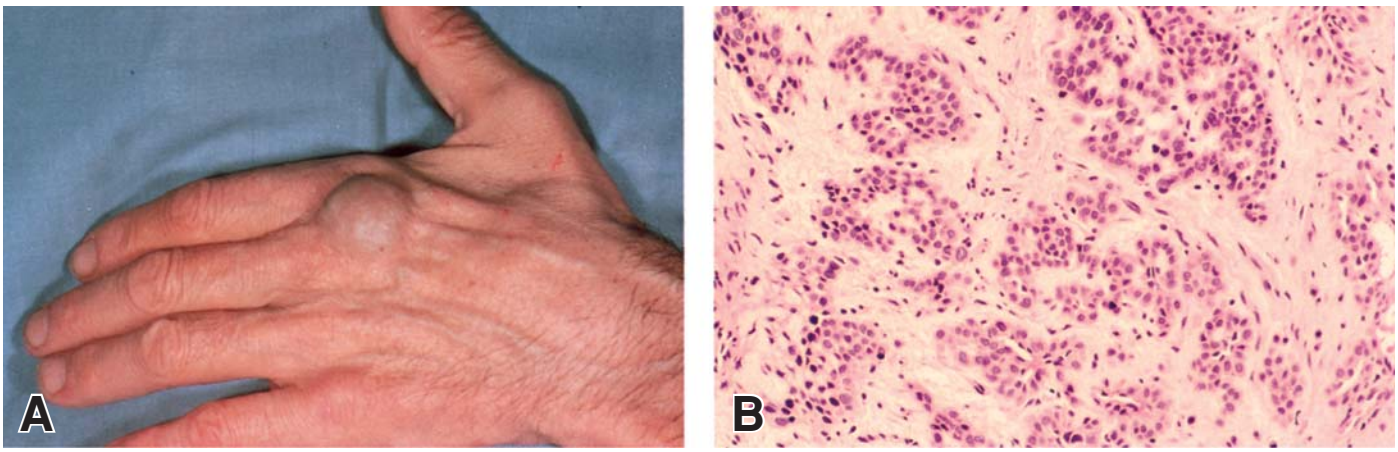

FIGURE 16-44. Glomus tumor. A. The dorsal surface of the hand displays a prominent tumor nodule on the proximal third finger. **B.** A photomicrograph of (A) reveals nests of glomus tumor cells embedded in a fibrovascular stroma.

medium (Thorotrast) used by radiologists prior to 1950. Thorotrast is engulfed by macrophages of the liver sinusoids, where it remains for life.

There is a long latent period between exposure to the chemicals or radionuclide and development of hepatic angiosarcoma. The earliest detectable changes are atypia and diffuse hyperplasia of the cells lining the hepatic sinusoids. The tumors are frequently multicentric and may arise in the spleen as well. Hepatic angiosarcomas are highly malignant and spread by both local invasion and metastasis.

Hemangiopericytoma

Hemangiopericytoma is a rare neoplasm previously thought to arise from pericytes, which are modified smooth muscle cells outside the walls of capillaries and arterioles. However, it is not clear that the neoplasm actually derives from these cells. These tumors present as small masses of capillary-like channels surrounded by, and frequently enclosed within, nests and masses of round to spindle-shaped cells. The tumor cells are characteristically invested by a basement membrane.

Hemangiopericytomas can occur anywhere but are most common in the retroperitoneum and lower extremities. Most are removed surgically without having invaded or metastasized. Malignant hemangiopericytomas metastasize to lungs, bone, liver and lymph nodes.

Kaposi Sarcoma Is Caused by Human Herpesvirus 8

Kaposi sarcoma is a malignant angioproliferative tumor derived from endothelial cells.

EPIDEMIOLOGY: Kaposi sarcoma was originally described in the 19th century by Moritz Kaposi in Vienna. It also occurred as a sporadic tumor endemic in parts of central Africa, but was otherwise an oddity that mainly afflicted older men. Kaposi sarcoma is now seen in epidemic form in immunosuppressed patients, especially those with AIDS. Human herpesvirus 8 (HHV8), also called Kaposi sarcoma–associated herpes virus (KSHV), is responsible for this tumor, which arises in endothelial cells. Only a small fraction of HHV8-infected people develop Kaposi sarcoma. VEGF and hypoxia-inducible factor (HIF) seem to play important roles in pathogenesis of the tumor, as does the PI3K/Akt/mTOR pathway. Cofactors that determine the occurrence of Kaposi sarcoma in individuals who are at risk are not well understood.

PATHOLOGY: Kaposi sarcoma begins as painful purple or brown 1-mm to 1-cm cutaneous nodules. They appear most often on the hands or feet but may occur anywhere. Their microscopic appearance is highly variable. One form resembles a simple hemangioma, with tightly packed clusters of capillaries and scattered hemosiderin-laden macrophages. Other types are highly cellular with less prominent vascular spaces (Fig. 16-46). They may be difficult to distinguish from fibrosarcomas, but their endothelial origin is demonstrable by immunochemistry and by electron microscopy. Although Kaposi sarcoma is considered a malignant lesion and may be widely disseminated in the body, it rarely causes death.

TUMORS OF THE LYMPHATIC SYSTEM

Many histologic and clinical variants of local enlargements of the lymphatics have been described. It is difficult to distinguish among anomalies, proliferations due to stasis and true neoplasms. In general, lymphatic tumors are distinguished by their size and location. The spaces may be small, as in capillary lymphangiomas, or large and dilated, as in cystic or cavernous lesions. Lymphangiomatous lesions can arise at almost any site, including skin, mediastinum, retroperitoneum, spleen and elsewhere.

Capillary Lymphangioma

Sometimes called "simple lymphangiomas," these benign tumors are small, circumscribed, grayish pink, fleshy nodules, which can be single or multiple. They are subcutaneous and occur on the skin of the face, lips, chest, genitalia or extremities. Capillary lymphangiomas are composed of variably

sized, thin-walled spaces lined by endothelial cells and contain lymph and occasional leukocytes.

Cystic Lymphangiomas Are Often Congenital Lesions

These benign lesions (also called cystic hygromas) are most common in the neck and axilla but also occur in the mediastinum and sometimes in the retroperitoneum. They may reach 10–15 cm or more in diameter and fill the axilla or distort the neck.

PATHOLOGY: Cystic lymphangiomas are soft, spongy and pink. Watery fluid exudes from their cut surfaces. Microscopically, they contain endothelial-lined spaces with a protein-rich fluid. These spaces are distinguished from blood vessels because they lack erythrocytes and leukocytes. Abundant irregularly distributed smooth muscle and connective tissue cells may be present.

Lymphangiosarcoma May Occur after Lymphedema or Radiation

These are rare malignant tumors that develop in 0.1%–0.5% of patients with lymphedema of the arm after radical mastectomy. Distinction between this tumor and angiosarcoma is difficult, and some authors equate the two. Lymphangiosarcoma may also occur in other regions, for example, in the leg following radiation therapy for uterine cervical carcinoma.

PATHOLOGY: Lymphangiosarcomas are purplish, frequently multiple, nodules in edematous skin. They are composed of cells resembling capillary endothelial cells and showing zonulae adherentes between cells. The walls of tumor vessels have a rudimentary form of basal basement membrane. Lymphangiosarcomas are highly malignant and, despite radical surgery, have a poor prognosis.

The heart is a fist-sized muscular pump that has the remarkable capacity to work unceasingly for the 90 or more years of a human lifetime. As demand requires, it can increase its output manyfold, in part because the coronary circulation can augment its blood flow to over 10 times normal. The ventricles also respond to short-term increases in workload by increasing heart rate and contractility, the latter in accordance with Starling's law of the heart. When an increased workload is imposed for longer periods (e.g., systemic hypertension), the left ventricle hypertrophies, an adaptation that increases its work capacity. However, this compensatory mechanism has its limits: a point is reached when the heart can no longer supply blood adequately to peripheral tissues; the result is congestive heart failure. Damage to the myocardium, caused most commonly by coronary artery disease, also limits left ventricular capacity to pump blood and similarly results in heart failure.

ANATOMY OF THE HEART

The heart of a normal adult man weighs 280–340 g, and that of a normal adult woman, 230–280 g. It is a two-sided pump. Blood enters each side through a thin-walled **atrium,** from which it is propelled forward by thicker muscular **ventricles**. The right ventricle is considerably thinner (<0.5 cm) than the left ventricle (1.3–1.5 cm) owing to the low venous pressure and relatively low afterload on the right side. Blood enters the ventricles across atrioventricular valves, the mitral valve on the left and the tricuspid valve on the right. These valves'

leaflets are held in place by chordae tendineae, strong fibrous cords attached to the inner surface of the ventricular wall via papillary muscles. The entrances to the aorta and pulmonary arteries are guarded respectively by the aortic and pulmonary valves, each with three semilunar cusps.

The heart wall has three layers: outer epicardium, middle myocardium and inner endocardium. The heart is surrounded and enclosed by visceral and parietal pericardia, which are separated by the pericardial cavity.

Cardiac Myocytes Generate Contractile Force

The myocardium is a network of individual myocytes, most of which normally have a single nucleus. They are separated from each other by intercalated disks that contain cell–cell adhesion and electrical junctions. Electron microscopy reveals the structure and distribution of the sarcolemma, **sarcoplasmic reticulum** (SR), T system of tubules, nucleus and many mitochondria (Fig. 17-1A). The contractile elements of the myocyte, the **myofilaments,** are arranged in bundles called **myofibrils**. These are separated by mitochondria and SR. Myofibrils are organized into repeating units termed **sarcomeres**.

The sarcomere is the basic functional unit of the contractile apparatus. It consists of a Z disk on each end and interdigitated thick and thin filaments, oriented perpendicular to the Z disk (Fig. 17-1). The thick filaments contain myosin heavy chains, myosin-binding protein C and myosin light chains. The thick filaments are limited to the A band and interact with the giant sarcomeric protein, titin (~27,000 amino acids), which spans from the Z disk to the M line, to form a third sarcomere filament system. Titin helps maintain precise assembly of myofibrillar proteins and contributes to the viscoelastic properties of cardiac muscle. The thin filaments contain actin and regulatory proteins, including **α-tropomyosin-1** and the **troponin complex** (cardiac troponins I, C and T), and extend from the Z disk through the I band and into the A band. Interaction of these myofilaments generates the force for contraction. The amount of force that can be produced is proportional to the overlap between adjoining thick and thin filaments and is maximum when sarcomeres are 2.0–2.2 μm in length.

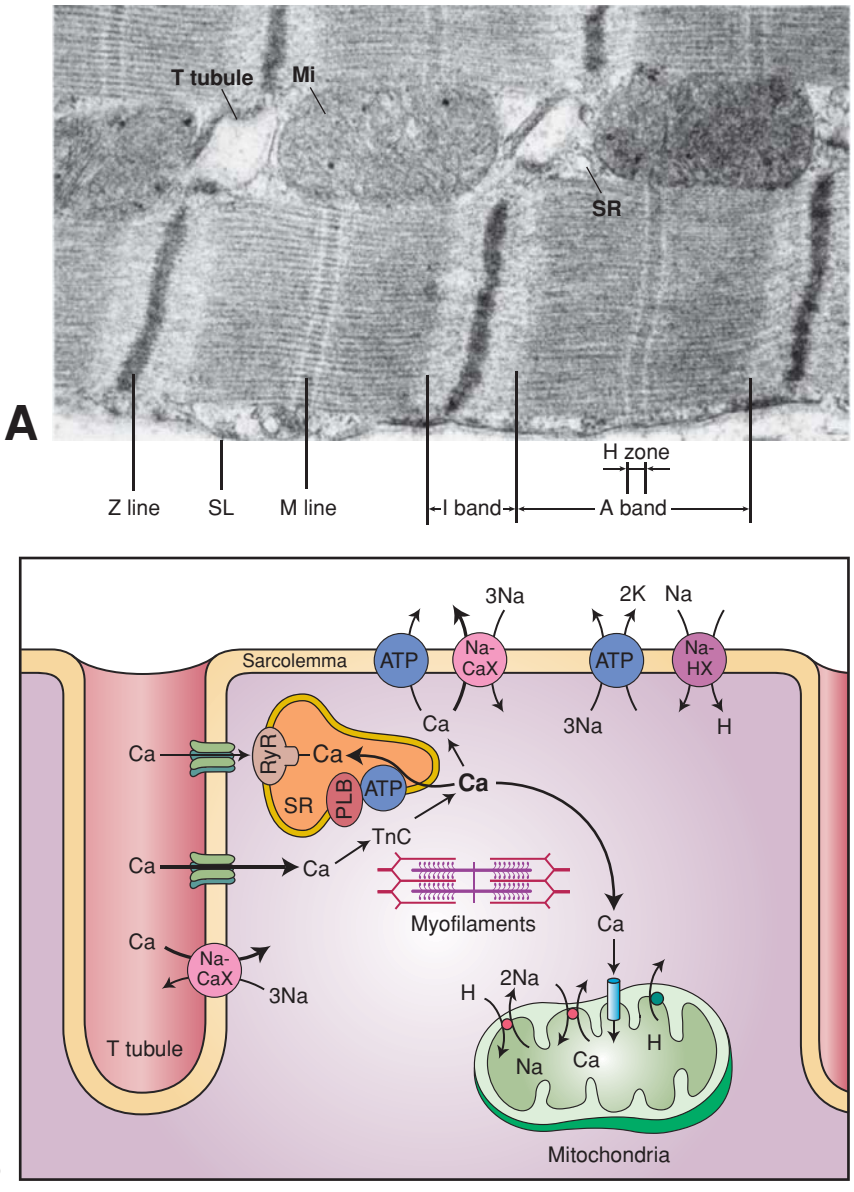

FIGURE 17-1. Ultrastructure of the myocardium. A. Electron micrograph of left ventricle in the longitudinal plane, showing the sarcolemma (SL); the sarcomeres of the myofibrils, delimited by Z lines; A bands; I bands; H zones; and M lines. Also present are mitochondria (Mi), sarcoplasmic reticulum (SR) and T tubules. The I bands and H zones are absent when the myofibrils are shortened. The structural basis for the banding is shown in the electron micrograph. The fine threads that extend at right angles to the thick (myosin) filaments are the cross-bridges that form the force-generating cross-links with actin. The amount of force that can be generated is proportional to the length of the adjoining myofilaments and is at a maximum when the sarcomeres are between 2 and 2.2 μm in length. When the sarcomeres are less than 2 μm in length, the thin filaments slide across each other and overlap, decreasing the potential for force-generating cross-links; similarly, when the sarcomeres are stretched beyond 2.2 μm, there is a decrease in force that is proportional to the widening of the H zone. This mechanism can be invoked as the basis for Starling's law of the heart. **B.** Pathways regulating Ca^{2+} homeostasis and excitation–contraction coupling in cardiac myocytes. The cardiac action potential brings depolarizing current into T tubules where voltage-gated L-type Ca^{2+} channels reside in high concentrations (green channel structures). Influx of Ca^{2+} through these channels (ICa) stimulates release of Ca^{2+} from the SR (located in immediate proximity to the T tubule) via RyR2. The transient increase in cytosolic Ca^{2+} promotes contraction through interactions with cardiac troponin T (TnC). Resting diastolic Ca^{2+} levels are restored by reuptake into the SR and extrusion via sodium–calcium exchange (Na-CaX) and an adenosine triphosphate (ATP) pump.

When sarcomere length is under 2 μm, the thin filaments slide across each other and overlap, decreasing the potential for force-generating cross-links. If it is stretched over 2.2 μm, force decreases in proportion to the widening of the H zone. ***This is the basis for Starling law of the heart, which states that cardiac contractile force is a function of fiber length during diastole.*** Average sarcomere length is about 2.2 μm when left ventricular end-diastolic pressure is at the upper limit of normal.

Contraction of cardiac muscle is initiated by increases in cytosolic free calcium. In a normal myocyte, an action potential triggers entry of calcium ions into the myocyte through voltage-gated L-type Ca^{2+} channels in T tubules. These invaginations of the sarcolemma bring depolarizing current and resultant voltage-gated Ca^{2+} entry into intimate proximity to intracellular organelles regulating calcium homeostasis (lateral cisterns of the SR) and the contractile apparatus itself (Fig. 17-1B). The entering calcium stimulates release of Ca^{2+} sequestered in the SR (Ca^{2+}-induced Ca^{2+} release) via cardiac ryanodine receptors (RyR2). Increased cytosolic Ca^{2+} produces a conformational change in the regulatory myofilament proteins, in particular troponin, allowing cross-bridges between actin and myosin to break and reform repeatedly. As a result, the filaments slide over one another, causing myocardial contraction. ***The number of contractile sites activated and the resulting force generated are directly proportional to the concentration of Ca^{2+} near the myofibrils.***

The myocardium relaxes when cytosolic Ca^{2+} returns to its normal low (diastolic) concentration of 10^{-7} M. This process depends on calcium adenosine triphosphatase (ATPase) of the SR, which pumps Ca^{2+} from the cytosol into the SR. Cytosolic Ca^{2+} also returns to the normal resting diastolic concentration by its outward transport through Na^{+}–Ca^{2+} exchange and sarcolemmal calcium pumps (Fig. 17-1B). ***Thus, myocardial relaxation is an active, energy-requiring event.***

The Conduction System Consists of Specialized Myocytes

These myocytes have two major functions: (1) they initiate heartbeats by generating electrical current through their automatic rhythmicity, which is more rapid in the sinoatrial (SA) node than more distally in the system; and (2) they distribute this current to activate atrial and ventricular myocardium in an appropriate temporal–spatial pattern. Fibers of the atrioventricular conduction system generally conduct impulses faster (~1–2 m/sec) than do working (contractile) atrial and ventricular fibers (~0.5–1 m/sec). By contrast, conduction through the atrioventricular node is exceptionally slow (~0.1 m/sec). Slow conduction at the atrioventricular junction delays ventricular activation and facilitates ventricular filling.

Heartbeats normally originate in the SA node, which is near the junction of the superior vena cava and the roof of the right atrium. If the node is diseased or otherwise prevented from functioning as the pacemaker, more distal components of the conduction system or even ventricular muscle itself assume the role of pacemaker. ***As a rule, the more distal the pacemaker site, the slower the heart rate.*** On leaving the SA node, an electrical impulse activates the atria. Atrial wavefronts converge on the atrioventricular (AV) node, which conducts the impulse through the common bundle (bundle of His) to the left and right bundle branches of the Purkinje system. Purkinje fibers run within the endocardium on both sides of the interventricular septum and distribute current to overlying ventricular muscles. Each cycle, ventricular contraction begins along the interventricular septum and at the apex. It progresses from apex to base, resulting in smooth and efficient ejection of blood into the great vessels.

The His bundle in normal adult hearts is the only electrical connection between atria and ventricles. Additional abnormal connections may occasionally arise as small bundles or tracts of cardiac myocytes. Such "bypass tracts" can activate ventricular muscle before the normal impulse arrives via the conduction system. They are found in patients with the **Wolff-Parkinson-White syndrome** and can establish circuits that promote **supraventricular tachycardia**. Congenital conduction system discontinuities may be caused by placentally transmitted autoantibodies in mothers with diseases such as systemic lupus erythematosus (SLE). Acquired defects may arise due to infarction, inflammatory or infiltrative disease, cardiac surgery or cardiac catheterization.

Coronary Arteries Supply Blood to the Heart

The right and left main coronary arteries originate in, or immediately above, the sinuses of Valsalva of the aortic valve. The left main coronary artery bifurcates within 1 cm of its origin into the left anterior descending (LAD) and left circumflex coronary arteries. The latter rests in the left atrioventricular groove and supplies the lateral wall of the left ventricle (Fig. 17-2). The LAD coronary artery lies in the anterior interventricular groove and provides blood to the (1) anterior left ventricle, (2) adjacent anterior right ventricle and (3) anterior 1/2 to 2/3 of the interventricular septum. In the apical region, the LAD artery supplies the ventricles circumferentially (Fig. 17-2).

The right coronary artery travels along the right atrioventricular groove and feeds most of the right ventricle and posteroseptal left ventricle (Fig. 17-2), including the posterior third to half of the interventricular septum at the base of the heart (also referred to as the "inferior" or "diaphragmatic" wall). Thus, one can predict locations of infarcts that result from occlusion of any of these major epicardial coronary arteries.

The epicardial coronary arteries are usually arranged in a so-called right coronary–dominant distribution. The pattern of dominance is defined by the coronary artery that contributes the most blood to the posterior descending coronary artery. In 5–10% of human hearts, the left circumflex coronary artery supplies the posterior descending coronary artery (left dominant).

Blood flows in the myocardium inward from epicardium to endocardium. Thus, as a general rule, endocardium is most vulnerable to ischemia when flow through a major epicardial coronary artery is compromised. Some of the small intramyocardial coronary arteries branch as they traverse the ventricular wall; others maintain a large diameter and pass to the endocardial surface without branching (Fig. 17-3). Because capillary networks arising from penetrating arteries do not interconnect, the borders between viable and infarcted myocardium after coronary artery occlusion are distinct.

The epicardial portion of each coronary artery fills and expands during systole and empties and narrows during diastole. Intramyocardial arteries do the opposite and are

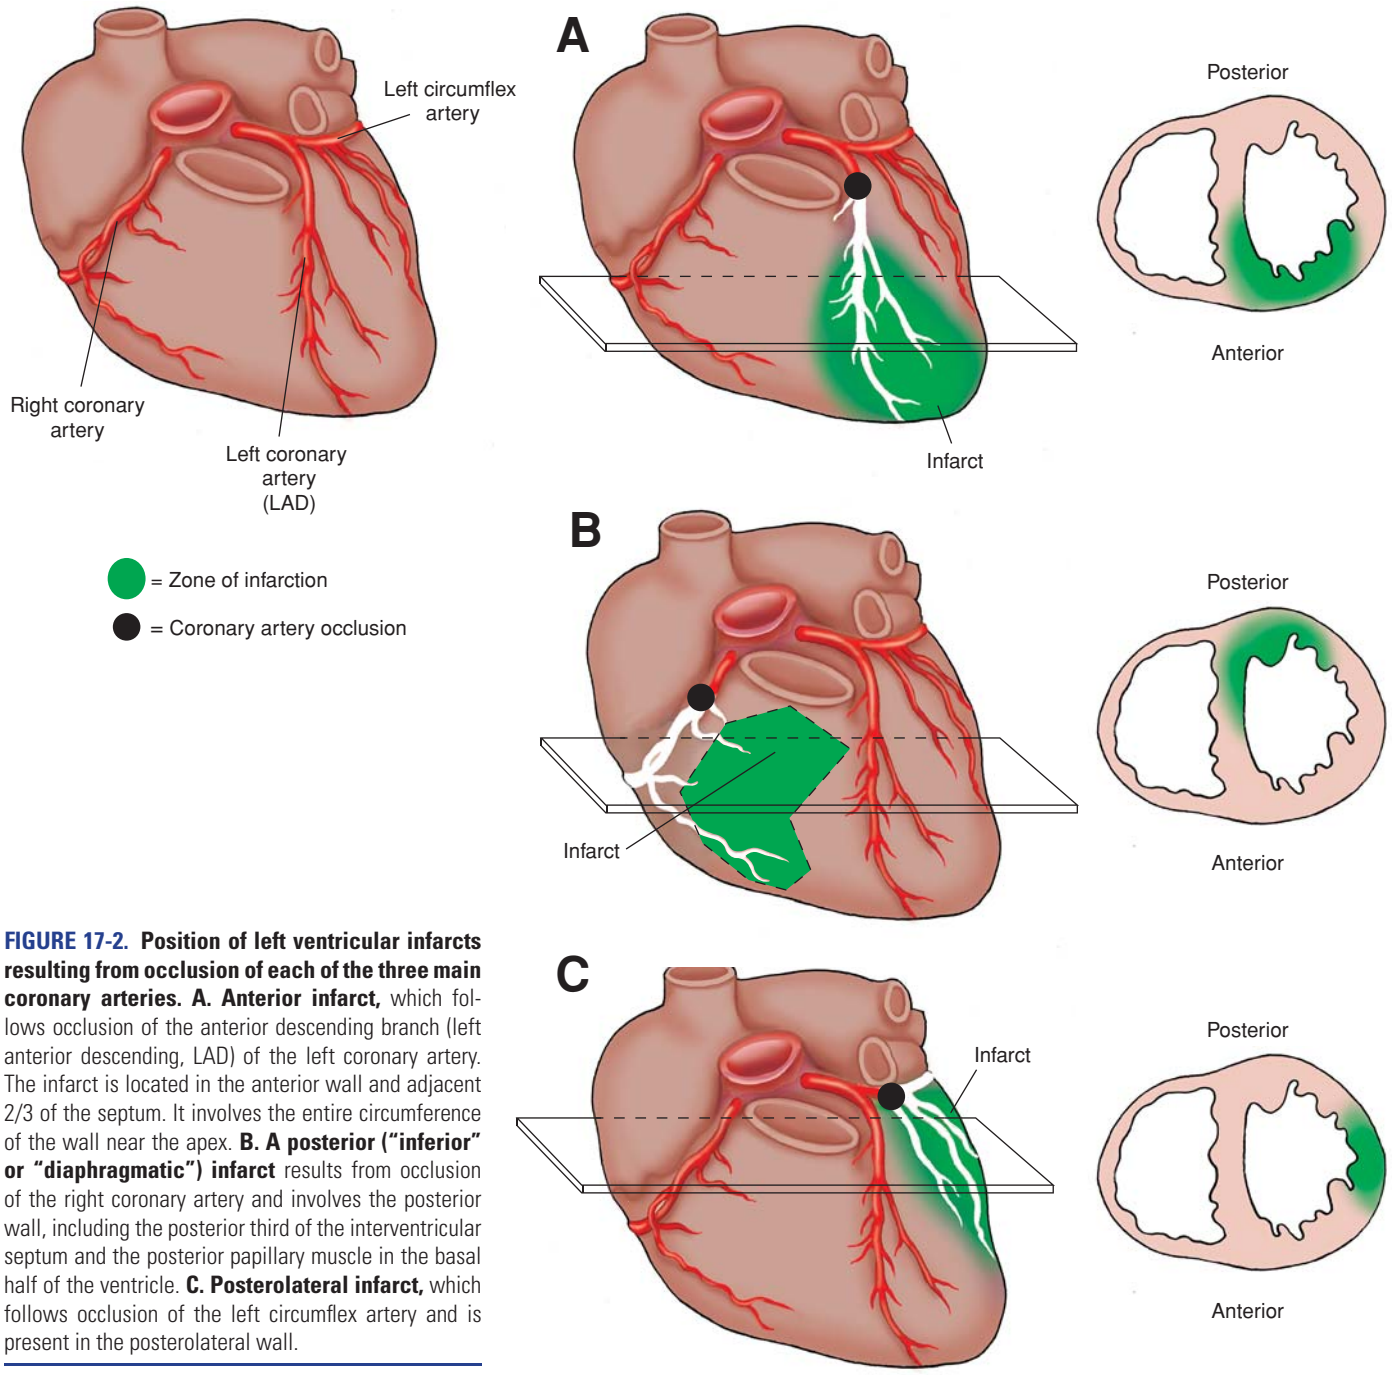

FIGURE 17-2. Position of left ventricular infarcts resulting from occlusion of each of the three main coronary arteries. A. Anterior infarct, which follows occlusion of the anterior descending branch (left anterior descending, LAD) of the left coronary artery. The infarct is located in the anterior wall and adjacent 2/3 of the septum. It involves the entire circumference of the wall near the apex. **B. A posterior ("inferior" or "diaphragmatic") infarct** results from occlusion of the right coronary artery and involves the posterior wall, including the posterior third of the interventricular septum and the posterior papillary muscle in the basal half of the ventricle. **C. Posterolateral infarct,** which follows occlusion of the left circumflex artery and is present in the posterolateral wall.

compressed by systolic muscular pressure. Thus, blood flow in the myocardium, especially in subendocardial ventricular regions, is lower or absent in systole. Autoregulation of blood flow roughly equalizes the myocardial supply, however.

MYOCARDIAL HYPERTROPHY AND HEART FAILURE

The ventricles are compliant in a normal heart, and diastolic filling occurs at low atrial pressures. During systole, ventricles contract vigorously and eject about 60% of the blood in them at the end of diastole **(ejection fraction)**. If a heart is injured, the clinical consequences are similar, regardless of the cause of cardiac dysfunction. ***When initial impairment is severe, cardiac output is not maintained despite compensatory changes and the result is acute, life-threatening,*** **cardiogenic shock.** For a lesser impairment, compensatory mechanisms (see below) maintain cardiac output by increasing diastolic ventricular filling pressure and end-diastolic volume. This results in the characteristic signs and symptoms of congestive heart failure. Because of the heart's capacity to compensate, congestive heart failure is often tolerated for years.

The heart's ability to adapt to injury is based on the same mechanisms that allow cardiac output to rise in response to stress. ***Compensation reflects the Frank-Starling law: cardiac stroke volume is a function of diastolic fiber length;***

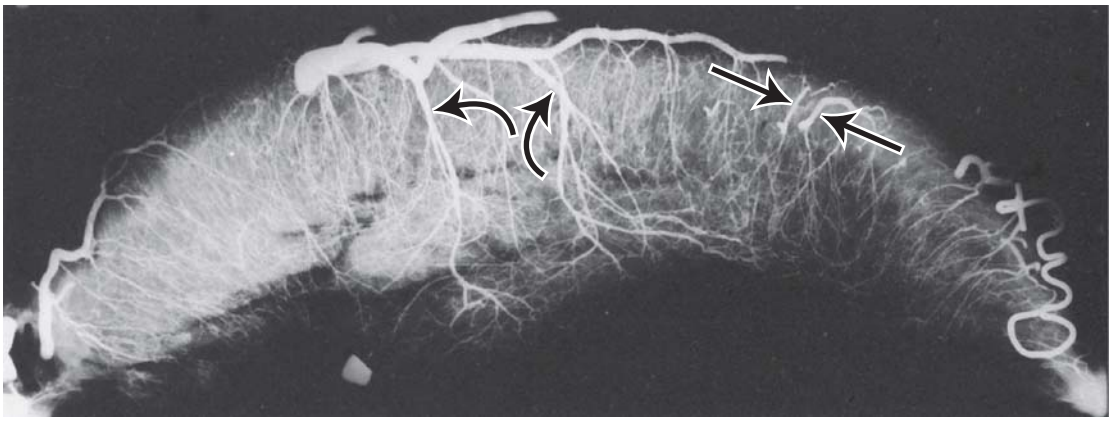

FIGURE 17-3. Arteriogram of a longitudinal segment of the posterior wall of the left ventricle including the posterior papillary muscle. Note the two types of branches passing into the myocardium at right angles to the epicardial artery (*top*): class A, which quickly divide into a fine network (*straight arrows*), and class B, which maintain a large diameter and pass with little branching into the subendocardial region and the papillary muscle (*curved arrows*).

within certain limits, a normal heart will pump whatever volume the venous circulation brings to it (Fig. 17-4). Stroke volume, a measure of ventricular function, increases with greater ventricular end-diastolic volume owing to increased atrial filling pressure.

Increased contractile force in response to ventricular dilation is a result of myofibrillar organization: stretching of sarcomeres allows greater potential overlap of thick and thin filaments during contraction. This permits enhanced force generation, as long as the sarcomere is not stretched beyond 2.2 μm. When there is a sudden need to increase cardiac output in a normal heart, as during exercise, catecholamine stimulation increases both heart rate and contractility. The latter is mainly mediated by modulating the activities of key proteins that regulate Ca^{2+} transients during excitation–contraction coupling. Thus, the normal relationship between end-diastolic volume and stroke volume is shifted upward (from curve A to curve X in Fig. 17-4). End-diastolic volume may also increase, causing a large increase in cardiac output.

If a heart is injured, overall cardiac function tends to be depressed in the basal state. Higher than normal filling pressures are then required to maintain cardiac output (curve Y in Fig. 17-4). Moreover, in cardiac failure, catecholamine stimulation is often present in the basal state. Comparable increases in cardiac output thus require greater increases in atrial pressure in failing hearts than in normal ones. ***The most prominent feature of heart failure is abnormally high atrial filling pressure relative to stroke volume.*** However, the absolute values of stroke volume and cardiac output are generally well maintained.

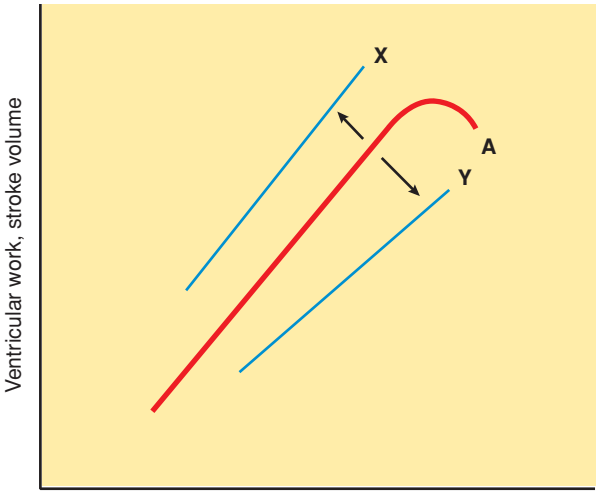

FIGURE 17-4. Relation between the work of the heart (or stroke volume) and the level of venous inflow, as measured by atrial pressure, ventricular end-diastolic volume (EDV) or end-diastolic pressure (EDP). *Curve A* indicates that as ventricular EDV, EDP or left atrial pressure increases, the amount of work done by the heart increases linearly up to a point. Beyond this point, the work done decreases, and the heart fails. However, the downslope of this curve is reached only at very high left atrial pressures. The curve may shift upward to position *X* or downward to position *Y*, depending on whether contractility has increased (e.g., because of the action of norepinephrine) or decreased (i.e., in failure), respectively. The failing heart usually functions on the ascending limb of a depressed curve.

PATHOPHYSIOLOGY: Myocardial hypertrophy is an adaptive response that augments myocyte contractile strength. There is a distinction between **physiologic hypertrophy,** which develops in highly trained athletes, and **pathologic hypertrophy,** which occurs because of injury or disease. While there is considerable overlap in the molecular mechanisms leading to these different forms of hypertrophy, there must also be important differences, since the athlete's enlarged heart is highly efficient while a diseased heart of similar mass is structurally and functionally deficient. These disparities are not well understood but may reflect the fact that the demands of exercise are intermittent, while those of disease (e.g., chronic hypertension) are unceasing. Differences in angiogenesis may also play a role.

Pathologic hypertrophy is a compensatory response to hemodynamic overload, which occurs in association with chronic hypertension or valvular stenosis **(pressure overload),** myocardial injury, valvular insufficiency

(volume overload) and other stresses that increase the heart's workload. It also develops as a response to primary injury of cardiac myocytes as in cardiomyopathies (see below). It results in enlargement of cardiac myocytes by assembly of new sarcomeres. Until recently, this had been thought to occur without an increase in the number of cardiac myocytes, but it is now known that cardiac progenitor cells exist with at least the potential to contribute to hyperplastic growth (see below).

Hypertrophy at first entails compensatory and possibly reversible mechanisms, but with persistent stress, the myocardium becomes irreversibly enlarged and dilated.

MOLECULAR PATHOGENESIS: ***Receptor-mediated myocardial events that are triggered by a stimulus promote the hypertrophic response by autocrine and paracrine mechanisms.*** Contractile cells respond to mechanical stimuli, such as stretching or pressure overload, by releasing ligands that activate receptor-mediated signaling pathways to produce hypertrophy (Fig. 17-5). Among the most important ligands are (1) angiotensin II (AngII), (2) endothelin-1 (ET-1), (3) norepinephrine (NE) and (4) various growth factors, including insulin-like growth factor-I (IGF-I) and transforming growth factor-I (TGF-I). Some of these mediators may also act on interstitial fibroblasts in the heart to promote synthesis and deposition of extracellular matrix. These ligands bind to and activate G-protein–coupled receptors and receptor tyrosine kinases to initiate intracellular signaling cascades, the most important of which include (1) mitogen-activated protein kinases (MAPKs), phosphoinositide-3-kinases (PI3Ks) and β-adrenergic (protein kinase A) and protein kinase C (PKC) pathways, which are all activated by G-protein–coupled receptors; and (2) Ca^{2+}/calmodulin-dependent protein kinase (CaMK) pathways, which are regulated by Ca^{2+}. Events mediated by β-adrenergic receptors are implicated in the transition from compensatory hypertrophy to heart failure. Ligands, signaling cascades, downstream targets and mechanisms mediating the hypertrophic response are described below (see also Chapter 1).

ANGIOTENSIN II: Cardiac myocytes and fibroblasts both contain all components of the renin–angiotensin system (renin, angiotensinogen, angiotensin-converting enzyme [ACE] and AngII receptors). AngII is released locally in response to load or stress stimuli and acts by autocrine and paracrine mechanisms to promote myocyte protein synthesis and hypertrophy and stimulate fibroblast proliferation and secretion of extracellular matrix. AngII interacts with two different classes of receptors to activate, directly or indirectly, multiple signaling cascades including those involving MAPKs and CaMK. Use of ACE inhibitors tends to reverse cardiac hypertrophy and to normalize heart size.

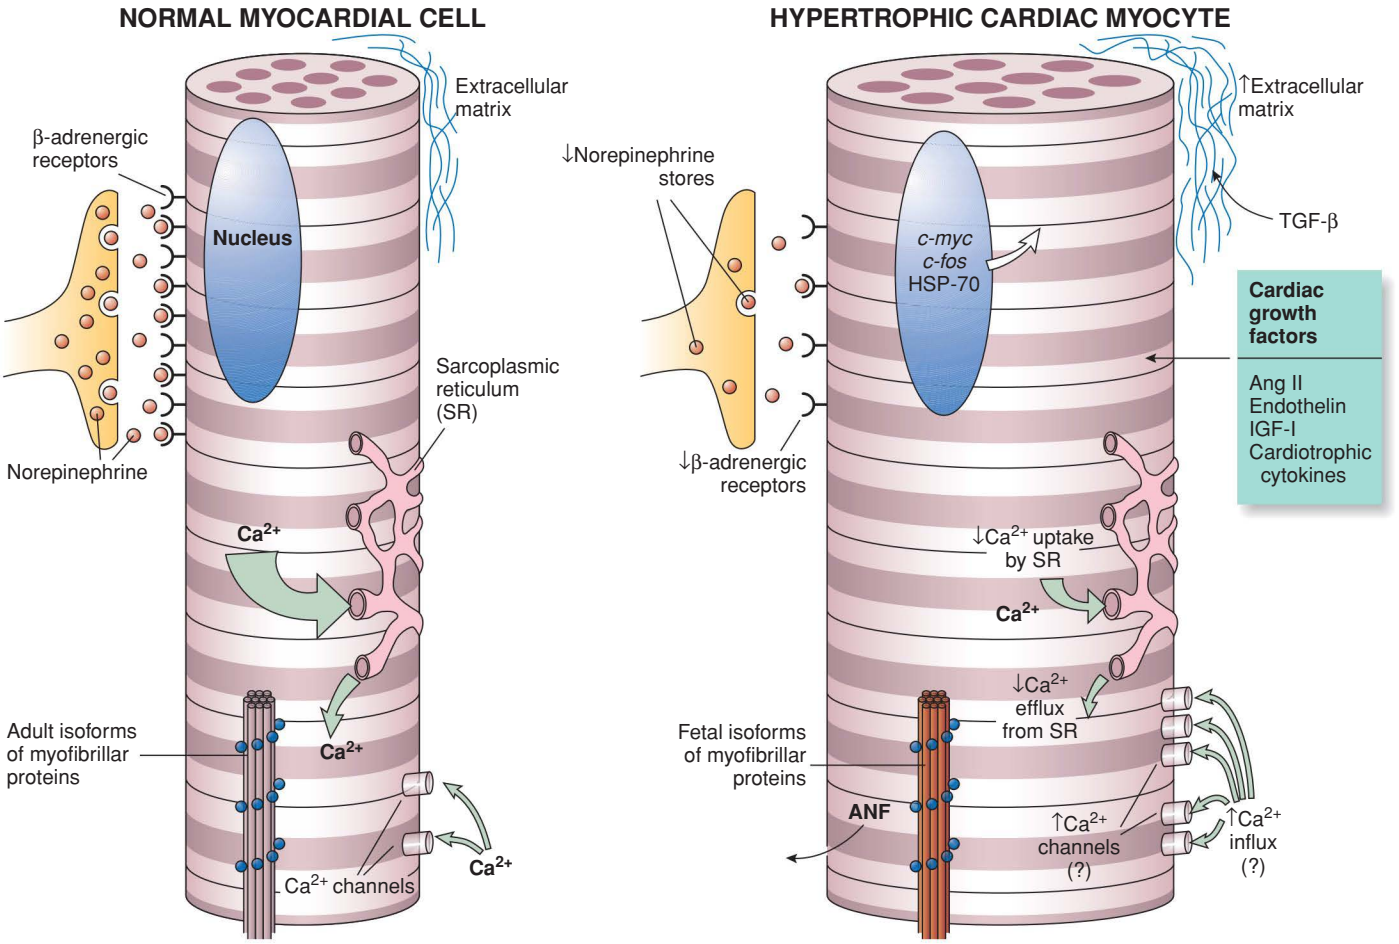

FIGURE 17-5. Biochemical characteristics of myocardial hypertrophy and congestive heart failure. *ANF* = atrial natriuretic factor; *Ang II* = angiotensin II; *HSP-70* = heat shock protein 70; *IGF* = insulin-like growth factor; *TGF* = transforming growth factor.

ACE inhibitors also prevent cardiac hypertrophy induced by experimental hypertension, without reducing the elevated arterial pressure.

ENDOTHELIN-1: ET-1 is a powerful vasoconstrictor produced by many cells, including endothelial cells and cardiac myocytes. It is also a potent growth factor for cardiac myocytes. Like AngII, ET-1 activates MAPK cascades upon binding to its receptor, to promote cardiac hypertrophy.

INSULIN-LIKE GROWTH FACTOR-I: IGF-I is a growth-promoting peptide synthesized in most tissues. As a growth factor for cardiac myocytes, IGF-I acts through PI3K pathways to promote cardiac hypertrophy.

EXTRACELLULAR MATRIX: Short-term heart overload leads to a prompt increase in collagen synthesis. Interstitial fibrosis, which occurs in virtually all forms of heart failure, is an obligatory feature of the hypertrophic response. Deposition of matrix proteins results, at least in part, from stimulation of cardiac fibroblasts by TGF-β and AngII. After myocardial infarction, fibrosis is important in replacing necrotic myocytes and preventing cardiac rupture. However, when it occurs diffusely, myocardial fibrosis can interfere with diastolic relaxation and impair diffusion of oxygen and nutrients. It can also lead to remodeling of electrical conduction pathways, and so is a major factor in the pathogenesis of atrial fibrillation and ventricular tachycardia.

MITOGEN-ACTIVATED PROTEIN KINASE PATHWAYS: MAPK cascades modulate hypertrophic responses to pressure overload. Activation of ERK1/2 (extracellular receptor kinase 1/2) signaling stimulates growth and survival of cardiac myocytes, while activation of JNK (c-Jun N-terminal kinase) and p38 MAPK cascades is involved in pathologic remodeling and apoptosis of cardiac myocytes.

PI3K PATHWAYS: Activation of PI3K leads to phosphorylation of membrane lipids and generation of second messengers such as phosphatidylinositol-3,4,5-trisphosphate. Receptor tyrosine kinases like IGF-I receptor activate the p110α isoform of PI3K. This isoform helps mediate physiologic hypertrophy in response to exercise training, promotes cell survival, inhibits cardiac fibrosis and attenuates pathologic hypertrophy. By contrast, activation of the p110α isoform of PI3K is detrimental as it promotes internalization of β-adrenergic receptors and inhibits sarco/endoplasmic reticulum Ca^{2+}-ATPase (SERCA) activity.

β-ADRENERGIC SIGNALING AND DESENSITIZATION: Stimulation of β-adrenergic receptors by norepinephrine (NE) turns on the stimulatory G protein G_S and activates adenylyl cyclase. The latter produces cyclic adenosine monophosphate (cAMP) as a second messenger, activating protein kinase A to enhance contractility. Poor responses to catecholamines by chronically failing hearts likely reflect adaptive responses to increases in circulating NE in heart failure. Desensitization of β-adrenergic receptors contributes to sluggish responses of a failing heart to exercise. Chronic overstimulation leads to decreased numbers and responsiveness of β-adrenergic receptors and a defect in coupling to adenylyl cyclase. Failing hearts also store less norepinephrine in autonomic nerve endings. Although β_1-adrenergic receptors are desensitized in heart failure, treatment to block this receptor class reduces mortality and improves contractile function in patients with advanced heart failure. Seemingly paradoxically, this response is consistent with abundant evidence that β_1-adrenergic receptors mediate cardiotoxic effects of NE in the failing heart including maladaptive cardiac myocyte hypertrophy and apoptosis, interstitial fibrosis, contractile dysfunction and sudden death.

CALCIUM HOMEOSTASIS: Defects in Ca^{2+} homeostasis occur in hypertrophy and heart failure. Expression and function of key Ca^{2+}-regulating proteins in cardiac myocytes are altered (see Fig. 17-1B):

- **Ryanodine receptor-2 (RyR2),** the major Ca^{2+} release channel in the SR, is activated during the action potential by influx of extracellular Ca^{2+} through voltage-gated channels in T tubules. Decreased numbers of RyR2 channels impair contractile function by reducing the rate of Ca^{2+} release from SR.
- **SERCA** is the pump responsible for Ca^{2+} reuptake into SR after contraction. Lower SR Ca^{2+} uptake is caused by fewer and abnormal regulation of SERCA. As a result, impaired Ca^{2+} sequestration in diastole leads to impaired relaxation.
- **Phospholamban** is a key regulator of cardiac contractility that inhibits SERCA. Enhanced phospholamban–SERCA interactions lead to chronically elevated Ca^{2+} levels during diastole, which is considered to play a critical role in chronic heart failure and arrhythmias.
- **CaMK pathways** are important in excitation–contraction coupling. CaMKII, the main cardiac isoform, modulates actions of Ca^{2+} handling proteins such as SERCA, phospholamban, RyR2 and the voltage-gated L-type Ca^{2+} channel. Myocardial CaMKII is increased in heart failure, contributing to abnormal Ca^{2+} homeostasis.

PROTO-ONCOGENES AND MYOCARDIAL HYPERTROPHY: Cardiac myocytes respond to acute pressure overload within an hour of its onset, by expressing proto-oncogenes c-*jun* and c-*fos* and heat shock protein 70 (Hsp70). These effects are mediated by AngII signaling and other pathways. Transcription of proto-oncogenes helps to reexpress fetal protein isoforms in the hypertrophic heart.

EXPRESSION OF FETAL GENES: Several protein isoforms are expressed in fetal hearts, but not after birth. In cardiac hypertrophy induced by hemodynamic overload, many of these genes are reexpressed. For example, atrial natriuretic factor (ANF) is made in the fetal ventricle and atrium, but its production is restricted to the atrium after birth. In hypertrophic ventricles, however, ANF and brain natriuretic protein (now called B-type natriuretic protein or BNP) are abundantly reexpressed and reduce hemodynamic overload via effects on salt and water metabolism (see Chapter 7). Blood BNP levels are a useful biomarker of the severity of heart failure.

Cardiac hypertrophy also elicits reexpression of fetal isoforms of several contractile proteins. In the rat, the normal adult isoform is a β-myosin with high ATPase activity and a rapid shortening velocity. By contrast, the fetal β-myosin has less ATPase activity and a slower shortening velocity. In experimental cardiac hypertrophy, "fast" β-myosin is replaced by "slow" β-myosin, leading to impaired myocardial contractility. However, this change in myosin gene expression is also adaptive, as it increases the tension generated during systole and improves contraction efficiency, thus conserving energy. Hypertrophied hearts exhibit similar, but not identical, changes in myosin isoforms. Ventricles contain only slow myosin, and hypertrophic hearts change from fast to slow myosin only in the atrium. However, fetal isoforms of other myofibrillar proteins appear in ventricular myocardium, including fetal forms of actin and

tropomyosin. Hypertrophied hearts also contain abnormal varieties of lactic dehydrogenase (LDH), creatine kinase (CK) and the sarcolemmal sodium pump.

Another adaptive gene switch occurs in energy metabolism. Fetal hearts rely mainly on maternally derived glucose for ATP production. After birth, however, the heart downregulates glycolytic enzymes and increases expression of genes that encode proteins mediating β-oxidation of fatty acids derived from breast milk. The failing heart reverts to using glucose by reexpressing fetal patterns of genes for energy generation. Although a mole of glucose yields less ATP than a mole of fatty acid, glycolytic metabolism uses less oxygen. For a failing heart, this switch is therefore advantageous.

Recent advances in understanding the molecular pathogenesis of heart failure have identified a role for histone acetylases and deacetylases in stress-activated myocyte signaling pathways. DNA-binding histone proteins control gene expression by modulating chromatin structure and controlling access of transcriptional activators and repressors to critical regulatory DNA sequences. Activation of stress-related signaling pathways involving G-protein–coupled receptors for NE, ET-1, AngII and others ultimately shifts patterns of histone acetylation and gene expression patterns. This switch entails changes in subcellular localization and activities of histone acetylases and deacetylases, suggesting that manipulation of histone-modifying enzymes may be useful in preventing heart failure.

Another emerging regulatory network in cardiac myocytes involves microRNAs (miRNAs; see Chapter 5), hundreds of species of which are expressed in the heart, where they may help to orchestrate expression of large groups of genes important in development and phenotypic specification. miRNAs do not encode proteins but rather bind target mRNAs in a sequence-specific manner, to promote their degradation or inhibit their translation. Specific patterns of miRNAs are upregulated in response to stress and have been implicated in mediating the hypertrophic response.

Apoptosis of cardiac myocytes may be important in heart failure. Apoptosis of cardiac myocytes increases 5-fold in animal models of heart disease, and senescent rats have 30% fewer cardiac myocytes than do young ones. Pathologic hypertrophy is generally associated with greater cardiac myocyte apoptosis, which may help transition from compensated hypertrophy to heart failure. Signaling by agonists such as AngII and ET-1 increases expression of proapoptotic genes via JNK and p38 MAPK pathways, and signaling by adrenergic agonists increases cardiac myocyte sensitivity to apoptotic stimuli. In contrast, p110α PI3K signaling via the IGF-I receptor enhances survival. Thus, diverse signaling pathways in cardiac hypertrophy may exert both proapoptotic and antiapoptotic influences, the final outcome depending on the balance between them.

CARDIAC STEM CELLS AND MYOCARDIAL REGENERATION: The heart has traditionally been thought of as a static organ incapable of growing new myocytes to regenerate or repair damage owing to a lack of cardiac stem cells. A few binucleated cardiac myocytes occur in normal hearts. These increase in number with age or in disease, indicating a capacity for nuclear division. However, it is clear that cardiac stem cells exist in adults and that during a lifetime, the heart continuously replaces myocytes, endothelial cells and fibroblasts at a slow rate (see Chapter 1). Increasing evidence also indicates that new cardiac myocytes can also arise directly from existing myocytes, and this process is increased in response to stress or disease. Still, the heart's regenerative capacity is quite limited. Current research focuses on strategies to exploit this capacity in order to replace damaged or necrotic muscle.

PATHOLOGY: Anything that increases cardiac workload for a prolonged period or produces structural damage may lead to myocardial failure. ***Ischemic heart disease is by far the most common cause of cardiac failure, accounting for more than 80% of deaths from heart disease.*** Most of the rest are caused by nonischemic heart muscle disease (cardiomyopathies) and congenital heart diseases. Virtually all body organs suffer when the heart fails (see Chapter 7).

Other than changes characteristic of specific diseases (e.g., ischemic heart disease or cardiac amyloidosis), the morphology of failing hearts is nonspecific. ***Ventricular hypertrophy is seen in virtually all conditions associated with chronic heart failure.*** Initially, only the left ventricle may be hypertrophied, as in compensated hypertensive heart disease. But when the left ventricle fails, some right ventricular hypertrophy usually follows, as the increased workload is imposed on the right ventricle by the failing left ventricle. ***In most cases of clinically apparent systolic heart failure, the ventricles are conspicuously dilated.*** The distribution of end-organ involvement depends on whether the heart failure is predominantly left sided or right sided.

Left-sided heart failure is more common, as the most common causes of cardiac injury (e.g., ischemic heart disease and hypertension) primarily affect the left ventricle. To compensate for left ventricular failure, left atrial and pulmonary venous pressures rise, resulting in passive pulmonary congestion. Alveolar septal capillaries fill with blood and small ruptures allow erythrocytes to escape. As a result, alveoli contain many hemosiderin-laden macrophages (so-called heart failure cells). If capillary hydrostatic pressure exceeds plasma osmotic pressure, fluid leaks from capillaries into alveoli. Resultant **pulmonary edema** (see Chapters 16 and 18) may be massive, with alveoli being "drowned" in a transudate. Interstitial pulmonary fibrosis results when congestion is present over an extended period.

Right-sided heart failure most commonly complicates left-sided failure, but it can develop independently due to intrinsic lung disease or pulmonary hypertension. The latter creates resistance to blood flow through the lung, causing right atrial pressure and systemic venous pressure to increase. Jugular veins become distended, edema accumulates in the legs and the liver and spleen become congested. Hepatic congestion in heart failure is characterized by distended central veins, which stand out on the cut surface of the liver as dark red foci against the yellow of cells in the lobular periphery. This gives the liver a gross appearance that has been compared to the cut surface of a nutmeg (hence, "nutmeg liver"; see Chapter 20).

Chronically injured cardiac myocytes lose myofibrils. Regardless of the type of injury, dysfunctional myocytes lose sarcomeres and correspondingly increase cytosol and glycogen. This process **(myocytolysis)** makes cells appear vacuolated (Fig. 17-6 shows a dramatic example). These changes likely result from reversible perturbations in myocyte metabolism. Myocytolysis may be an adaptive response to keep myocytes alive in the face of chronic injury and is quite prominent in "hibernating myocardium," in which contractile function is impaired at rest owing to reduced coronary blood flow.

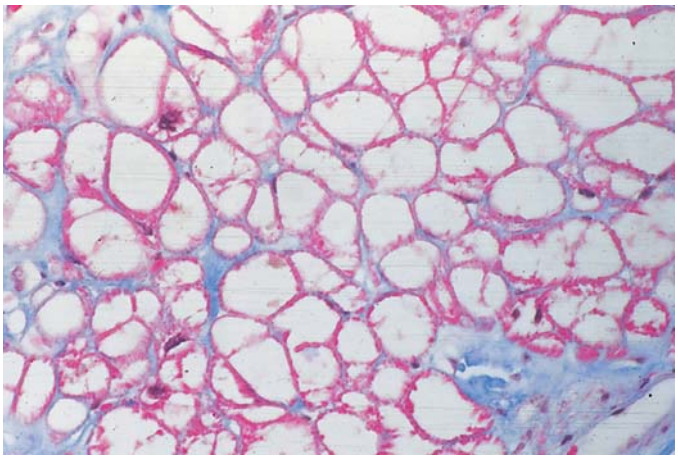

FIGURE 17-6. Severe myocytolysis in a patient with end-stage heart failure. Chronically injured myocytes show dramatic loss of myofibrils, giving the cells a marked vacuolated appearance. Only a thin rim of contractile cytoplasm is present, immediately beneath the sarcolemma.

TABLE 17-1

RELATIVE INCIDENCE OF SPECIFIC ANOMALIES IN PATIENTS WITH CONGENITAL HEART DISEASE

Ventricular septal defects: 25%–30%
Atrial septal defects: 10%–15%
Patent ductus arteriosus: 10%–20%
Tetralogy of Fallot: 4%–9%
Pulmonary stenosis: 5%–7%
Coarctation of the aorta: 5%–7%
Aortic stenosis: 4%–6%
Complete transposition of the great arteries: 4%–10%
Truncus arteriosus: 2%
Tricuspid atresia: 1%

Diastolic heart failure, often seen in elderly patients, has become an important clinical problem as life expectancy has increased. Ventricles become progressively stiffer with advancing age and require greater filling (diastolic) pressures. Some patients exhibit signs and symptoms of heart failure even though their hearts are normal in size and have normal systolic contractile function. These patients do not tolerate increases in blood volume well and are susceptible to developing pulmonary edema in response to a fluid challenge. These hearts typically show interstitial fibrosis, which may contribute to the decreased compliance of ventricular myocardium. Still, mechanisms responsible for diastolic heart failure are poorly understood.

CLINICAL FEATURES: Symptoms of left-sided failure include respiratory distress with exercise **(dyspnea on exertion), orthopnea** (dyspnea when lying down) and **paroxysmal nocturnal dyspnea** (dyspnea that awakens patients from sleep). Dyspnea on exertion reflects the increasing pulmonary congestion that accompanies a higher end-diastolic pressure in the left atrium and ventricle. Orthopnea and paroxysmal nocturnal dyspnea result when lung blood volume increases, owing to reduced blood volume in the legs during recumbency.

Although much of the clinical presentation of heart failure can be explained by venous congestion **(backward failure),** important aspects of congestive failure involve inadequate perfusion of vital organs **(forward failure)**. Most patients with left-sided heart failure retain sodium and water (edema) owing to poor renal perfusion, decreased glomerular filtration rate and renin–angiotensin–aldosterone system activation (see Chapter 7). Inadequate cerebral perfusion can lead to confusion, memory loss and disorientation. Reduced perfusion of skeletal muscle leads to fatigue and weakness.

CONGENITAL HEART DISEASE

Congenital heart disease (CHD) results from faulty embryonic development, expressed either as misplaced structures (e.g., transposition of the great vessels) or arrested progression of a normal structure from an early stage to a more advanced one (e.g., atrial septal defect).

Significant CHD occurs in almost 1% of live births. This does not include certain common defects that are not functionally important, such as an anatomically patent foramen ovale that is functionally closed by the left atrial flap that covers it. In this case, the foramen ovale remains closed as long as left atrial pressure exceeds that in the right atrium. Bicuspid aortic valves are also common and are usually asymptomatic until adulthood. Estimates of the incidence of specific cardiovascular anomalies depend on many factors. A range derived from several sources is shown in Table 17-1.

ETIOLOGIC FACTORS: The best evidence for a role of intrauterine influence in congenital cardiac defects is maternal rubella infection during the first trimester, especially during the first 4 weeks of gestation. Associations with other viral infections are suspected but are not as well documented. Maternal use of certain drugs in early pregnancy is also associated with increased cardiac defects in offspring. For example, 10% of babies with thalidomide syndrome (phocomelia) had CHD (see Chapter 6). Other drugs implicated in CHD include alcohol, amphetamines, phenytoin, lithium and estrogens. Maternal diabetes is also associated with increased incidence of CHD.

MOLECULAR PATHOGENESIS: Causes of CHD are not usually clear. However, it is worthwhile to determine whether a defect in any one case is most likely to be of genetic origin or probably acquired, as this issue is important to parents in planning future pregnancies. Most congenital heart defects reflect multifactorial genetic, epigenetic and environmental influences. As in other diseases with complex inheritance (see Chapter 6), risk of recurrence is greater among siblings of an affected child: CHD occurs in 1% of the general population; this increases to 2–15% for pregnancies after the birth of a child with a heart defect. The risk of a third affected child may reach 30%. Also, infants born to mothers with CHD have increased risk for CHD.

Chromosomal abnormalities may cause CHD, most prominently Down syndrome (trisomy 21), other trisomies, Turner syndrome and DiGeorge syndrome. Together, these account for no more than 5% of cases of CHD.

Much has been learned recently about genes encoding transcription factors that regulate cardiogenesis. The best studied is *Csx/NKX2.5,* a member of the evolutionarily conserved *NK* homeobox gene family. *Csx/NKX2.5* is a mammalian homolog of the *Drosophila* gene *NK4,* also known as *tinman* (from the *Wizard of Oz*) because deletion of this gene leads to failure of cardiac myocyte fate specification and lack of formation of a heart. Cardiac myocytes are formed when *Csx/NKX2.5* is deleted in mammals, but certain features of morphogenesis are arrested and growth of the heart tube is retarded. Expression of several cardiac genes is also reduced, including genes encoding myosin light chain 2v, ANF, cardiac ankyrin repeat protein and various transcription factors such as dHAND and eHAND, which are expressed in chamber-specific patterns and exert important regulatory influences over the development of the right and left ventricles. Various mutations in *Csx/NKX2.5* in humans have been associated with a spectrum of congenital cardiac malformations including atrial and ventricular septal defects, tetralogy of Fallot, double-outlet right ventricle, tricuspid valve abnormalities and hypoplastic left heart syndrome. Mutations in other transcription factors have been linked to congenital heart disease (*GATA4* and atrial and ventricular septal defects; *TBX1* and malformations of outflow septation such as tetralogy of Fallot and persistent truncus arteriosus), and mutations in *NOTCH1* (see Chapter 5) are linked to congenital malformations of the aortic valve. Increasing evidence also implicates alterations in histone methylation, an epigenetic mechanism that regulates expression of many genes during ontogeny and afterward. As many as 10% of patients with severe congenital cardiac malformations may harbor somatic mutations that arose during development in genes regulating histone methylation in the heart.

Classifications of Congenital Heart Disease Reflect Cyanosis and Shunting

There are several ways to categorize congenital heart defects. One clinically useful approach puts cases into three groups based on the presence or absence of cyanosis:

- **The acyanotic group** does not have an abnormal communication between systemic and pulmonary circuits. Examples of the acyanotic group include coarctation of the aorta, right-sided aortic arch and Ebstein malformation.
- **The cyanose tardive group** is defined as an initial left-to-right shunt with late reversal of flow, including patent ductus arteriosus (PDA), patent foramen ovale and ventricular septal defect. In patients with these anomalies, cyanosis supervenes later (i.e., tardive). Although the shunt is initially left to right, it later becomes right to left (**Eisenmenger complex**) because progressive increases in pulmonary vascular resistance cause the right ventricular pressure to rise to the point where it exceeds that in the left ventricle (see below).
- **The cyanotic group** entails a permanent right-to-left shunt. These CHDs include tetralogy of Fallot, truncus arteriosus, tricuspid atresia and complete transposition of the great vessels.

TABLE 17-2
CLASSIFICATION OF CONGENITAL HEART DISEASE

Initial Left-to-Right Shunt
Ventricular septal defect
Atrial septal defect
Patent ductus arteriosus
Persistent truncus arteriosus
Anomalous pulmonary venous drainage
Hypoplastic left heart syndrome
Right-to-Left Shunt
Tetralogy of Fallot
Tricuspid atresia
No Shunt
Complete transposition of the great vessels
Coarctation of the aorta
Pulmonary stenosis
Aortic stenosis
Coronary artery origin from pulmonary artery
Ebstein malformation
Complete heart block
Endocardial fibroelastosis

Additional classification schemes have been developed to provide the detail necessary to meet clinical requirements, especially those of the cardiac surgeon. **A more contemporary classification divides cases into the groups shown in Table 17-2.**

Early Left-to-Right Shunt Reflects the Higher Pressure on the Left Side of the Heart

Ventricular Septal Defect

Ventricular septal defects (VSDs) are among the most common congenital heart lesions (Table 17-1). They occur as isolated lesions or in combination with other malformations.

ETIOLOGIC FACTORS: The fetal heart consists of a single chamber until the fifth week of gestation, after which development of interatrial and interventricular septa and formation of atrioventricular valves from endocardial cushions divide it. A muscular interventricular septum grows upward from the apex toward the base of the heart (Fig. 17-7). It is joined by the downward-growing membranous septum, separating right and left ventricles. ***The most common VSD is related to partial or incomplete formation of the membranous portion of the septum.***

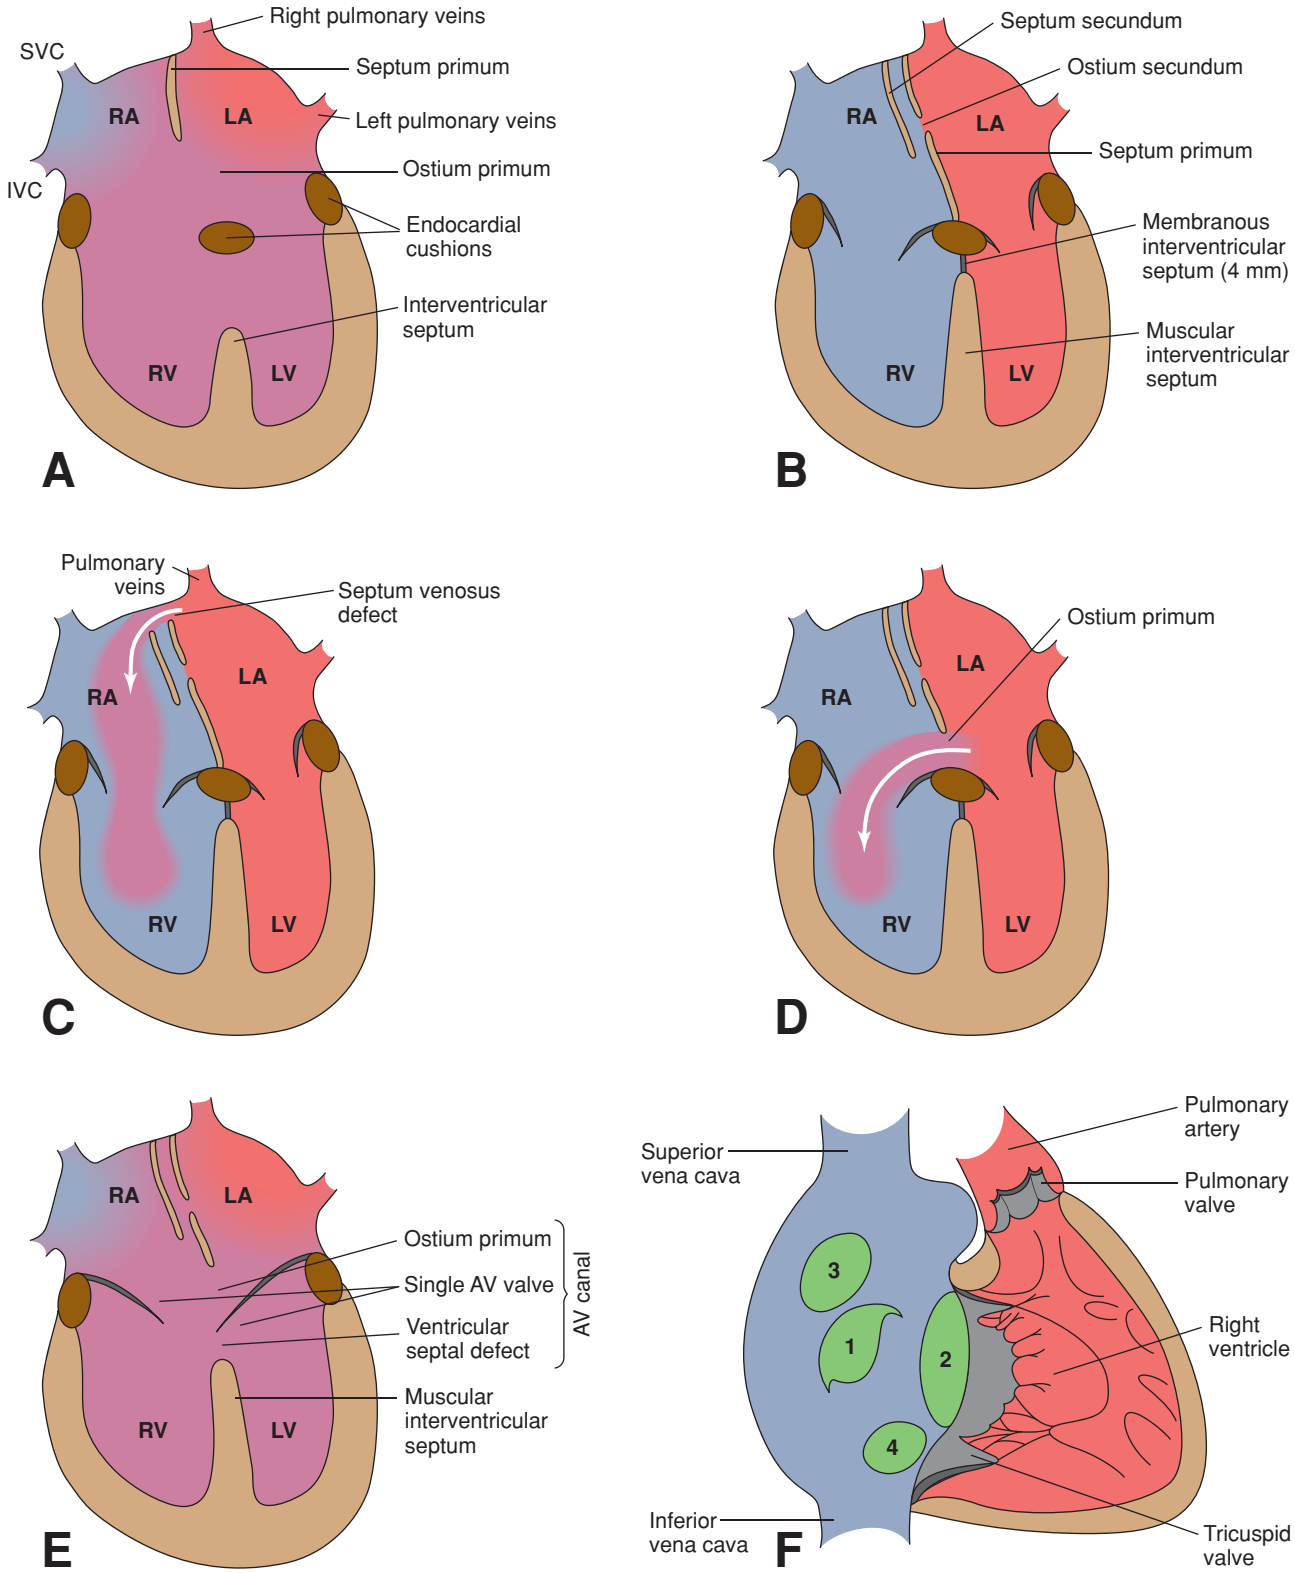

FIGURE 17-7. Pathogenesis of ventricular and atrial septal defects. A. The common atrial chamber is being separated into the right and left atria (RA and LA) by the septum primum. Because the septum primum has not yet joined the endocardial cushions, there is an open ostium primum. The ventricular cavity is being divided by a muscular interventricular septum into right and left chambers (right and left ventricles, RV and LV). *IVC* = inferior vena cava; *SVC* = superior vena cava. **B.** The septum primum has joined the endocardial cushions but at the same time has developed an opening in its midportion (the ostium secundum). This opening is partly overlaid by the septum secundum, which has grown down to cover, in part, the foramen ovale. Simultaneously, the membranous septum joins the muscular interventricular septum to the base of the heart, completely separating the ventricles. **C.** The **sinus venosus type of atrial septal** defect is located in the most cephalad region and is adjacent to the inflow of the right pulmonary veins, which thus tend to open into the RA. **D.** The **ostium primum defect** occurs just above the atrioventricular (AV) valve ring, sometimes in the presence of an intact valve ring. It may also, in conjunction with a defect of the valve ring and ventricular septum, form an AV canal, as shown in panel **E.** This common opening allows free communication between the atria and the ventricles. **F. Location of atrial septal defects.** In decreasing order of frequency: 1. Ostium secundum. 2. Ostium primum. 3. Sinus venosus. 4. Coronary sinus type.

PATHOLOGY: VSDs occur as (1) a small hole in the membranous septum; (2) a large defect involving more than the membranous region (perimembranous defects); (3) defects in the muscular portion, which are more common anteriorly but can occur anywhere in the muscular septum and are often multiple; or (4) complete absence of the muscular septum (leaving a single ventricle).

VSDs are most common in the superior portion of the septum below the pulmonary artery outflow tract (below the crista supraventricularis, i.e., infracristal) and behind the septal leaflet of the tricuspid valve. The common bundle (bundle of His) is located immediately below the defect (inlet type). Less commonly, the defect is above the crista supraventricularis (supracristal) and just below the pulmonary valve (infra-arterial). The supracristal variety of septal defect is often associated with other defects, such as an overriding pulmonary artery (the **Taussig-Bing** type of double-outlet right ventricle), transposition of the great vessels or persistent truncus arteriosus.

CLINICAL FEATURES: ***A small septal defect may have little functional significance and may close spontaneously as the child matures.*** Either hypertrophy of adjacent muscle or adherence of tricuspid valve leaflets to the margins of the hole may close the defect. In infants with large septal defects, higher left ventricular pressure creates initially a left-to-right shunt. Left ventricular dilation and congestive heart failure are common complications of such shunts. If a defect is small enough to permit prolonged survival, augmented pulmonary blood flow caused by shunting of blood into the right ventricle eventually results in thickening of pulmonary arteries and increased pulmonary vascular resistance. This increased vascular resistance may be so great that the direction of the shunt reverses, and goes from right to left **(Eisenmenger complex)**. A patient with this condition displays late onset of cyanosis (i.e., tardive cyanosis), right ventricular hypertrophy and right-sided heart failure.

Additional complications of ventricular septal defects include (1) infective endocarditis at the lesional site, (2) paradoxical emboli and (3) prolapse of an aortic valve cusp (with resulting aortic insufficiency). Large ventricular septal defects are repaired surgically, usually in infancy.

Atrial Septal Defects

Atrial septal defects (ASDs) range in severity from clinically insignificant and asymptomatic to life-threatening conditions. They arise embryologically by defects in atrial septum formation. Embryologic development of the atrial septum occurs in a sequence that permits continued passage of oxygenated placental blood from the right to the left atrium through the patent foramen. The developing atrial septum allows this right-to-left shunt to continue until birth. Beginning at the fifth week of intrauterine life, the septum primum extends downward from the roof of the common atrium to join to the endocardial cushions, thus closing the incomplete segment, or "ostium primum" (Fig. 17-7A). Before this closure is complete, the midportion of the septum primum develops a defect, or "ostium secundum," so that right-to-left flow continues. During the sixth week, a second septum (septum secundum) develops to the right of the septum primum, passing from the roof of the atrium toward the endocardial cushions (Fig. 17-7B). This process leaves a patent foramen, the **foramen ovale,** in the position of the original ostium secundum. The defect persists until it is sealed off after birth by fusion of the septum primum and septum secundum, whereupon it is termed the **fossa ovalis**.

MOLECULAR PATHOGENESIS: The cause of most ASDs is not known, but a minority of them are parts of certain genetic syndromes. About 15% of familial ASDs and 3% of sporadic ASDs are associated with coding errors in *NKX2.5.* Deletion of the T-box gene *TBX1* in DiGeorge syndrome (chromosome 22Q11 deletion) has been implicated in ASD formation. Mutations in a related T-box gene, *TBX5,* cause Holt-Oram syndrome in which large secundum-type ASDs typically occur. Mutations in the cardiac transcription factor *GATA4* are associated with both ASDs and VSDs.

PATHOLOGY: ASDs occur at a number of sites (Fig. 17-7).

- **Patent foramen ovale:** Tissue derived from the septum primum situated on the left side of the foramen ovale functions as a flap valve that normally fuses with the margins of the foramen ovale, thereby sealing the opening. An incomplete seal of the foramen ovale, which can be traversed with a probe **(probe patent foramen ovale),** occurs in 25% of normal adults and is not normally problematic. However, it may become a true shunt if right atrial pressure increases (e.g., with recurrent pulmonary thromboemboli). In this case, a right-to-left shunt develops, and emboli from the right-sided circulation pass directly into the systemic circuit. Such **paradoxical emboli** may cause infarcts in many parts of the arterial circulation, most commonly in the brain, heart, spleen, intestines, kidneys and lower extremities. A widely patent foramen ovale is occasionally encountered and is actually an acquired atrial septal defect caused by a disproportion between the size of the foramen ovale and the length of the valve covering it.
- **Atrial septal defect, ostium secundum type:** This defect accounts for 90% of ASDs. It is a true deficiency of the atrial septum and should not be confused with a patent foramen ovale. Ostium secundum defects occur in the middle portion of the septum and vary from trivial openings to large defects of the entire fossa ovalis region. Small defects are usually not problematic, but larger ones may allow sufficient blood to shunt from left to right to cause dilation and hypertrophy of the right atrium and ventricle. In this setting, pulmonary artery diameter may exceed that of the aorta.

  Lutembacher syndrome, a variant of the ostium secundum atrial septal defect, combines mitral stenosis and an ostium secundum atrial septal defect. Mitral stenosis may be due to a congenital malformation or rheumatic fever. Increased left atrial pressure due to mitral valve obstruction keeps the atrial septum patent.
- **Sinus venosus defect:** This anomaly, accounting for 5% of ASDs, occurs in the upper portion of the atrial septum, above the fossa ovalis, near the entry of the superior vena cava (Fig. 17-7C). It is usually accompanied by drainage of right pulmonary veins into the right atrium or superior vena cava.
- **Atrial septal defect, ostium primum type:** This condition involves the region adjacent to the endocardial cushions

(Fig. 17-7D) and makes up 7% of atrial septal defects. There are usually clefts in the anterior mitral valve leaflet and the septal leaflet of the tricuspid valve, which may be accompanied by a defect in the adjacent interventricular septum.

- **Atrioventricular canal:**
  - **Persistent common atrioventricular canal** represents fully developed combined atrial and ventricular septal defects (Fig. 17-7E). Although quite uncommon, this defect occurs often in patients with Down syndrome.
  - **Complete atrioventricular canal** occurs when atrioventricular endocardial cushions fail to fuse. As a result, the defect includes (1) an enlarged ostium primum atrial septal defect, (2) an inlet ventricular septal defect and (3) clefts in the mitral valve anterior leaflet and the tricuspid valve septal leaflet.
  - **Incomplete (partial) atrioventricular canal** is a situation in which an ostium primum atrial septal defect is adjacent to the atrioventricular valves, which are often abnormal.
- **Coronary sinus atrial septal defect:** This is the rarest of atrial septal defects. It is situated in the posteroinferior part of the interatrial septum by the coronary sinus ostium and is associated with a persistent left superior vena cava, which drains into the roof of the left atrium.

CLINICAL FEATURES: Young children with atrial septal defects usually are asymptomatic, although they may complain of easy fatigability and dyspnea on exertion. Later in life, usually in adulthood, changes in the pulmonary vasculature may reverse blood flow through the defect and create a right-to-left shunt. Then, cyanosis and clubbing of the fingers ensue. Complications of atrial septal defects include atrial arrhythmias, pulmonary hypertension, right ventricular hypertrophy, heart failure, paradoxical emboli and bacterial endocarditis. Symptomatic cases are treated surgically or with new closure devices, which can be delivered and placed percutaneously.

Patent Ductus Arteriosus

The early embryo supposedly recapitulates an ancestral evolutionary stage, with six aortic arches connecting ventral and dorsal aortas as part of the branchial cleft system (Fig. 17-8A). The left sixth aortic arch is partly preserved as the pulmonary arteries, and the arterial continuation on the left to the descending thoracic aorta becomes the **ductus arteriosus**. The ductus conveys most of the pulmonary outflow into the aorta. It constricts after birth in response to increased arterial oxygen content and becomes occluded by fibrosis **(ligamentum arteriosus)** (Fig. 17-8B).

ETIOLOGIC FACTORS: Persistent PDA is one of the most common congenital cardiac defects, especially in infants whose mothers were infected with rubella virus early in pregnancy. It is also common in premature infants, in whom prematurity precluded closure. In these patients, the ductus usually closes spontaneously. In full-term infants with PDA, however, the ductus has an abnormal endothelium and media, and only rarely closes spontaneously. PDAs occur in some patients with Down and DiGeorge syndromes.

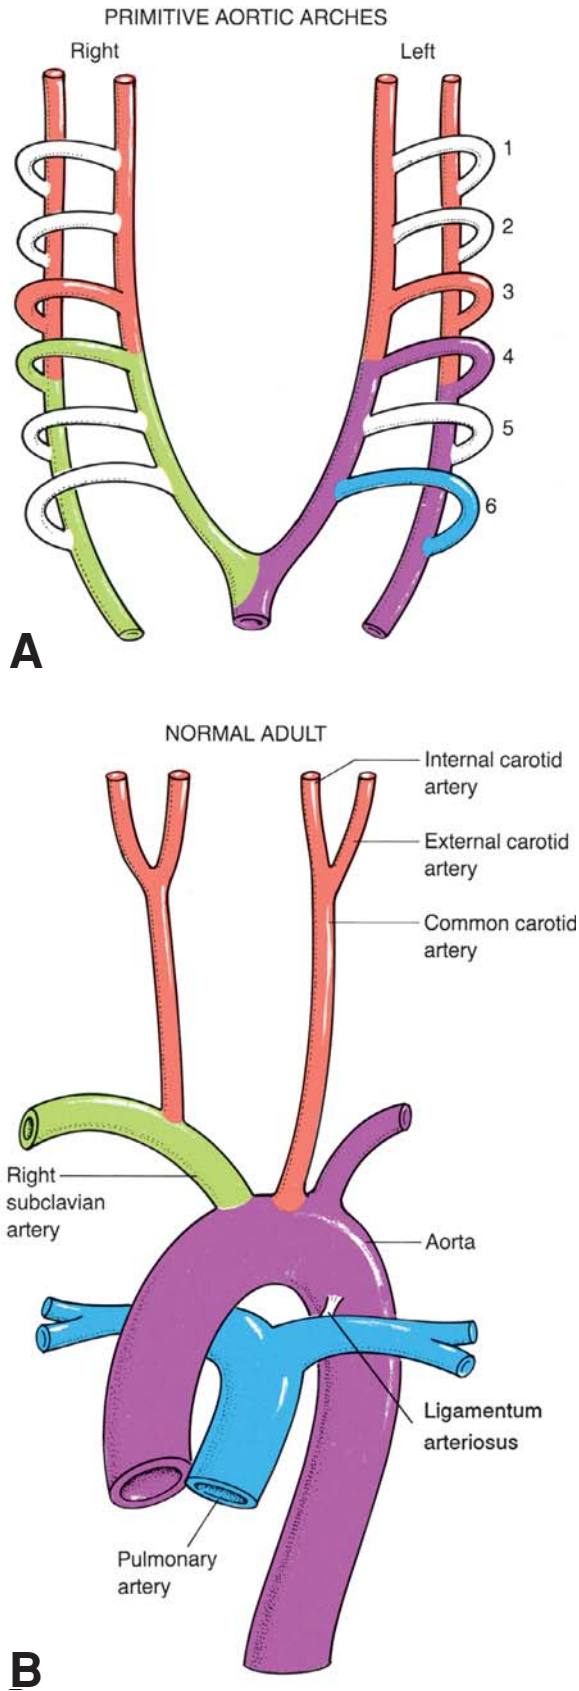

FIGURE 17-8. Derivatives of the aortic arches. A. Complete primitive aortic arch system. **B.** In the normal adult, the left fourth aortic arch is preserved as the arch of the adult aorta, and the left sixth arch gives rise to the pulmonary artery and ligamentum arteriosus (closed ductus arteriosus).

CLINICAL FEATURES: Luminal diameters of PDAs vary greatly. A small shunt has little effect on the heart, but a large one may divert blood from the aorta to the low-pressure pulmonary artery. In severe cases, over half of the left ventricular output may be shunted into the pulmonary circulation. Left ventricular hypertrophy and heart failure ensue owing to increased demand for cardiac output. In patients with large PDAs, the increased volume and pressure of blood in the pulmonary circulation eventually lead to pulmonary hypertension and its cardiac complications. Infective endarteritis involving the pulmonary artery side of the ductus is a frequent complication of untreated PDA.

PDA can be corrected surgically or by interventional cardiac catheterization. It can be caused to contract and then close by instilling prostaglandin synthesis inhibitors (e.g., indomethacin). Conversely, it can be kept open after birth by administering prostaglandins (PGE_2) if survival of patients born with a cardiac defect requires a left-to-right or right-to-left shunt. Examples include patients with isolated pulmonary stenosis, complete transposition of the great vessels or hypoplastic left heart syndrome.

Aortopulmonary window is a defect between the base of the aorta and the pulmonary artery. It is a rare condition that is functionally similar to PDA and is clinically difficult to differentiate from it.

Other abnormalities of the aortic arches can be understood in terms of variations that could occur if the complete aortic arch system develops incorrectly (Fig. 17-8). Thus, the right side of the arch system rather than the left may be retained, resulting in a **right aortic arch**. This is seen in about 25% of patients with tetralogy of Fallot and 50% of patients with truncus arteriosus. A right aortic arch is innocuous unless it creates a vascular ring that compresses the esophagus and trachea.

Persistent Truncus Arteriosus

The truncus arteriosus is the embryonic arterial trunk that initially opens from both ventricles and is later separated into the aorta and pulmonary trunk by the spiral septum. ***Persistent truncus arteriosus is a common trunk of origin for the aorta, pulmonary arteries and coronary arteries, resulting from absent or incomplete partitioning of the truncus arteriosus by the spiral septum. Truncus arteriosus always overrides a VSD and receives blood from both ventricles.*** The valve of the truncus usually has three or four semilunar cusps but may have as few as two or as many as six. The coronary arteries arise from the base of the valve.

PATHOLOGY: There are several variants of truncus arteriosus:

- **Type 1** is most common and consists of a single trunk that gives rise to a common pulmonary artery and ascending aorta.
- **Type 2** displays right and left pulmonary arteries that originate from a common site in the posterior midline of the truncus.
- **Type 3** has separate pulmonary arteries arising laterally from a common trunk.
- **Type 4** covers other rare variants in which there is no pulmonary trunk at all and in which the pulmonary circulation is supplied from the aorta by enlarged bronchial arteries. This type is difficult to differentiate from tetralogy of Fallot with pulmonary artery atresia.

CLINICAL FEATURES: Most infants with truncus arteriosus have torrential pulmonary blood flow, causing heart failure, recurrent respiratory infections and often early death. Pulmonary vascular disease develops if children survive, in which case cyanosis, polycythemia and clubbing of the fingers appear. Open-heart surgery before significant pulmonary vascular changes develop is effective treatment.

Hypoplastic Left Heart Syndrome

PATHOLOGY: This usually profound malformation features hypoplasia of the left ventricle and ascending aorta and hypoplasia or atresia of the left-sided valves. Severe aortic valvular stenosis or aortic atresia is often the main defect. Some mitral valve structures are usually present, but the mitral valve may also be atretic. If the mitral valve is atretic rather than hypoplastic, the left ventricle may only be a thin slit lined by endocardium.

MOLECULAR PATHOGENESIS: No specific mutations are implicated in this complex malformation, but there is a 2–4% risk of recurrence in future pregnancies. In families with two affected children, the risk increases to 25%. Maternal chromosome abnormalities have been implicated in about 10% of cases, the most common being terminal 11q deletion (Jacobsen syndrome), in which 10% of children have hypoplastic left heart syndrome.

CLINICAL FEATURES: Aortic valve atresia precludes left ventricular outflow into the aorta. There is an obligate left-to-right shunt through a patent foramen ovale. Cardiac output is entirely via the right ventricle and pulmonary artery. Systemic blood flow depends on flow from the pulmonary trunk to the aorta through a PDA. Coronary blood flow depends on retrograde flow from a hypoplastic ascending aorta to the sinuses of Valsalva. Because pulmonary vascular resistance is high at birth and both the foramen ovale and ductus arteriosus are patent, newborns with hypoplastic left heart syndrome may appear well initially. As pulmonary vascular resistance falls and systemic (and especially coronary) blood flow decreases, infants become symptomatic. Without surgical correction or transplantation, over 95% die within their first month.

Anomalous Pulmonary Vein Drainage

The pulmonary veins form a network in the dorsal mesoderm. A bud from the region of the atrium joins the pulmonary venous confluence, and eventually all four pulmonary veins drain into the left atrium. Failure of these tissues to join correctly results in various venous anomalies.

PATHOLOGY: **Total anomalous pulmonary vein drainage** may occur as an isolated defect or as part of the asplenia syndrome (splenic agenesis, congenital heart defects and situs inversus of abdominal organs). Most commonly, the pulmonary veins drain into a common pulmonary venous chamber and then via a

persistent left superior vena cava (persistent left pericardial vein) into the innominate vein or right superior vena cava. Alternate routes for common pulmonary vein drainage may lead into the coronary sinus or entail persistent posterior and subcardinal veins. The latter form a middorsal trunk that crosses the diaphragm and enters the portal vein or ductus venosus, and may be associated with some pulmonary venous obstruction.

CLINICAL FEATURES: In total anomalous pulmonary drainage, there is no direct venous return to the left side of the heart. Life is sustained only by an atrial septal defect or patent foramen ovale. Heart failure, severe hypoxemia and pulmonary venous obstruction result from total anomalous pulmonary vein drainage. Good results have been obtained with surgical correction.

Partial anomalous pulmonary venous drainage may result from less severe circulatory impairment. This anomaly may involve one or two pulmonary veins, especially in association with a sinus venosus type of atrial septal defect. The prognosis is excellent, similar to that for atrial septal defects.

Right-to-Left Shunt Is the Most Common Cyanotic Congenital Heart Disease

Tetralogy of Fallot

Tetralogy of Fallot represents 10% of CHD. It has a familial recurrence rate of 2–3%, but little is known of its potential genetic and epigenetic causes.

PATHOLOGY: Four changes define the tetralogy of Fallot (Fig. 17-9):

- **Pulmonary stenosis**
- **Ventricular septal defect**
- **Dextroposition of the aorta so that it overrides the ventricular septal defect**
- **Right ventricular hypertrophy**

The VSD, which may be as large as the aortic orifice, results from incomplete closure of the membranous septum and affects both the muscular septum and the endocardial cushions. In addition, development of the spiral septum, which normally divides the common truncus region into an aorta and a pulmonary artery, is abnormal. As a result, the aorta is displaced to the right and overlies the septal defect. The ventricular septal defect is immediately below the overriding aorta. Pulmonary stenosis is often due to subpulmonary muscular hypertrophy, with an enlarged infundibular muscle obstructing blood flow into the pulmonary artery. In about 1/3 of these hearts, the valve itself is the main cause of stenosis; in such cases, the valve is usually funnel shaped, with the narrow part more distal.

The heart is hypertrophied so as to give it a boot shape. Almost half of patients with tetralogy of Fallot have other cardiac anomalies, including ostium secundum atrial septal defects, PDA, left superior vena cava and endocardial cushion defects. The aortic arch is on the right side in about 25% of cases of tetralogy of Fallot. The surgeon must remember that a large branch of the right coronary artery may cross the pulmonary conus region, which is the site of the cardiotomy made to enlarge the outflow tract. Patency of the ductus arteriosus is actually protective, because it provides a source of blood to the otherwise deprived pulmonary vascular bed.

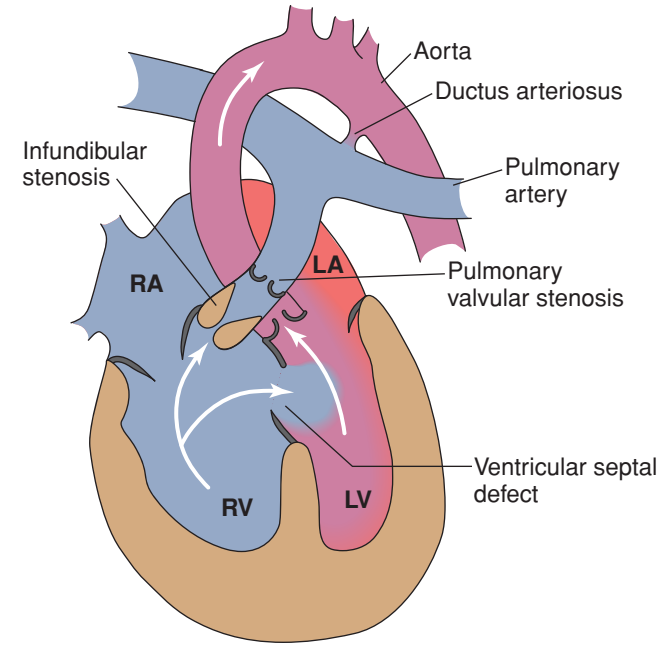

FIGURE 17-9. Tetralogy of Fallot. Note the pulmonary stenosis, which is due to infundibular hypertrophy as well as pulmonary valvular stenosis. The ventricular septal defect involves the membranous septum region. Dextroposition of the aorta and right ventricular hypertrophy are shown. Because of the pulmonary obstruction, the shunt is from right to left, and the patient is cyanotic. *LA* = left atrium; *LV* = left ventricle; *RA* = right atrium; *RV* = right ventricle.

CLINICAL FEATURES: In the face of severe pulmonary stenosis, right ventricular blood is shunted through the ventricular septal defect into the aorta, causing arterial desaturation and cyanosis. Surgical correction is typically done in the first 2 years of life. Otherwise, the affected child complains of dyspnea on exertion and often assumes a squatting position to relieve the shortness of breath. Physical development is characteristically slow. Cerebral thromboses due to marked polycythemia may occur. Patients are also at risk for bacterial endocarditis and brain abscesses. Increasing cyanosis and shortness of breath may indicate that a beneficial PDA has closed spontaneously. Left-sided heart failure is not common.

Without treatment, the prognosis of tetralogy of Fallot is dismal. However, total correction is possible with surgery, which has less than 10% mortality. After successful surgery, patients become asymptomatic and have excellent long-term prognoses.

Tricuspid Atresia

PATHOLOGY: ***Tricuspid atresia, a congenital absence of the tricuspid valve, causes obligate right-to-left shunting through the patent foramen ovale.*** This defect usually occurs with a VSD through which blood gains access to the pulmonary artery. In **type I** tricuspid atresia (75% of patients), the great arteries are normal, while in **type II** D-transposition of the great arteries occurs. The rare **type III** has L-malposition (see below).

CLINICAL FEATURES: Infants with tricuspid atresia present with cyanosis due to atrial right-to-left shunt. If the VSD is small, the limitation of pulmonary blood flow can result in even worse cyanosis. In that case, a cardiac murmur is prominent. Surgical intervention tries to bypass the atretic tricuspid valve and small right ventricle. Staged surgical palliation is the goal of current therapy.

Congenital Heart Diseases May Occur without Shunting of Blood

Transposition of the Great Arteries

In transposition of the great arteries (TGA), the aorta arises from the right ventricle and the pulmonary artery from the left ventricle. TGA has a male predominance and is more common if mothers are diabetic. It causes over half of deaths from cyanotic heart disease in the first year of life.

ETIOLOGIC FACTORS: Abnormal development of the spiral septum can produce aberrant positioning of the great arteries, such that the aorta is anterior to the pulmonary artery and connects to the right ventricle. Then, the pulmonary artery receives the left ventricular outflow (Fig. 17-10). Because the venous blood from the right side of the heart flows to the aorta and the oxygenated blood from the lungs returns to the pulmonary artery, there are in effect two independent and parallel blood circuits for systemic and pulmonary circulations. Survival requires a communication between the circuits. Virtually all such infants have an ASD, 1/2 have a VSD and 2/3 have a PDA.

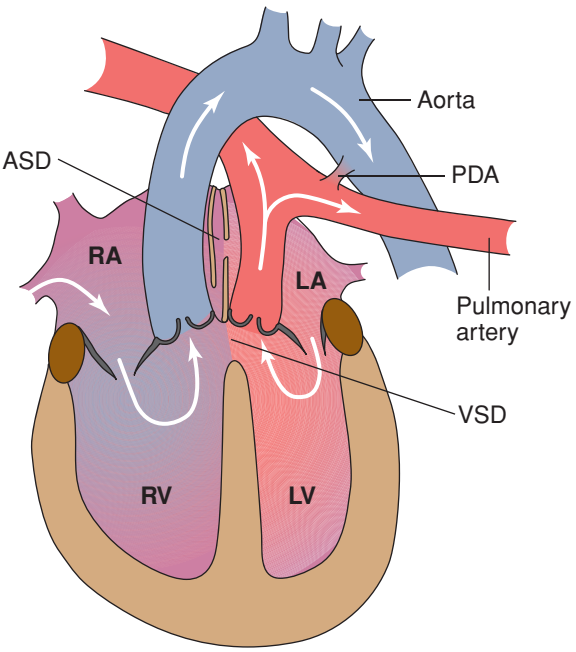

FIGURE 17-10. Complete transposition of great arteries, regular type. The aorta is anterior to, and to the right of, the pulmonary artery ("D-transposition") and arises from the right ventricle. In the absence of interatrial or interventricular connections or patent ductus arteriosus, this anomaly is incompatible with life. The volume and direction of blood flow through intracardiac communications and patent ductus arteriosus, if present, depend on pressure gradients across the communications, which can vary during early stages of extrauterine life. *ASD* = atrial septal defect; *LA* = left atrium; *LV* = left ventricle; *RA* = right atrium; *RV* = right ventricle; *PDA* = patent ductus arteriosus; *VSD* = ventricular septal defect.

PATHOLOGY: The aorta normally arises posterior and left of the pulmonary artery and ascends behind and right of it. In TGA, the aorta is anterior and right of the pulmonary artery **("D" or dextrotransposition)** all the way from its origin.

CLINICAL FEATURES: It is possible to correct the malformation within the first 2 weeks of life using an arterial-switch operation, with overall survival of 90%.

Congenitally corrected transposition is a condition in which the aorta is anterior to, but passes to the left of, the pulmonary artery **("L" transposition)**. Although the great arteries are thus abnormally related to each other and arise from discordant ventricles, the circulatory pattern is functionally corrected because of coexistent atrioventricular discordance. Patients in whom corrected TGA is the only malformation are clinically entirely normal. Unfortunately, many cases are complicated by other anomalies that require their own specific interventions.

Taussig-Bing malformation is a double-outlet right ventricle (both great vessels arise from the right ventricle) in which a VSD is above the crista supraventricularis and directly beneath an overriding pulmonary artery. This condition is functionally and clinically similar to TGA with a VSD and pulmonary hypertension.

MOLECULAR PATHOGENESIS: Various types of double-outlet right ventricle occur in patients with autosomal trisomies (13, 18, 21) and 22q11 deletions. Mutations in *NKX2.5* and maternal exposure to teratogens that influence neural crest development have also been implicated in a few cases.

Coarctation of the Aorta

Coarctation of the aorta is a local constriction that almost always occurs immediately below the origin of the left subclavian artery at the site of the ductus arteriosus. Rare coarctations may occur at any point from the aortic arch to the abdominal bifurcation. The condition is two to five times more common in males than females and is associated with a bicuspid aortic valve in 2/3 of cases. Mitral valve malformations, VSDs and subaortic stenosis may also be present. Turner syndrome, in particular, is associated with coarctation, and berry aneurysms in the brain are also more common.

ETIOLOGIC FACTORS AND PATHOGENESIS: The pathogenesis of coarctation of the aorta reflects the pattern of flow in the ductus arteriosus in fetal life (Fig. 17-11). In utero, considerably more blood flows through the ductus than across the aortic valve. The blood leaving the ductus is diverted into two streams by a posterior aortic shelf opposite the orifice of the ductus. One stream passes cephalad into a relatively hypoplastic aortic isthmus to supply the head and arms; the other enters the descending thoracic aorta. In late

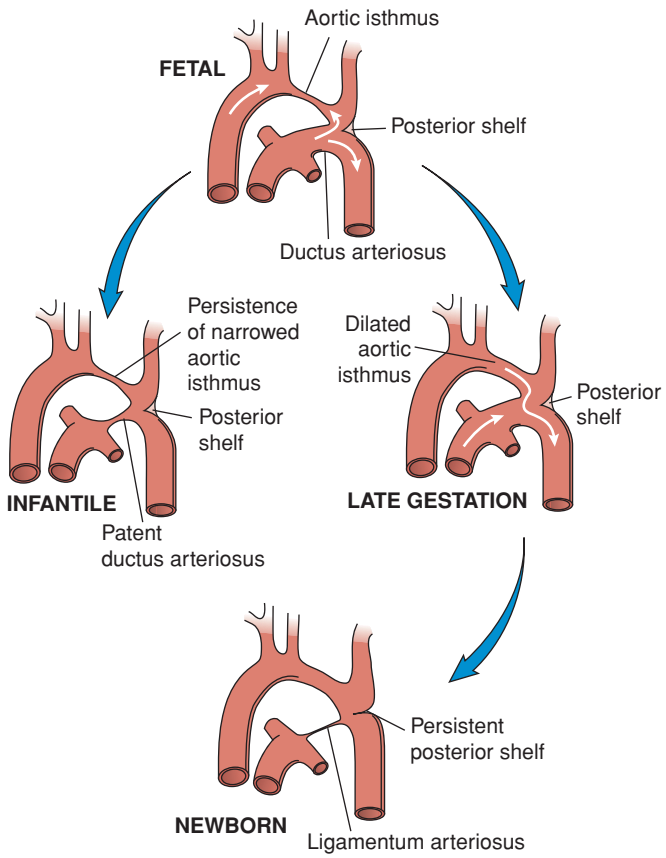

FIGURE 17-11. Pathogenesis of coarctation of the aorta. In the fetus, ductal blood is diverted into cephalad and descending streams by the posterior aortic shelf. In late fetal life, the isthmus dilates and the increased descending blood flow is accommodated by the ductal orifice. After birth, if the shelf does not undergo the normal involution, obliteration of the ductal orifice does not permit free flow around the persistent posterior shelf, thereby creating a juxtaductal obstruction of blood flow to the distal aorta. If the aortic isthmus does not dilate during late fetal life, it remains narrow, resulting in an infantile or preductal coarctation. In this circumstance, the ductus arteriosus usually remains patent.

fetal life, increasing left ventricular output dilates the isthmus and bypasses the obstruction (represented by the posterior shelf) through the wide ductal orifice. After birth, the ductal orifice is obliterated and the posterior shelf normally involutes, removing the obstruction. The shelf may not involute because of inadequate antegrade flow in the aortic arch in utero due to anomalies that limit left ventricular output (e.g., bicuspid aortic valve). Often the obstructing shelf fails to involute for unknown reasons. In any event, the result is the most common type of coarctation of the aorta, a **juxtaductal constriction**.

The **infantile (preductal) type of coarctation** occurs when the aortic isthmus remains narrow (hypoplastic) into late fetal life and after birth. This lesion is usually accompanied by a PDA and a right-to-left shunt through a VSD.

CLINICAL FEATURES: ***The clinical hallmark of coarctation of the aorta is a discrepancy in blood pressure between the upper and lower extremities.*** The pressure gradient produced by the coarctation causes hypertension proximal to the narrowed segment and, occasionally, dilation of that portion of the aorta.

Hypertension in the upper part of the body results in left ventricular hypertrophy and may produce dizziness, headaches and nosebleeds. The increased pressure may also increase the risk of rupture of a berry aneurysm and consequent subarachnoid hemorrhage (see Chapter 32). Hypotension below the coarctation leads to weakness, pallor and coldness of the lower extremities. In an attempt to bridge the obstruction between the upper and lower aortic segments, collateral vessels enlarge. Chest radiography shows notching of the inner surfaces of the ribs, caused by increased pressure in markedly dilated intercostal arteries.

Most patients with coarctation of the aorta die by age 40 unless they are treated. Complications include (1) heart failure, (2) rupture of a dissecting aneurysm (secondary to cystic medial necrosis of the aorta), (3) infective endarteritis at the point of narrowing or at the site of jet-stream impingement on the wall immediately distal to the coarctation, (4) cerebral hemorrhage and (5) stenosis or infective endocarditis of a bicuspid aortic valve. Surgical excision of the narrowed segment, preferably between 1 and 2 years of age for asymptomatic patients, is effective treatment. Balloon dilation of the narrowed area by cardiac catheterization has also been performed.

Pulmonary Stenosis

Pulmonary stenosis results from (1) developmental deformities from the endocardial cushion region (with involvement of the pulmonary valves), (2) an abnormality of the right ventricular infundibular muscle (subvalvular or infundibular stenosis, especially as part of tetralogy of Fallot) or (3) abnormal development of the more distal parts of the pulmonary artery tree (peripheral pulmonary stenosis). Peripheral pulmonary stenosis, which is much less common than the other two, may cause pulmonary artery "coarctation" at one or more sites. This anomaly is more common in newborns with **Williams syndrome,** in which there are deletion mutations in the gene encoding elastin.

Isolated pulmonary stenosis ordinarily involves the valve cusps, which are fused to form an inverted cone or funnel type of constriction. The artery distal to the valve may develop poststenotic dilation after several years. In severe cases, infants have right ventricular and atrial hypertrophy. If the foramen ovale is patent, there is a right-to-left shunt with cyanosis, secondary polycythemia and clubbing of the fingers. Balloon dilation of the stenotic valve by cardiac catheterization can be effective.

Congenital Aortic Stenosis

The types of congenital aortic stenosis are valvular, subvalvular and supravalvular.

VALVULAR AORTIC STENOSIS: The most common congenital aortic stenosis, bicuspid valve, arises through abnormal development of the endocardial cushions. A congenitally bicuspid aortic valve is much more frequent (4:1) in males than females and is associated with other cardiac anomalies (e.g., coarctation of the aorta) in 20% of cases. Typically, two of the three semilunar cusps (the right coronary cusp with one of the adjacent two cusps) are fused.

CLINICAL FEATURES: Many children with bicuspid aortic stenosis are asymptomatic. Over the years, the resulting bicuspid valve tends to become thickened and calcified, generally causing symptoms

in adulthood. More severe forms of congenital aortic stenosis result in a unicommissural valve or one without any commissures. These malformations cause symptoms in early life. Exertional dyspnea and angina pectoris may be prominent. Sudden death, principally due to ventricular arrhythmias, is a distinct threat for patients with severe obstruction. Bacterial endocarditis sometimes complicates the disease. Valve replacement may be indicated.

SUBVALVULAR AORTIC STENOSIS: This defect accounts for 10% of cases of congenital aortic stenosis and is caused by abnormal development of a band of subvalvular fibroelastic tissue or a muscular ridge. Stenosis results from a membranous diaphragm or fibrous ring that surrounds the left ventricular outflow tract immediately below the aortic valve. It is twice as common in males as in females.

Many people with subvalvular aortic stenosis develop thickening and immobility of the aortic cusps, with mild aortic regurgitation. Bacterial endocarditis carries its own risks and may also aggravate the regurgitation. Surgical treatment of subvalvular aortic stenosis involves excising the membrane or fibrous ridge.

SUPRAVALVULAR AORTIC STENOSIS: This type of stenosis is much less common than the other two, and is often associated with idiopathic infantile hypercalcemia **(Williams syndrome)** characterized by mental retardation and multiple system disorders.

Origin of a Coronary Artery from the Pulmonary Artery

A single coronary artery or, rarely, both may originate from the pulmonary artery rather than the aorta. When one coronary artery has an anomalous origin (most often the left coronary), anastomoses develop between right and left coronary arteries. This produces an arterial–arterial shunt through which blood flows from the artery originating from the aorta to that arising from the pulmonary artery. The myocardium supplied by the anomalous artery is vulnerable to episodes of ischemia. The result may be myocardial infarction, fibrosis and calcification and endocardial fibroelastosis.

Ebstein Malformation

Ebstein malformation results from downward displacement of an abnormal tricuspid valve into an underdeveloped right ventricle. One or more tricuspid valve leaflets are plastered to the right ventricular wall for a variable distance below the right atrioventricular annulus.

PATHOLOGY: Septal and posterior tricuspid valve leaflets are usually affected. They are irregularly elongated and adherent to the right ventricular wall, so that the upper part of the right ventricular cavity (inflow region) functions separately from the distal chamber. The anterior leaflet is usually the least involved, and may be normal. The valve ring may or may not be displaced downward from its usual position. In any event, the effective tricuspid valve orifice is displaced downward into the ventricle, thus dividing it into two separate parts: the "atrialized" (proximal) ventricle and the functional right (distal) ventricle. In 2/3 of cases, conspicuous dilation of the functional ventricle hinders its ability to pump blood efficiently via the pulmonary arteries. The degree of tricuspid valve insufficiency depends on the severity and configuration of the defect in the leaflets.

CLINICAL FEATURES: Ebstein malformation leads to heart failure, massive right atrial dilation, arrhythmias with palpitations and tachycardia and sudden death. Surgical treatment has met with variable success.

Congenital Heart Block

ETIOLOGIC FACTORS: Congenital complete heart block is usually associated with other cardiac anomalies. Discontinuity of the conduction system is probably caused by the accompanying cardiac abnormality. However, in cases of isolated complete heart block, failure of the atrioventricular conduction system is believed to result from lack of regression of the sulcus tissue, which entirely encloses the conducting tissue during early development. Congenital heart block without structural heart disease has been linked to maternal connective tissue disease, especially systemic lupus. If maternal SS-A/Ro or SS-B/La autoantibodies are transmitted to the fetus transplacentally, incidence of congenital complete heart block approaches 100%.

PATHOLOGY AND CLINICAL FEATURES: Hearts of patients with congenital heart block tend to show a discontinuity between the atrial myocardium and the AV node. Alternatively, the defect may be a fibrous separation of the AV node from the ventricular conducting tissue. The heart rate is abnormally slow, but patients with isolated heart block rarely have functional difficulty. Later in life, cardiac hypertrophy, attacks of Stokes–Adams syncope (dizziness and unexpected fainting), arrhythmias and heart failure may develop.

Endocardial Fibroelastosis

Endocardial fibroelastosis (EFE) is a fibroelastotic thickening of left ventricular endocardium. It may also affect the valves. This condition may be primary or, more often, secondary.

SECONDARY ENDOCARDIAL FIBROELASTOSIS: This occurs in association with underlying cardiovascular anomalies that lead to left ventricular hypertrophy in the face of inability to meet the increased myocardial oxygen demands. Thus, secondary EFE is a common complication of congenital aortic stenosis (including hypoplastic left ventricle syndrome) and coarctation of the aorta. Some type of endocardial injury is likely involved in its pathogenesis.

PATHOLOGY: On gross examination, the left ventricle endocardium has irregular, opaque, gray-white patches, which may also affect the cardiac valves. These plaques are areas of endocardial fibroelastotic thickening, often with degeneration of adjacent subendocardial myocytes. Valves may show collagenous thickening.

PRIMARY ENDOCARDIAL FIBROELASTOSIS: Defined as fibroelastosis without any associated lesion, this disorder is now quite rare. It afflicts infants, usually 4–10 months old. Although it has occurred in siblings, no specific mode of inheritance has been established. Some evidence links primary EFE to mumps infection, which may explain why this condition is now seen so infrequently.

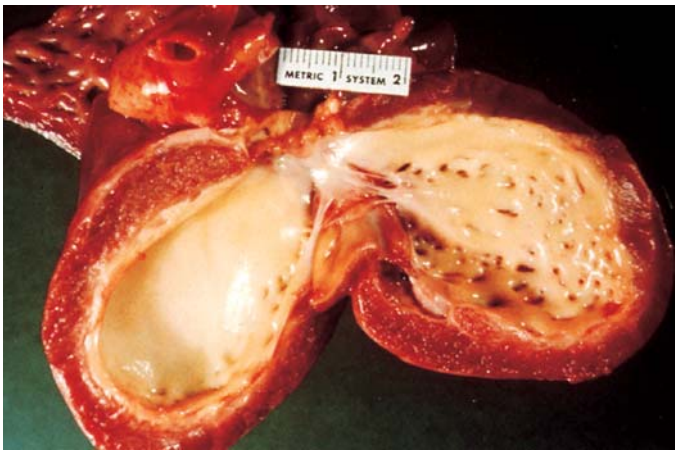

FIGURE 17-12. Endocardial fibroelastosis. The left ventricle of an infant who died of endocardial fibroelastosis has been opened to reveal a thickened endocardium lining most of the cavity and virtually obliterating the trabeculae carneae.

PATHOLOGY: The left ventricle is usually conspicuously dilated but may be contracted and hypertrophic. Diffuse endocardial thickening involves most of the left ventricle (Fig. 17-12) and aortic and mitral valve leaflets. The thickened endocardium tends to obscure the trabecular pattern of the underlying myocardium, and papillary muscles and chordae tendineae are thick and short. Mural thrombi may be present.

Infants with primary EFE develop progressive heart failure. The prognosis is dismal, and cardiac transplantation offers the only hope for a cure.

Dextrocardia

Dextrocardia is rightward orientation of the base–apex axis of the heart. It is often associated with a mirror image of the normal left-sided location and configuration. The position of the ventricles is determined by the direction of the embryonic cardiac loop. If the loop protrudes to the right, the future right ventricle develops on the right, and the left ventricle comes to occupy its proper position. If the loop protrudes to the left, the opposite occurs.

PATHOLOGY: Dextrocardia without abnormal positioning of the visceral organs **(situs inversus)** is invariably associated with severe cardiovascular anomalies. These include transposition of the great arteries, several atrial and ventricular septal defects, anomalous pulmonary venous drainage and others. If dextrocardia occurs with situs inversus, the heart is functionally normal, but minor anomalies may be seen.

ISCHEMIC HEART DISEASE

Ischemic heart disease is usually due to coronary artery atherosclerosis. It develops when blood flow is inadequate to meet the heart's oxygen needs. Ischemic heart disease is by far the most common type of heart disease in the United States and other industrialized nations, where it is the leading cause of death and is responsible for at least 80% of all deaths from heart disease. By contrast, atherosclerotic heart disease is far less frequent in underdeveloped countries. The principal effects of ischemic heart disease are angina pectoris, myocardial infarction, chronic congestive heart failure and sudden death.

ANGINA PECTORIS: This is the pain of myocardial ischemia. It typically feels like severe crushing or burning in the substernal portion of the chest, which may radiate to the left arm, jaw or epigastrium. It is the most common symptom of ischemic heart disease. Coronary atherosclerosis usually becomes symptomatic only when the luminal cross-sectional area of the affected vessel is reduced by more than 75%. A patient with angina pectoris typically has recurrent episodes of chest pain, usually brought on by physical or emotional stress. The pain is of limited duration (1–15 minutes) and is relieved by rest or treatment with sublingual nitroglycerin (a potent vasodilator).

Although the most common cause of angina pectoris is severe coronary atherosclerosis, decreased coronary blood flow can result from other conditions, including coronary vasospasm, aortic stenosis or aortic insufficiency. Angina pectoris is not usually associated with myocardial pathology as long as the duration and severity of the episodes do not cause myocardial necrosis. However, repetitive bouts of angina may eventually contribute to myocytolytic degeneration of the myocardium (Fig. 17-6).

Prinzmetal angina (variant angina) ***is an atypical form of angina that occurs at rest and is caused by coronary artery spasm.*** The mechanisms responsible are not fully understood, but endothelial dysfunction plays a major role. Patients typically show vasoconstrictor responses to acetylcholine, reflecting abnormal nitric oxide production. Thromboxane, derived from platelet activation, may also be involved. Spasm in structurally normal coronary arteries may be part of a systemic syndrome of abnormal arterial vasomotor reactivity, which includes migraine headache and Raynaud phenomenon. Usually, though, it develops in atherosclerotic coronary arteries, often in a portion of a vessel near an atherosclerotic plaque. In this case, coronary artery spasm may contribute to acute myocardial infarction or affect the size of an infarct but is generally not the principal cause of infarction.

In **unstable angina,** ***chest pain has a less predictable relationship to exercise than does stable angina, may occur during rest or sleep and is often associated with nonocclusive thrombi over atherosclerotic plaques.*** In some cases of unstable angina, episodes of chest pain become progressively more frequent and longer over a 3- to 4-day period. Electrocardiographic (ECG) changes are not characteristic of infarction and serum levels of cardiac-specific intracellular proteins, such as the MB isoform of CK (MB-CK) or cardiac troponins T or I (evidence of myocardial necrosis), remain normal. Unstable angina is also called **preinfarction angina, accelerated angina** or **"crescendo" angina**. Without pharmacologic or mechanical intervention to treat the coronary narrowing, many such patients progress to myocardial infarction.

MYOCARDIAL INFARCTION: A myocardial infarct is a discrete focus of ischemic muscle necrosis in the heart. This definition excludes patchy foci of necrosis caused by drugs, toxins or viruses. Development of an infarct is related to the duration of ischemia and the metabolic demands of the ischemic tissue. In experimental coronary artery ligation, foci of necrosis form after 20 minutes of ischemia and become more extensive as the period of ischemia lengthens.

CHRONIC CONGESTIVE HEART FAILURE: Early mortality associated with acute myocardial infarction is now less

than 5%. Many patients with ischemic heart disease survive longer and develop chronic congestive heart failure. Coronary artery disease is responsible for over 75% of heart failure in patients. Contractile impairment in these people is due to irreversible loss of myocardium (previous infarcts) and hypoperfusion of surviving muscle, which leads to chronic ventricular dysfunction ("hibernating" myocardium; Fig. 17-6). Some of these patients die suddenly, especially those in whom contractile impairment is not severe. Others develop progressive pump failure and die of multiorgan failure. Because their coronary artery disease is often so extensive and many have already had coronary artery bypass surgery, the only treatments available for end-stage disease in these patients are heart transplantation or the use of artificial pumps (ventricular assist devices).

SUDDEN DEATH: In some patients, the first and only clinical manifestation of ischemic heart disease is sudden death due to spontaneous ventricular tachycardia that degenerates into ventricular fibrillation. Diagnoses of sudden death vary. Some authorities only consider death to be sudden if it occurs within 1 hour of the onset of symptoms. Others regard death within 24 hours after the onset of symptoms to be sudden or require that sudden death be diagnosed only if it is unexpected. ***In any event, coronary atherosclerosis underlies most cases of cardiac death occurring during the first hour after the onset of symptoms.***

Experimental animals subjected to acute coronary occlusion show a high incidence of ventricular fibrillation within 1 hour. Sudden cardiac death due to ventricular fibrillation also occurs in humans as a result of acute coronary artery thrombosis. On the other hand, such an arrhythmia also appears in patients with marked coronary artery disease and no detectable thrombosis. Most patients who have been defibrillated and survived an arrhythmia have not suffered acute myocardial infarction: serum markers and ECG changes characteristic of infarction do not develop. ***Thus, in many cases, lethal arrhythmia is likely triggered by acute ischemia without overt myocardial infarction.*** The presence of a healed infarct or ventricular hypertrophy increases the risk that an episode of acute ischemia will initiate life-threatening ventricular arrhythmia.

EPIDEMIOLOGY: ***The major risk factors predisposing to coronary artery disease are (1) systemic hypertension, (2) cigarette smoking, (3) diabetes mellitus and (4) elevated blood cholesterol.*** Any one of these factors significantly increases the risk of myocardial infarction, but a combination of multiple factors increases that risk by over 7-fold (see Chapter 8).

During the 20th century, the United States first experienced a dramatic increase and then a marked decrease in mortality from ischemic heart disease. In 1950, the age-adjusted death rate from myocardial infarction was 226 per 100,000 cases; 40 years later it was 108. This shift reflects many factors, including reduced smoking, lower dietary saturated fat and new drugs that control hypertension, reduce cholesterol and dissolve coronary thrombi. Important advances in medical technology include construction of coronary care units, coronary revascularization procedures and use of defibrillators and ventricular assist devices. Concurrently, the role of hyperlipidemia in the pathogenesis of coronary artery atherosclerosis attracted much more attention. This was driven initially by epidemiologic evidence showing that populations in which men have high mean serum cholesterol values had higher rates of coronary artery disease. Since then, multiple studies established that elevated serum low-density lipoproteins (LDLs) increase risk of myocardial infarction, but that high levels of high-density lipoproteins (HDLs) decrease that risk. The total cholesterol–to–HDL cholesterol ratio appears to be a better predictor of coronary artery disease than is serum cholesterol level alone.

Although blood lipid profile is an important indicator of risk of atherogenesis, other risk factors exert powerful independent effects. Someone whose blood pressure is 160/95 mm Hg has twice the risk of ischemic heart disease as someone whose blood pressure is 140/75 mm Hg or less. Risk of ischemic heart disease increases in proportion to the numbers of cigarettes smoked. Serum factors involved in thrombosis or thrombolysis or that contribute to endothelial injury have also been implicated in atherogenesis. For example, plasma fibrinogen levels directly correlate with risk of ischemic heart disease, presumably because of the role of fibrinogen in atherogenesis and coronary artery thrombosis. Other factors that increase risk of myocardial infarction include factor VII, plasminogen activator inhibitor-1 (PAI-1), homocysteine and low fibrinolytic activity. Levels of selected serum markers of inflammation such as C-reactive protein also predict greater ischemic heart disease risk.

In recent years, there has been a remarkable increase in the incidence of type 2 diabetes in the United States, which mirrors a similar increase in obesity (see Chapter 13). Ischemic heart disease is a complication of both type 1 and type 2 diabetes, the risk being 2- to 3-fold greater than in nondiabetic people. Conversely, atherosclerotic cardiovascular disease (myocardial infarction, stroke, peripheral vascular disease) accounts for 80% of all deaths in diabetics.

Other risk factors for ischemic heart disease include:

- **Obesity:** In a major, longitudinal study of one population (Framingham Heart Study), obesity was an independent risk factor for cardiovascular disease, with an increased risk for obese people over lean ones of 2–2.5.
- **Age:** Risk of infarction increases with increasing age, up to 80 years.
- **Sex:** Sixty percent of coronary events occur in men. Angina pectoris is more common in men than women; the ratio at ages under 50 years is 4:1, and is 2:1 after age 60.
- **Family history:** In one study that controlled for other risk factors, relatives of patients with ischemic heart disease had 2- to 4-fold higher risk for coronary artery disease. The genetics of familial risk may interact with other risk factors.
- **Use of oral contraceptives:** Women over 35 years of age who smoke cigarettes and use oral contraceptives have modestly increased chances of myocardial infarction.
- **Sedentary life:** Regular exercise reduces risk of myocardial infarction, perhaps by increasing HDL. In one study, people in the least-fit quartile had six times the risk of myocardial infarction of those in the fittest quartile.
- **Personality features:** Early studies suggested that aggressive, time-conscious, executive-type individuals ("type A" personality) have more heart disease than do easygoing, relaxed people ("type B" personality). "Coronary-prone" subjects, with type A behaviors, differ from type B individuals in having higher plasma triglyceride and cholesterol levels and greater urinary catecholamine excretion. Yet, the link between coronary

artery disease and personality is controversial. Recent studies have not shown the strong association previously reported.

Many Conditions Limit Blood Supply to the Heart

The heart is an aerobic organ, using oxidative phosphorylation to generate energy for contraction. The anaerobic glycolysis used by skeletal muscle under conditions of extreme physical exertion is insufficient to sustain the heart. Ischemic heart disease is caused by an imbalance between myocardial oxygen requirements and the supply of oxygenated blood (Table 17-3).

Atherosclerosis and Thrombosis

The pathogenesis of atherosclerosis is detailed in Chapter 16. Here we discuss only briefly the features of special importance to ischemic heart disease. Coronary arteries are conductance vessels—small muscular arteries with a prominent internal elastic lamina. Their main role is to deliver blood to the regulatory vasculature (small intramural arteries and arterioles), which controls nutritive myocardial blood flow. A healthy person has substantial coronary flow reserve and myocardial perfusion can increase to four to eight times the resting blood flow. In a normal heart, the large coronary arteries provide almost no resistance to blood flow and myocardial circulation is mainly controlled by constriction and dilation of small, intramyocardial branches less than 400 μm in diameter. In advanced atherosclerosis of the main epicardial coronary arteries, luminal stenosis decreases blood pressure distal to the narrowed zone. To compensate for reduced perfusion pressure, microvessels dilate, thus maintaining normal resting blood flow. Most patients with coronary atherosclerosis do not, as a result, have ischemia or angina at rest. However, the capacity of the microcirculation to dilate further is limited, so if myocardial oxygen demand with exercise exceeds the supply, the result is ischemia and angina.

Maximal blood flow to the myocardium is not impaired until about 75% of the cross-sectional area of an epicardial coronary artery (~50% of the diameter as assessed during coronary angiography) is compromised by atherosclerosis. Resting blood flow is not reduced until over 90% of the lumen is occluded. In patients with long-standing angina pectoris, the extent and distribution of collateral circulation exerts an important influence on the risk of acute myocardial infarction. In some settings (e.g., hypotension or tachycardia), demand for oxygen and perfusion pressure may be so out of balance that myocardial infarction ensues even when a coronary artery is not ordinarily sufficiently narrowed to produce ischemia.

Although myocardial infarction often occurs during physically demanding activities such as running or shoveling snow, many infarcts occur at rest or even while asleep. Thus, for most people, conversion of clinically silent coronary atherosclerosis to a catastrophic myocardial infarction involves a sudden, marked decrease in myocardial blood flow, with or without increased myocardial oxygen demand. ***Coronary artery thrombosis is the event that usually precipitates acute myocardial infarction. Thrombosis typically results from spontaneous rupture of an atherosclerotic plaque, usually in a region with numerous inflammatory cells and a thin fibrous cap.*** The initiating event may be hemorrhage into or beneath the plaque.

TABLE 17-3
CAUSES OF ISCHEMIC HEART DISEASE

Decreased Supply of Oxygen
Conditions that influence the supply of blood
Atherosclerosis and thrombosis
Thromboemboli
Coronary artery spasm
Collateral blood vessels
Blood pressure, cardiac output, and heart rate
Miscellaneous: arteritis (e.g., periarteritis nodosa), dissecting aneurysm, luetic aortitis, anomalous origin of coronary artery, muscular bridging of coronary artery
Conditions that influence the availability of oxygen in the blood
Anemia
Shift in the hemoglobin–oxygen dissociation curve
Carbon monoxide
Cyanide
Increased Oxygen Demand (i.e., Increased Cardiac Work)
Hypertension
Valvular stenosis or insufficiency
Hyperthyroidism
Fever
Thiamine deficiency
Catecholamines

Thromboemboli

Thromboembolism is a rare cause of myocardial infarction. The coronary embolus often comes from the heart itself, usually valvular vegetations due to infective or nonbacterial endocarditis. Coronary emboli occur in patients with atrial fibrillation and mitral valve disease who have mural thrombi in the left atrial appendage (Fig. 17-13). Thromboembolic occlusion of a coronary artery is also seen in patients with left ventricular mural thrombi due to infarction, aneurysm or dilated cardiomyopathy.

Coronary Collateral Circulation

Normal coronary arteries act as endarteries. Most normal hearts have anastomoses 20–200 μm in diameter between coronary vessels. Collateral vessels do not function under normal circumstances as there is no pressure gradient between the arteries that they connect. However, a pressure differential resulting from abrupt occlusion of a coronary artery allows blood to flow from the patent artery to

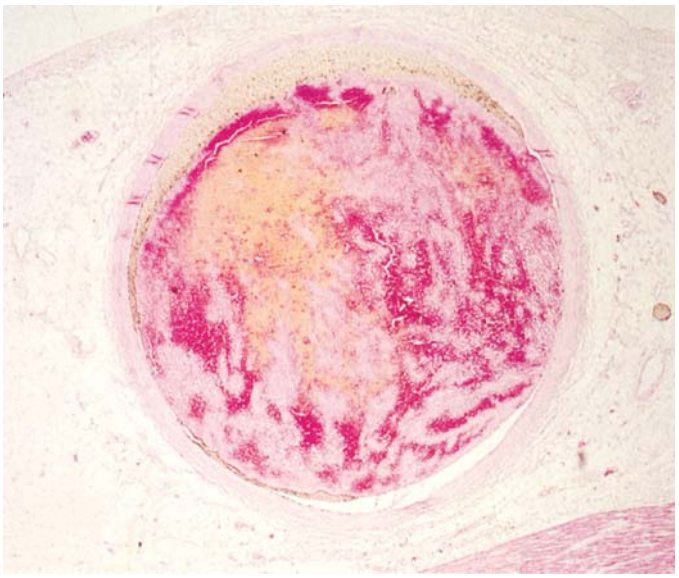

FIGURE 17-13. Thromboembolus in the left anterior descending coronary artery of a man who had old rheumatic heart disease, mitral stenosis and a mural thrombus in the left atrial appendage.

the ischemic area. Extensive collateral connections develop in hearts with severe coronary atherosclerosis. These collaterals may actually provide enough arterial flow to prevent infarction completely or to limit infarct size when a major epicardial coronary artery is acutely occluded.

Well-developed coronary collaterals can explain certain unusual situations, such as anterior infarction after recent thrombotic occlusion of the right coronary artery (so-called *infarction at a distance*). This reflects the opening of collaterals between the LAD and right coronary arteries (formed, e.g., in response to gradual atherosclerotic narrowing of the LAD). As a result, myocardium normally supplied by the LAD distal to the occlusion now depends on blood flow from the right coronary artery via collaterals. Acute thrombosis of the right coronary artery may then cause paradoxical infarction of the anterior left ventricular wall.

Other Conditions That Limit Coronary Blood Flow

- **Coronary arteritis** occurs in various vasculitides, such as polyarteritis nodosa or Kawasaki disease. It may cause luminal narrowing from vessel wall thickening. It can also create local aneurysms that may become occluded by thrombus.
- **Dissecting aortic aneurysms** may involve and obstruct coronary arteries. Rarely, medial necrosis and dissecting aneurysms are limited to a coronary artery.
- **Syphilitic aortitis** characteristically affects the ascending aorta, where it may obliterate a coronary artery orifice.
- **Congenital anomalous origin of a coronary artery** (origin of a coronary artery from the pulmonary trunk or passage of an anomalous coronary artery between the aorta and pulmonary artery) may cause sudden death in young, otherwise healthy individuals.
- **An intramural course of the LAD coronary artery** may cause myocardial ischemia and sudden death. The artery normally runs in the epicardial fat, but in some hearts, it dips into the myocardium for a short distance. The muscular bridge may compress the artery during systole or predispose to coronary spasm.

If the Blood Cannot Deliver Enough Oxygen, the Myocardium Is at Risk for Ischemia

Anemia is a common cause of decreased myocardial oxygen delivery. Although a heart with normal circulation can survive severe anemia, severe coronary atherosclerosis may limit the effectiveness of compensatory increases in coronary blood flow so severely that cardiac necrosis results. Anemia also increases cardiac workload because increased output is required to oxygenate vital organs adequately.

Carbon monoxide (CO) poisoning (see Chapter 8) decreases oxygen delivery to tissues. The high affinity of hemoglobin for CO displaces oxygen, thus depriving tissues of oxygen. It should be noted that cigarette smoking generates significant levels of carboxyhemoglobin (a measure of CO) in the blood.

Increased Oxygen Demand May Cause Cardiac Ischemia

Any increase in cardiac workload increases the heart's need for oxygen. Conditions that raise blood pressure or cardiac output, such as exercise or pregnancy, increase myocardial demand, which may lead to angina pectoris or infarction. Disorders in this category include valvular disease (mitral or aortic insufficiency, aortic stenosis), infection and conditions such as hypertension, coarctation of the aorta and hypertrophic cardiomyopathy (HCM) (Table 17-3).

Hyperthyroid patients have increased metabolic rates and tachycardia, leading to increased oxygen demand and greater cardiac workload. Treatment of the underlying thyroid disease is the best therapy for a hyperthyroid patient with symptoms of cardiac ischemia. Fever also increases basal metabolic rate, cardiac output and heart rate.

Myocardial Infarcts Are Mainly Subendocardial or Transmural

PATHOLOGY: Location of Infarcts

There are important differences between these two types of infarction (Table 17-4).

A **subendocardial infarct** affects the inner 1/3 to 1/2 of the left ventricle. It may arise within the territory of one of the major epicardial coronary arteries or it may be circumferential, involving subendocardial distributions of multiple coronary arteries. ***Subendocardial infarction generally results from hypoperfusion.*** It may be due to atherosclerosis in one coronary artery or due to diseases that limit myocardial blood flow globally, such as aortic stenosis, hemorrhagic shock or hypoperfusion during cardiopulmonary bypass. Most subendocardial infarcts are not consequences of occlusive coronary thrombi, although small particles of platelet–fibrin thrombus may be seen in the epicardial coronary artery that supplies the affected region. Circumferential subendocardial infarction caused by global hypoperfusion of the myocardium does not require that coronary artery stenosis to be present. Because necrosis is limited to the inner layers of the heart, complications arising in transmural infarcts (e.g., pericarditis and ventricular rupture) do not follow subendocardial infarction.

TABLE 17-4
DIFFERENCES BETWEEN SUBENDOCARDIAL AND TRANSMURAL INFARCTS

Subendocardial Infarcts	Transmural Infarcts
Multifocal	Unifocal
Patchy	Solid
May be circumferential	In distribution of a specific coronary artery
Coronary thrombosis rare	Coronary thrombosis common
Often result from hypotension or shock	Often cause shock
No epicarditis	Epicarditis common
Do not form aneurysms or lead to ventricular rupture	May result in aneurysm or ventricular rupture

A **transmural infarct** involves the full left ventricular wall thickness, usually after occlusion of a coronary artery. As a result, transmural infarcts typically conform to the distribution of one of the three major coronary arteries (Fig. 17-2).

- **Right coronary artery:** Occlusion of this vessel's proximal portion results in an infarct of the posterior basal region of the left ventricle and the posterior third to half of the interventricular septum ("inferior" infarct).
- **LAD coronary artery:** Blockage of the LAD produces an infarct of the apical, anterior and anteroseptal walls of the left ventricle.
- **Left circumflex coronary artery:** Obstruction of this vessel is the least common cause of myocardial infarction, causing infarcts of the lateral left ventricle wall.

Myocardial infarction does not occur instantaneously. Rather, it first develops in the subendocardium and progresses as a wavefront of necrosis from subendocardium to subepicardium over several hours. Transient coronary occlusion may cause only subendocardial necrosis, but persistent occlusion eventually leads to transmural necrosis. The goal of acute coronary interventions (pharmacologic or mechanical thrombolysis) is to interrupt this wavefront and limit myocardial necrosis.

The volume of arterial collateral flow is the chief determinant of transmural progression of an infarct. In chronic cardiac hypoperfusion, extensive collaterals, which preferentially supply the outer or subepicardial layer, often limit infarction to the subendocardial myocardium. However, in fatal cases, acute transmural infarcts are more common than those restricted to the subendocardium.

Infarcts involve the left ventricle much more often and extensively than the right ventricle. This difference may be partly explained by the greater workload imposed on the left ventricle by systemic vascular resistance and the greater thickness of the left ventricular wall. Right ventricular hypertrophy (e.g., in pulmonary hypertension) increases the incidence of right ventricular infarction. Infarction of the posterior right ventricle occurs in about a third of left ventricular posteroseptal infarcts (right coronary artery territory), but infarcts limited to the right ventricle are rare.

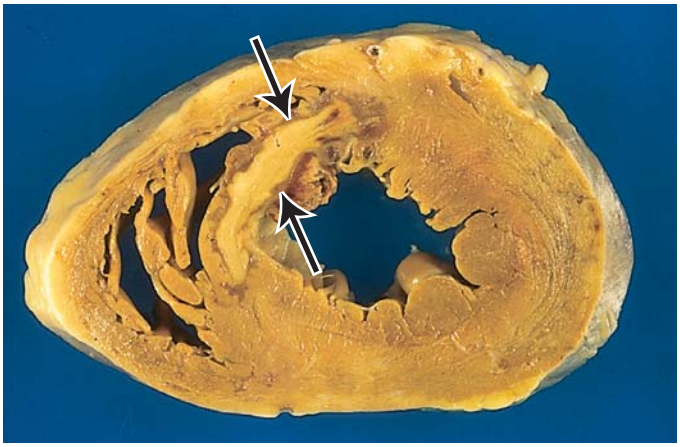

FIGURE 17-14. Acute myocardial infarct. A transverse section of the heart of a patient who died a few days after the onset of severe chest pain shows a transmural infarct in the anteroseptal region of the left ventricle (left anterior descending [LAD] coronary artery territory). The necrotic myocardium is soft, yellowish and sharply demarcated (*arrows*).

Macroscopic Characteristics of Myocardial Infarcts

The early stages of myocardial infarction have been characterized most thoroughly in experimental animals. Within 10 seconds after ligation of a coronary artery, the affected myocardium becomes cyanotic and, rather than contracting, bulges outward during systole. If the obstruction is promptly relieved, myocardial contractions resume and there is no anatomic damage, although contractility may be depressed in the affected area for many hours **(stunned myocardium)** owing to the effects of oxygen radicals formed by reperfusion of acutely ischemic myocardium (see below). This reversible stage lasts for 20–30 minutes of total ischemia, after which damaged myocytes progressively die.

Acute myocardial infarcts are not grossly identifiable within the first 12 hours. By 24 hours, they are recognized by pallor on cut surfaces of the involved ventricle. After 3–5 days, they become mottled and more sharply outlined, with a central pale, yellowish, necrotic region bordered by a hyperemic zone (Fig. 17-14). By 2–3 weeks, the infarcted region is depressed and soft, with a refractile, gelatinous appearance. Older, healed infarcts are firm and contracted, with pale gray scar tissue (Fig. 17-15).

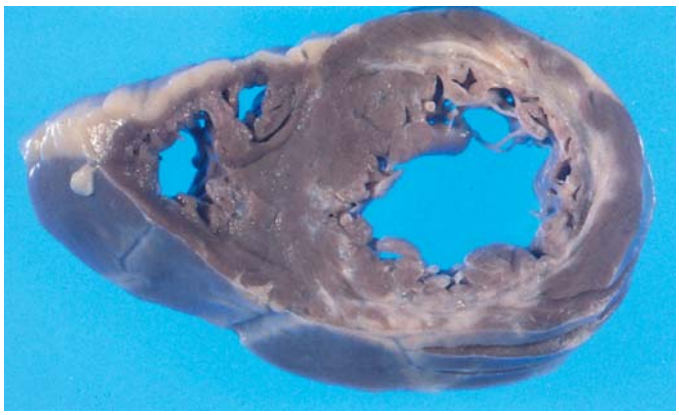

FIGURE 17-15. Healed myocardial infarct. A cross-section of the heart from a man who died after a long history of angina pectoris and several myocardial infarctions shows near-circumferential scarring of the left ventricle.

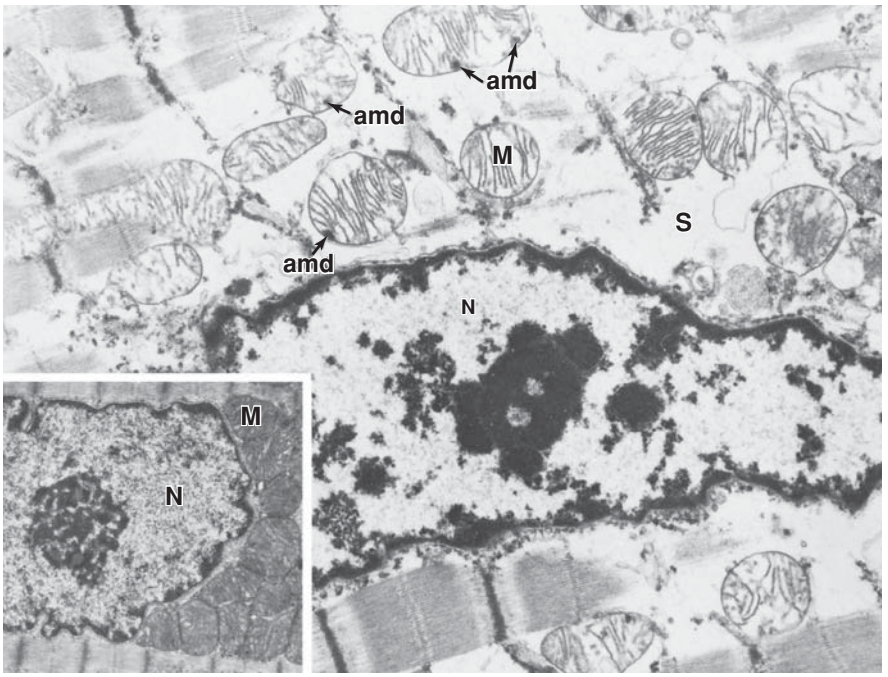

FIGURE 17-16. Ultrastructure of myocardial ischemia. Electron micrograph of an irreversibly injured myocyte from a canine heart subjected to 40 minutes of low-flow ischemia induced by proximal occlusion of the circumflex branch of the left coronary artery. (**Inset** shows a nonischemic control myocyte from the same heart. *N* = nucleus.) The affected myocyte is swollen and has abundant clear sarcoplasm (S). The mitochondria (M) are also swollen and contain amorphous matrix densities (amd), which are characteristic of lethal cell injury. The sarcolemma of this myocyte (*not shown*) exhibited small areas of disruption. The chromatin of the nucleus (N) is aggregated peripherally, in contrast to the uniformly distributed chromatin in normal tissue.

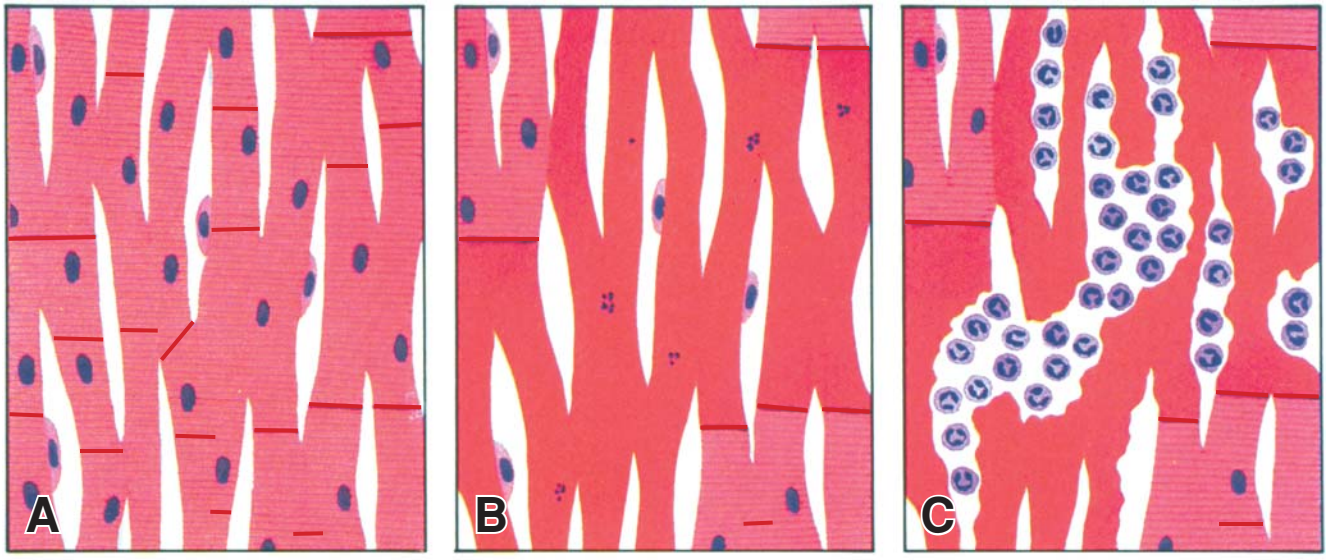

FIGURE 17-17. Development of a myocardial infarct. A. Normal myocardium. **B.** After about 12–18 hours, the infarcted myocardium shows eosinophilia (*red staining*) in sections of the heart stained with hematoxylin and eosin. **C.** About 24 hours after the onset of infarction, polymorphonuclear neutrophils infiltrate necrotic myocytes at the periphery of the infarct. **D.** After about 3 weeks, peripheral portions of the infarct are composed of granulation tissue with prominent capillaries, fibroblasts, lymphoid cells and macrophages. The necrotic debris has been largely removed from this area, and a small amount of collagen has been laid down. **E.** After 3 months or more, the infarcted region has been replaced by scar tissue.

Microscopic Characteristics of Myocardial Infarcts

THE FIRST 24 HOURS: Electron microscopy is required to discern the earliest morphologic features of ischemic injury (Fig. 17-16). Reversibly injured myocytes show subtle changes of sarcoplasmic edema, mild mitochondrial swelling and loss of glycogen (the ultrastructural correlates of stunned myocardium). After 30–60 minutes of ischemia, when myocyte injury has become irreversible, mitochondria are greatly swollen with disorganized cristae and amorphous matrix densities made of calcium phosphate salts formed by massive Ca^{2+} overload in severely injured cells. Nuclei show clumping and margination of chromatin and the sarcolemma is focally disrupted.

Loss of sarcolemmal integrity leads to release of intracellular proteins, such as myoglobin, LDH, CK and troponins I and T. Ion gradients are also dissipated, and tissue potassium decreases as sodium, chloride and calcium increase.

The noncontractile ischemic myocytes are stretched with each systole and become **"wavy fibers."** By 24 hours, they are deeply eosinophilic (Fig. 17-17) with the characteristic changes of coagulative necrosis (see Chapter 1). However, it takes several days for myocyte nuclei to disappear totally.

TWO TO 3 DAYS: Polymorphonuclear leukocytes are attracted to necrotic myocytes, but they gain access only at the edge of the infarct, where blood flow is intact. They accumulate at infarct borders and reach peak concentrations at 2–3 days (Figs. 17-17 and 17-18). Interstitial edema and microscopic areas of hemorrhage may also appear. By 2–3 days, muscle cells are more clearly necrotic, nuclei disappear and striations become less prominent. Some of the neutrophils begin to undergo karyorrhexis.

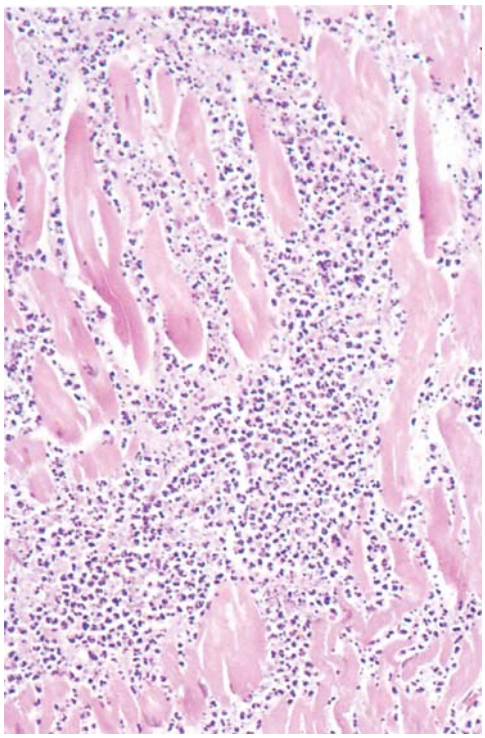

FIGURE 17-18. Acute myocardial infarct. The necrotic myocardial fibers, which are eosinophilic and devoid of cross-striations and nuclei, are immersed in a sea of acute inflammatory cells.

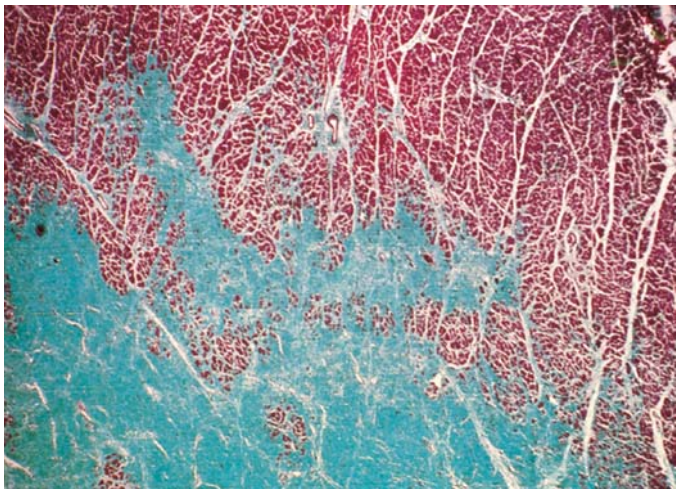

FIGURE 17-19. Healed myocardial infarct. A section at the edge of a healed infarct stained for collagen, which appears blue-green here, shows dense, acellular regions of collagenous matrix sharply demarcated from the adjacent viable myocardium.

FIVE TO 7 DAYS: By this time, few, if any, neutrophils remain. The periphery of the infarcted region shows phagocytosis of dead muscle by macrophages. Fibroblasts begin to proliferate. New collagen is deposited. Lymphocytes and pigment-laden macrophages are prominent. The process of replacing necrotic muscle with scar tissue starts at about 5 days, first at the edge of the infarct, gradually moving inward.

ONE TO 3 WEEKS: Collagen deposition proceeds, inflammation gradually recedes and the newly sprouted capillaries are progressively obliterated.

MORE THAN 4 WEEKS: Considerable dense fibrous tissue is present. The debris is slowly removed, and the scar is more solid and less cellular as it matures (Fig. 17-19).

This sequence of inflammatory and reparative events can be altered by local or systemic factors. For example, immediate extension of an infarct into a region that previously had patchy necrosis may not show expected changes. A large infarct tends not to mature at its center as rapidly as a smaller one. In estimating the age of a large infarct, it is more accurate to base interpretation on the outer border where repair begins, rather than on the central region. In fact, in some large infarcts, dead myocytes are not removed but rather remain indefinitely "mummified."

Reperfusion and Ischemic Myocardium

The above descriptions pertain to healing of infarcts caused by persistent coronary occlusion, such as those arising from thrombotic occlusion of an epicardial coronary artery. However, blood flow may be restored to regions of evolving infarcts either because of spontaneous thrombolysis or in response to therapeutic opening of occluded coronary arteries. When that happens, the infarct's gross and microscopic appearances change. Reperfused infarcts are typically hemorrhagic, from blood flow through damaged microvasculature. Thus, infarcts after persistent occlusion are only grossly apparent after about 12 hours and are pale, but hemorrhage immediately highlights reperfused infarcts. Reperfusion also accelerates acute inflammation: neutrophils gain access throughout

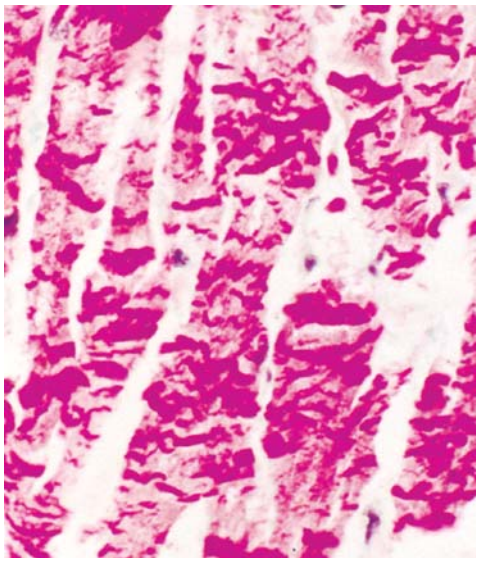

FIGURE 17-20. Contraction band necrosis. A section of infarcted myocardium shows prominent, thick, wavy, transverse bands in myofibers.

the infarct, rather than only at the periphery. They accumulate more rapidly, then also disappear more rapidly. Replacement of necrotic muscle by fibrous scar also occurs more quickly, at least in areas of the infarct in which perfusion persists.

One of the most characteristic features of reperfused infarcts is **contraction band necrosis**. Contraction bands are thick, irregular, transverse eosinophilic bands in necrotic myocytes (Fig. 17-20). By electron microscopy, these bands are small groups of hypercontracted and disorganized sarcomeres with thickened Z disks. The sarcolemma is disrupted and mitochondria located between the contraction bands swell. They may contain deposits of calcium phosphate in the matrix and amorphous matrix densities. Contraction bands occur whenever there is a massive influx of Ca^{2+} into cardiac myocytes. Reperfusion of ischemic myocardium causes extensive sarcolemmal damage mediated largely by reactive oxygen species (ROS), which permits unrestrained entry of extracellular Ca^{2+} into myocytes. This massive Ca^{2+} influx leads to hypercontraction in cells still able to contract. Ca^{2+} flow into more severely injured cells that can no longer contract but still produces dense deposits in mitochondria as in Fig. 17-16. Contraction band necrosis is most prominent when ischemic myocardium is reperfused (e.g., after thrombolytic therapy or with prolonged cardiopulmonary bypass during which the myocardium has sustained irreversible injury). In infarcts arising from persistent coronary occlusion, microscopic foci of contraction band necrosis are often seen at the margins, where dynamic ebb and flow of blood creates conditions that favor Ca^{2+} influx. Other conditions associated with contraction bands include massive catecholamine release in patients with pheochromocytoma or head injuries, or patients in shock treated with large doses of pressors.

CLINICAL FEATURES:

Clinical Diagnosis

The onset of acute myocardial infarction is often sudden, with severe, crushing substernal or precordial pain. The pain may be felt as epigastric burning (simulating indigestion) or it may extend into the jaw or down the inside of either arm. It is often accompanied by sweating, nausea, vomiting and shortness of breath. In some cases an acute myocardial infarction is preceded by unstable angina of several days' duration. ***One fourth to 1/2 of nonfatal myocardial infarctions occur without symptoms and are identified only later by ECG changes or at autopsy.*** These "clinically silent" infarcts are particularly common among diabetics with autonomic dysfunction and in cardiac transplant patients whose hearts are denervated.

The diagnosis of acute myocardial infarction is confirmed by ECG and by increased serum levels of certain enzymes or proteins. The electrocardiogram shows new Q waves, ST-segment changes and altered conformation of T waves. There is a reasonable correlation between the pathologic distinction of transmural versus subendocardial infarcts and ECG distinction of STEMI (ST elevation myocardial infarction) versus non-STEMI events. Identification in serum of cardiac proteins such as MB-CK or cardiac troponins T and I is evidence of myocardial necrosis.

Complications of Myocardial Infarction

Early mortality in acute myocardial infarction (within 30 days) has dropped from 30% in the 1950s to less than 5% today. Nevertheless, the clinical course after acute infarction may be dominated by functional or mechanical complications of the infarct.

ARRHYTHMIAS: Virtually all patients who have a myocardial infarct have abnormal cardiac rhythm at some time during their illness. Arrhythmias still account for half of deaths caused by ischemic heart disease, but the advent of coronary care units and defibrillators has greatly reduced early mortality. Acute infarction is often associated with premature ventricular beats, sinus bradycardia, ventricular tachycardia, ventricular fibrillation and paroxysmal atrial tachycardia. Partial or complete heart block can also occur. The causes of these arrhythmias are often multifactorial. Acute ischemia alters conduction, increases automaticity and promotes triggered activity related to after-depolarizations. Enhanced sympathetic activity mediated by increased levels of local or circulating catecholamines plays an important role.

LEFT VENTRICULAR FAILURE AND CARDIOGENIC SHOCK: Development of left ventricular failure soon after myocardial infarction is an ominous sign that generally indicates massive loss of muscle. Fortunately, cardiogenic shock occurs in fewer than 5% of cases, owing to the development of techniques that limit the extent of infarction (thrombolytic therapy, angioplasty) or assist damaged myocardium (intra-aortic balloon pump). Cardiogenic shock tends to develop early after infarction when 40% or more of the left ventricle has been lost; mortality is as high as 90%.

EXTENSION OF THE INFARCT: Clinically recognizable extension of an acute infarct occurs in the first 1–2 weeks in up to 10% of patients. In careful echocardiographic studies, half of all patients with anterior myocardial infarction showed some infarct extension during the first 2 weeks, indicating that many episodes of infarct extension are not recognized. Clinically significant infarct extension is associated with a doubling of mortality.

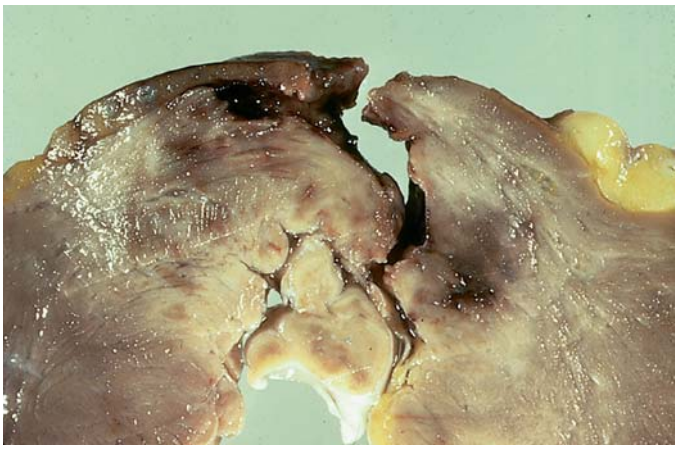

FIGURE 17-21. Rupture of an acute myocardial infarct. An elderly woman with a recent myocardial infarct died of cardiac tamponade. The pericardium was filled with blood, and the cut surface of the left ventricle shows a linear rupture of the necrotic myocardium.

RUPTURE OF THE FREE WALL OF THE MYOCARDIUM: Myocardial rupture (Fig. 17-21) may occur at almost any time in the 3 weeks after acute infarction but is most common between days 1 and 4, when the infarcted wall is weakest. During this vulnerable period, the infarct is composed of soft, necrotic tissue in which the extracellular matrix has been degraded by proteases released by inflammatory cells but new matrix deposition has not yet occurred. Once scars begin to form, rupture is less likely. Rupture of the free wall is a complication of transmural infarcts; surviving muscle overlying subendocardial infarcts prevents rupture. However, rupture usually occurs in relatively small transmural infarcts. The remaining viable, contractile myocardium produces mechanical forces that may initiate and propagate tearing along the infarct's edge, where neutrophils accumulate.

Rupture of the left ventricular free wall most often leads to hemopericardium and death from pericardial tamponade. Myocardial rupture accounts for 10% of deaths after acute myocardial infarction among hospitalized patients. It is more common in elderly people having a first infarct (most often women). Rarely, a ruptured ventricle may become walled off and the patient survives with a false aneurysm (Fig. 17-22).

OTHER FORMS OF MYOCARDIAL RUPTURE: A few patients in whom a myocardial infarct involves the interventricular septum develop **septal perforations,** 1 cm or longer. The magnitude of the resulting left-to-right shunt and, therefore, the prognosis depend on the size of the rupture.

Rupture of a portion of a papillary muscle results in mitral regurgitation. In some cases, an entire papillary muscle is transected, in which case, massive mitral valve incompetence may be fatal.

ANEURYSMS: Left ventricular aneurysms complicate 10%–15% of transmural myocardial infarcts. After acute transmural infarction, the affected ventricular wall tends to bulge outward during systole in 1/3 of patients. As the infarct heals, the newly deposited collagenous matrix is susceptible to further stretching, although eventually the scar tissue becomes nondistensible. Localized thinning and stretching of the ventricular wall in the region of a healing infarct is called "infarct expansion" but is actually an early aneurysm. Such an aneurysm is composed of a thin layer of necrotic myocardium and collagenous tissue, which expands with each contraction of the heart. As evolving aneurysms become more fibrotic, their tensile strength increases. However, the aneurysms continue to dilate with each beat, thus "stealing" some left ventricular output and increasing the workload of the heart. Patients with left ventricular aneurysms are at increased risk for ventricular tachycardia owing to increased opportunities for electrical current reentry at the periphery of the aneurysm. Mural thrombi often develop within aneurysms and can be sources of systemic emboli.

A distinction should be made between "**true**" and "**false**" **aneurysms** (Fig. 17-22). True aneurysms are much more common than false ones, and are caused by bulging

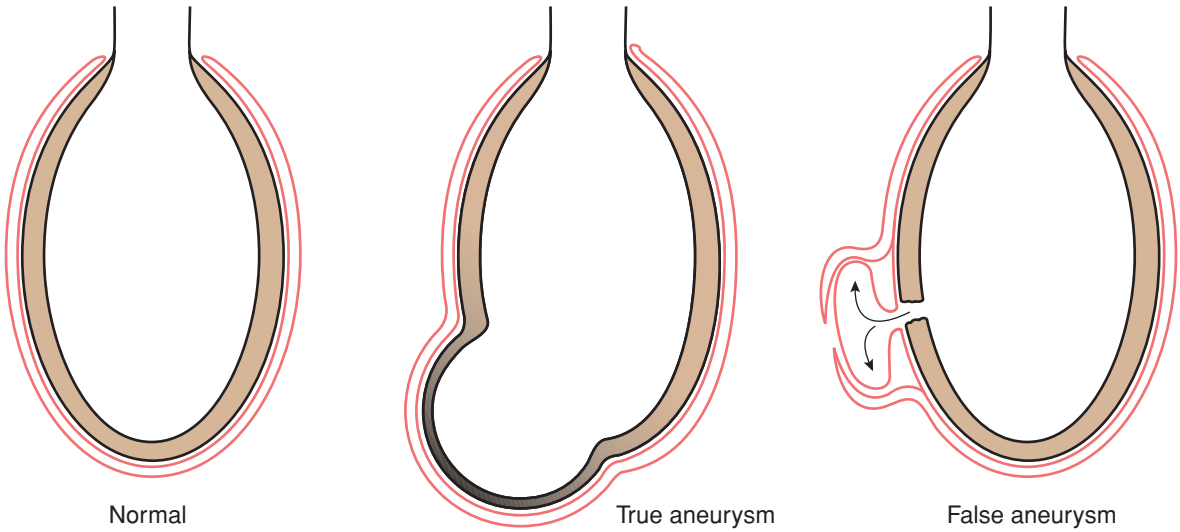

FIGURE 17-22. True and false aneurysms of the left ventricle. Left. Normal heart. The left ventricular wall (*shaded*) is enclosed by the pericardial sac. **Center.** True aneurysm shows an intact wall (*black*), which bulges outward. **Right.** False aneurysm shows a ruptured infarct that is walled off externally by adherent pericardium. Note that the mouth of the true aneurysm is wider than that of the false aneurysm.

FIGURE 17-23. Ventricular aneurysm. The heart of a patient with a history of an anteroapical myocardial infarct who developed a massive ventricular aneurysm. The apex of the heart shows marked thinning and aneurysmal dilation.

of an intact, but weakened, left ventricular wall (Fig. 17-23). By contrast, false aneurysms result from rupture of a portion of the left ventricle that has been walled off by pericardial scar tissue. Thus, the wall of a false aneurysm is composed of pericardium and scar tissue, not left ventricular myocardium.

MURAL THROMBOSIS AND EMBOLISM: One third to 1/2 of patients who die after myocardial infarction have mural thrombi overlying the infarct at autopsy (Fig. 17-24). This occurs particularly often when the infarct involves the apex of the heart. In turn, half of these patients have some evidence of systemic embolization. Inflammation of the endocardium lining an infarct promotes platelet adhesion and fibrin deposition. Also, poor contractile function of the underlying myocardium allows fibrin–platelet mural thrombi to grow. Pieces of thrombus can detach and be swept with the arterial blood, potentially causing strokes or myocardial or visceral infarcts. Documented mural thrombosis justifies anticoagulant and antiplatelet therapy.

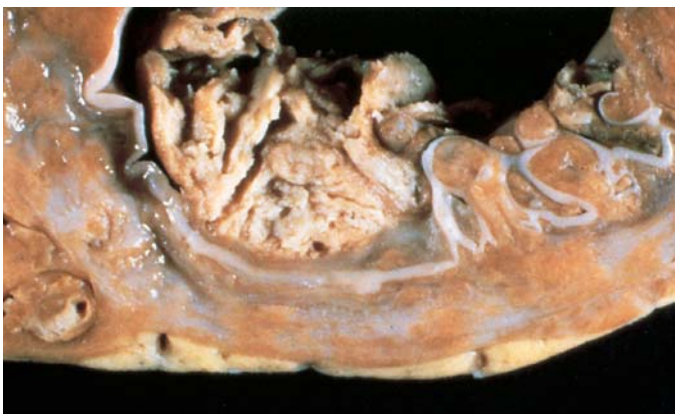

FIGURE 17-24. Mural thrombus overlying a healed myocardial infarct. In this cross-section of a fixed heart, an organized, friable, grayish white mural thrombus overlies a thickened endocardium situated over scarred myocardium.

PERICARDITIS: A transmural myocardial infarct involves the epicardium and leads to inflammation of the pericardium in 10%–20% of patients. Pericarditis manifests clinically as chest pain and may produce a pericardial friction rub. One quarter of patients with acute myocardial infarction, particularly those with larger infarcts and congestive heart failure, develop pericardial effusions, with or without pericarditis. Less often, anticoagulant therapy may lead to hemorrhagic pericardial effusions and even cardiac tamponade.

Postmyocardial infarction syndrome (Dressler syndrome) is a delayed form of pericarditis that develops 2–10 weeks after infarction. A similar disorder may occur after cardiac surgery. Patients develop antibodies to heart muscle and improve with corticosteroid therapy, suggesting that the syndrome may have an immunologic basis.

Therapeutic Interventions Can Limit Infarct Size

Because the amount of myocardium that undergoes necrosis is an important predictor of morbidity and mortality, any therapy that limits infarct size should be beneficial. By definition, such therapy is directed at preventing reversibly injured, ischemic myocytes from dying and limiting infarct extension. Damaged myocytes can be salvaged for some time after the onset of ischemia if arterial blood flow resumes.

- **Restoration of arterial blood flow** is the only way to salvage ischemic myocytes permanently, although other interventions can slow ischemic injury. The most notable is hypothermia, which is used to minimize myocardial damage during cardiopulmonary bypass. Several methods have been developed to restore blood flow to myocardium supplied by an obstructed coronary artery.
- **Thrombolytic enzymes** such as tissue plasminogen activator or streptokinase can be infused intravenously to dissolve a clot causing vascular obstruction.
- **Percutaneous coronary intervention (PCI)** is dilation of a narrowed coronary artery by inflation with a balloon catheter. PCI can be applied as a primary procedure immediately after onset of ischemia or as a rescue procedure if thrombolytic agents fail to restore arterial blood flow. It nearly always includes placement of a drug-eluting stent in the coronary artery to maintain its patency. The slow release of drugs such as everolimus, an inhibitor of the mTOR (mammalian target of rapamycin) pathway (see Chapters 1 and 5), limits subsequent restenosis by blocking smooth muscle cell proliferative responses to local injury caused by inflation of the balloon catheter and deployment of the stent.
- **Coronary artery bypass grafting** can restore blood flow to the coronary artery segment beyond a proximal occlusion.

Procedures that restore blood flow must be performed as quickly as possible, preferably within the first few hours after symptoms begin. Beyond 12 hours, it is unlikely that much salvageable ischemic myocardium remains, although reperfusion at this point may aid infarct healing and limit maladaptive postinfarct remodeling.

Chronic Ischemic Heart Disease Can Lead to Cardiomyopathy

In a minority of patients with severe coronary atherosclerosis, myocardial contractility is impaired globally without discrete infarcts, as in dilated cardiomyopathy. This situation usually reflects a combination of ischemic myocardial dysfunction, diffuse fibrosis and multiple small healed infarcts. However, there is a group of patients with left ventricular failure in whom cardiac dysfunction occurs without obvious infarction. These patients are said to have **ischemic cardiomyopathy**. In some, the dysfunctional myocardium has experienced repetitive episodes of ischemic injury, which causes degenerative changes in myocytes, with loss of myofibrils (hibernating myocardium) (Fig. 17-6). Contractile function of hibernating myocardium is restored when affected tissue is revascularized. Thus, to the extent that hibernation plays a role in ischemic cardiomyopathy, surgical revascularization may be beneficial.

HYPERTENSIVE HEART DISEASE

Effects of Hypertension on the Heart

The World Health Organization defines hypertension as persistent increase of systemic blood pressure above 140 mm Hg systolic or 90 mm Hg diastolic, or both (see Chapter 16). Chronic hypertension is one of the most prevalent and serious causes of coronary artery and myocardial disease in the United States. It leads to pressure overload resulting first in compensatory left ventricular hypertrophy and, eventually, cardiac failure. The term **hypertensive heart disease** is used when the heart is enlarged in the absence of a cause other than hypertension.

PATHOLOGY: The increased workload caused by hypertension leads to compensatory left ventricular hypertrophy. The left ventricular free walls and interventricular septum become thickened uniformly and concentrically (Fig. 17-25), and heart weight increases, exceeding 375 g in men and 350 g in women. Hypertrophic myocardial cells are thicker, with enlarged, hyperchromatic, and rectangular ("boxcar") nuclei (Fig. 17-26).

CLINICAL FEATURES: Myocardial hypertrophy clearly allows the heart to handle increased workload. However, there is a limit beyond which additional hypertrophy no longer compensates. This upper limit to useful hypertrophy may reflect increasing diffusion distance between the interstitium and the center of each myofiber; if that distance is too great, oxygen supply to the myofiber will be impaired.

Diastolic dysfunction is the most common operative abnormality caused by hypertension and by itself can lead to congestive heart failure. Hypertrophy causes some interstitial fibrosis, which makes the left ventricle stiffer.

FIGURE 17-25. Hypertensive heart disease. A transverse section of the heart shows marked hypertrophy of the left ventricular myocardium without dilation of the chamber. The right ventricle is of normal dimensions.

Hypertension also is associated with more severe coronary artery atherosclerosis. ***The combination of greater cardiac workload (systolic dysfunction), diastolic dysfunction and narrowed coronary arteries leads to greater risk of myocardial ischemia, infarction and heart failure.***

Congestive Heart Failure Is the Major Cause of Death in Patients with Untreated Hypertension

Fatal intracerebral hemorrhage is common as well. Death may also result from coronary atherosclerosis and myocardial infarction, dissecting aortic aneurysm or ruptured cerebral berry aneurysm. Renal failure may supervene when nephrosclerosis induced by hypertension becomes severe.

COR PULMONALE

Cor pulmonale is right ventricular hypertrophy and dilation due to pulmonary hypertension. Increased pulmonary

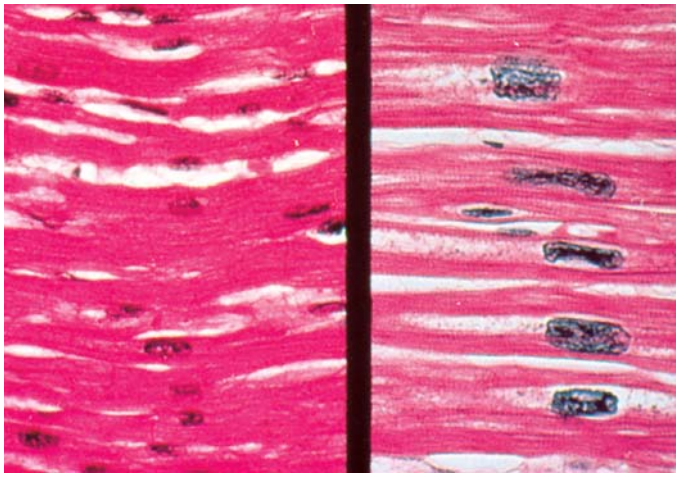

FIGURE 17-26. Hypertensive heart disease with myocardial hypertrophy. Left. Normal myocardium. Right. Hypertrophic myocardium (same magnification) shows thicker fibers and enlarged, hyperchromatic, rectangular nuclei.

arterial pressure may reflect a disorder of lung parenchyma or, more rarely, a primary vascular disease (e.g., primary pulmonary hypertension, recurrent small pulmonary emboli).

Acute cor pulmonale is an abrupt occurrence of pulmonary hypertension, most commonly due to sudden, massive pulmonary embolization. This condition causes acute right-sided heart failure and is a medical emergency. At autopsy, the only cardiac findings are severe right ventricular, and sometimes right atrial, dilation.

Chronic cor pulmonale is a common heart disease, accounting for 30%–40% of heart failure in an English study and 10%–30% in the United States. This frequency reflects the prevalence of lung disease in these countries, especially chronic bronchitis and emphysema. Often, in chronic lung disease, the degree of pulmonary hypertension correlates more closely with survival than any other variable: fewer than 10% of patients with pulmonary artery pressures over 45 mm Hg survive 5 years.

ETIOLOGIC FACTORS: Chronic cor pulmonale may be caused by any pulmonary disease that interferes with ventilatory mechanics or gas exchange or obstructs the pulmonary vasculature (Table 17-5). ***The most common causes of chronic cor pulmonale are chronic obstructive pulmonary disease and pulmonary fibrosis.*** Severe kyphoscoliosis may deform the chest wall and impede its function as a bellows, leading to hypoxemia and pulmonary vasoconstriction. **Primary pulmonary hypertension** is a rare disorder that may also cause cor pulmonale. Some congenital heart diseases associated with increased pulmonary blood flow (see above) are complicated by pulmonary hypertension and cor pulmonale.

PATHOPHYSIOLOGY: The pathogenesis of pulmonary hypertension due to recurrent pulmonary emboli is related clearly to progressive mechanical obstruction of blood flow. However, mechanisms of pulmonary hypertension in chronic parenchymal diseases of the lungs are more complicated. In addition to obliteration of blood vessels in the lung, these disorders also lead to pulmonary arteriolar vasoconstriction, which reduces the effective cross-sectional area of the pulmonary vascular bed without destroying vessels. Hypoxia, acidosis and hypercapnia directly cause pulmonary vasoconstriction. Hypoxia also raises pulmonary vascular resistance indirectly by leading to polycythemia, which increases blood viscosity. People living at very high altitude (e.g., natives of the Andes mountain range) often develop cor pulmonale because of the effects of chronic hypoxemia.

MOLECULAR PATHOGENESIS: Some people with primary pulmonary hypertension have a familial disease with dominant inheritance and incomplete penetrance. Many of these individuals have mutations in the gene encoding bone morphogenic protein receptor type 2 (*BMPR2*). BMPR2 participates in signaling pathways that regulate gene expression and intersect with other signaling cascades (e.g., MAPK pathway). A consequence of this aberrant signaling is endothelial dysfunction with insufficient production of vasodilators such as NO and prostacyclin and overexpression of vasoconstrictors such as thromboxane. Resulting imbalances promote vasoconstriction, which leads to smooth muscle hyperplasia and thickening of small pulmonary arteries, which is typically seen in pulmonary arterial hypertension.

TABLE 17-5
CAUSES OF COR PULMONALE

Parenchymal Diseases of the Lung

Intravenous drug abuse
Residence at high altitude
Schistosomiasis
Congenital Heart Diseases
Impaired Movement of the Thoracic Cage
Kyphoscoliosis
Pickwickian syndrome
Pleural fibrosis
Neuromuscular disorders
Idiopathic hypoventilation

PATHOLOGY: Chronic cor pulmonale is characterized by conspicuous right ventricular hypertrophy (Fig. 17-27), which may exceed 1.0 cm in thickness (normal, 0.3–0.5 cm). Right ventricular and right atrial dilatation are often present. Normally, the interventricular septum is concave to the left (i.e., it is part of the left ventricle). When right ventricular hypertrophy is severe, the interventricular septum remodels by straightening or even becoming concave to the right.

ACQUIRED VALVULAR AND ENDOCARDIAL DISEASES

Many inflammatory, infectious and degenerative diseases damage heart valves and impair their function. Valves normally are thin flexible membranes that close tightly to prevent backward blood flow. The semilunar valves are

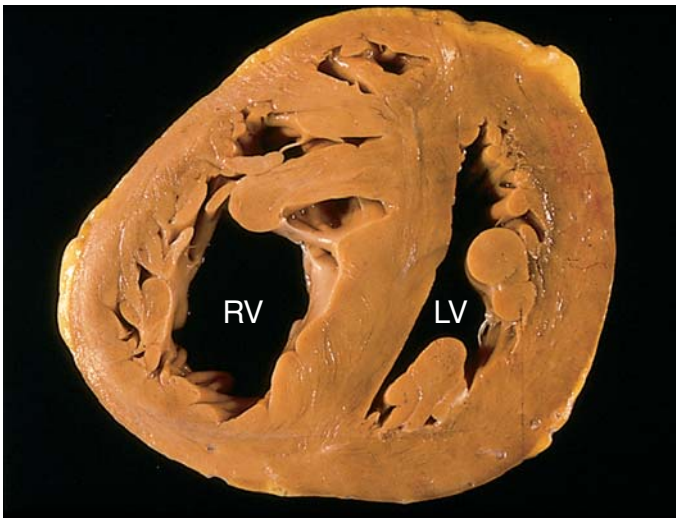

FIGURE 17-27. Cor pulmonale. A transverse section of the heart from a patient with primary (idiopathic) pulmonary hypertension shows a markedly hypertrophied right ventricle (on the left in this image). The right ventricular free wall has a thickness nearly equal to the left ventricular wall. The right ventricle is dilated. The straightened interventricular septum has lost its normal curvature toward the left ventricle as part of the remodeling process in cor pulmonale.

structurally and functionally simple compared with atrioventricular valves. The latter consist of the valve leaflets, muscular valve annuli and subvalvular apparatus (chordae tendineae and papillary muscles). In general, valvular stenosis involves pathologic changes of leaflets themselves, but regurgitation can be caused by abnormalities of valve leaflets, annulus or subvalvular apparatus.

When they become damaged, leaflets or cusps may be thickened and fused sufficiently to narrow the aperture and obstruct blood flow. This is called **valvular stenosis**. Diseases that destroy valve tissue may also allow retrograde blood flow into the atria during systole—**valvular regurgitation** or **insufficiency**. Diseases of the cardiac valves may produce both stenosis and insufficiency, but one or the other generally predominates.

Stenosis of a cardiac valve results in **pressure overload** hypertrophy of the myocardium proximal (i.e., upstream, in terms of blood flow) to the obstruction. Once compensatory mechanisms are exhausted, dilation and failure of the chamber proximal to the valve eventually occur. Thus, mitral stenosis leads to left atrial hypertrophy and dilation. As the left atrium decompensates and can no longer propel the pulmonary venous return through the stenotic mitral valve, blood backs up into the pulmonary venous circuit and signs of pulmonary congestion develop. This is followed by right ventricular hypertrophy and may even lead to cor pulmonale. Similarly, aortic stenosis causes left ventricular hypertrophy and eventually left heart failure.

Valvular regurgitation or insufficiency also results in hypertrophy and dilation of the chamber proximal to the valve, owing to **volume overload**. In aortic insufficiency, the left ventricle first hypertrophies, then, when it can no longer accommodate the regurgitant volume and maintain adequate cardiac output, it dilates. An incompetent mitral valve leads to hypertrophy and dilation of both the left atrium and left ventricle, as both experience volume overload.

Marked left ventricular dilation from any cause that limits cardiac contractility (e.g., congestive failure after a large myocardial infarct) may also widen the mitral valve ring and splay the left ventricular papillary muscles. These effects may be so severe that the valve leaflets do not close properly, leading to mitral regurgitation.

Rheumatic Heart Disease Encompasses Acute Myocarditis and Residual Valvular Deformities

Acute Rheumatic Fever

Rheumatic fever (RF) is a multisystem childhood disease that follows streptococcal infection. It entails an inflammatory reaction involving the heart, joints and central nervous system.

EPIDEMIOLOGY: RF is a complication of acute streptococcal infection, almost always pharyngitis (i.e., "strep" throat; see Chapter 9). The cause is *Streptococcus pyogenes,* also known as group A β-hemolytic *Streptococcus.* In some epidemics of streptococcal pharyngitis, incidence of RF may be as high as 3%. RF is mainly a disease of children, the median age being 9 to 11 years, although it can occur in adults.

In the first half of the 20th century, RF reached almost epidemic proportions in the United States, but its incidence has decreased dramatically. Between 1950 and 1972, the death rate fell from 14.5 to 6.8 per 100,000, and has decreased further since then. This decline in part reflects widespread antibiotic treatment, but that therapy cannot explain the entire reduction, because the death rate had begun to decrease well before antibiotics were generally available. Better socioeconomic conditions, particularly less crowded living circumstances, probably also contributed. ***RF, though less common in developed countries, is still a leading cause of cardiac deaths in young people elsewhere.***

MOLECULAR PATHOGENESIS: The pathogenesis of acute RF involves the triad of a genetically susceptible host, a rheumatogenic strain of group A *Streptococcus* and an abnormal host immune response. It remains unknown why only a small number of people infected with the offending *Streptococcus* develop RF. Human leukocyte antigen (HLA) class II molecules appear to play a role in disease susceptibility; exactly how is unclear. The specific HLA molecules may present the bacterial antigens differently from other HLA molecules; there are similarities between some HLA class II alleles and streptococcal antigens. This may lead to aberrant cytokine production, causing antibodies to be directed against proteins on valves and other host tissues. Alternatively, bacterial antigens may mimic HLA molecules, and so initiate an aberrant immune response. These mechanisms suggest the possibility of an autoimmune etiology (Fig. 17-28).

Streptococcal antigens structurally akin to those in the heart include hyaluronate in the bacterial capsule, cell wall polysaccharides like to carbohydrates of heart valve glycoproteins and bacterial membrane antigens that share epitopes with sarcolemma and smooth muscle constituents.

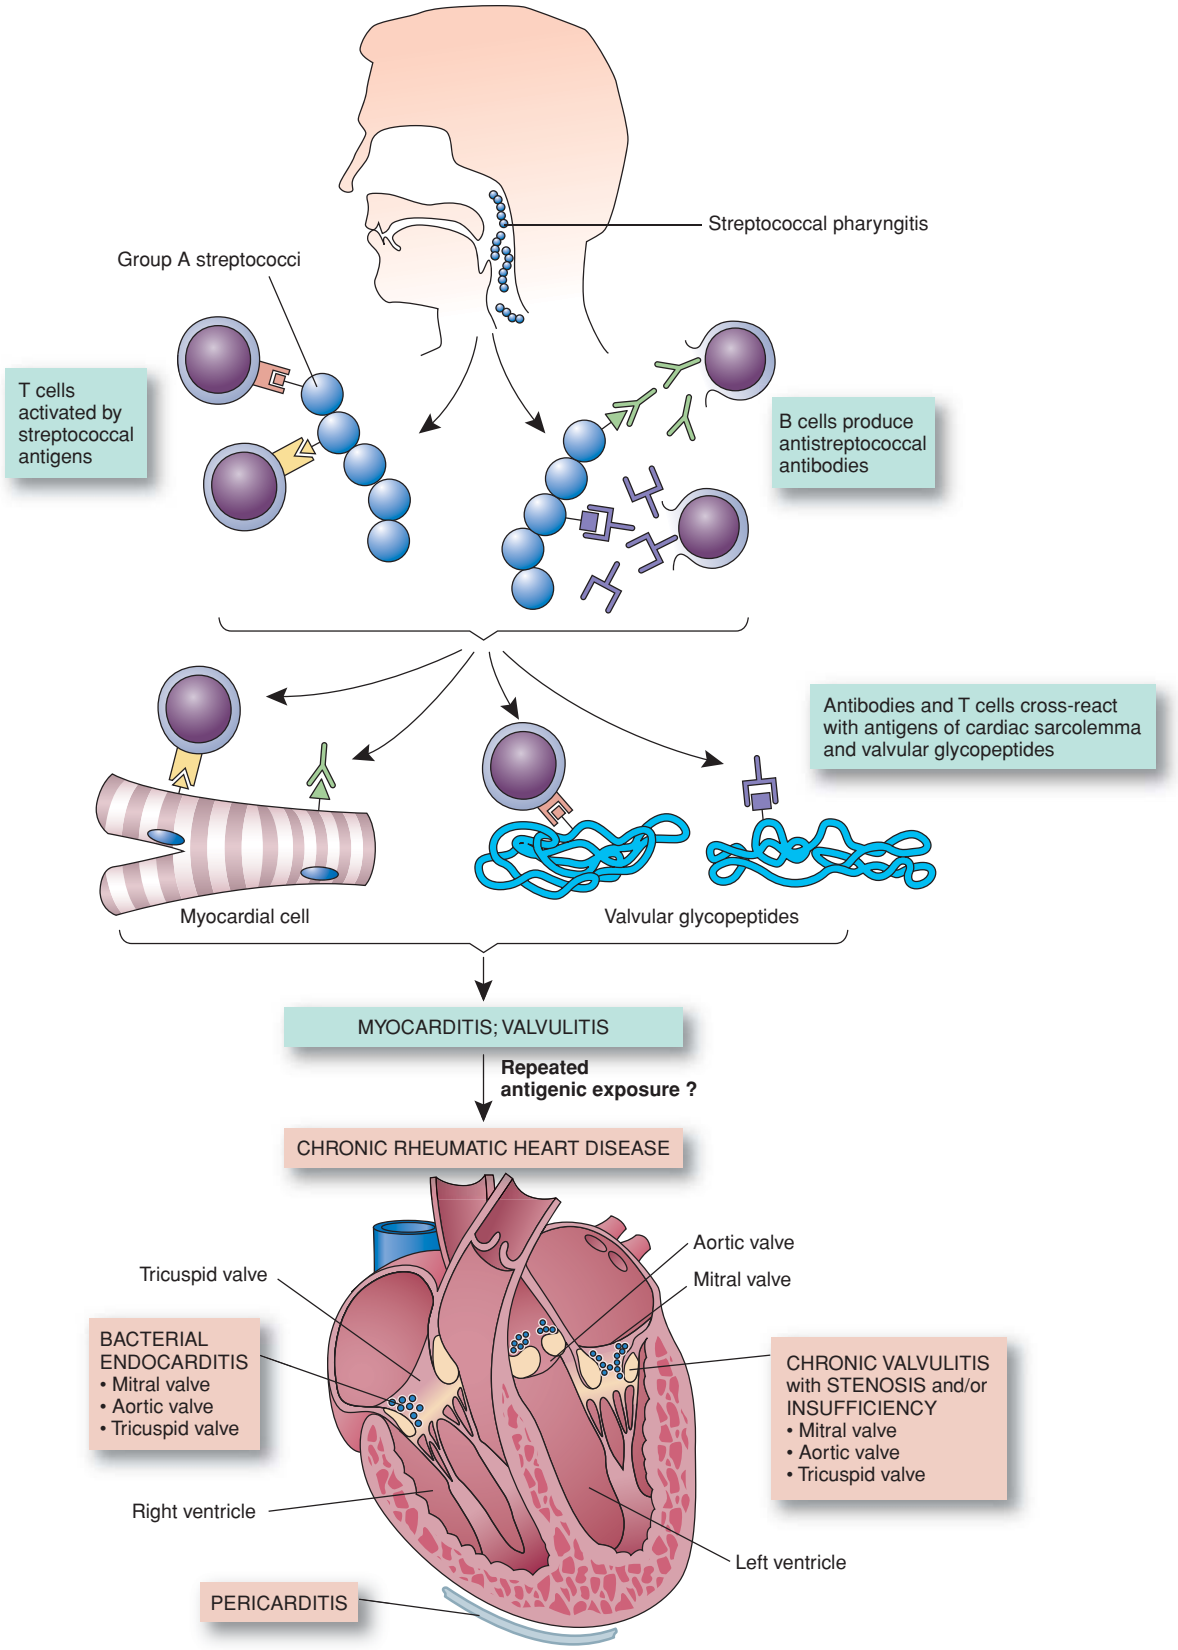

FIGURE 17-28. Biological factors in rheumatic heart disease. The upper portion illustrates the initiating β-hemolytic streptococcal infection of the throat, which introduces the streptococcal antigens into the body and may also activate cytotoxic T cells. These antigens lead to the production of antibodies against various antigenic components of the streptococcus, which can cross-react with certain cardiac antigens, including those from the myocyte sarcolemma and glycoproteins of the valves. This may be the mechanism for inflammation of the heart in acute rheumatic fever, which involves all cardiac layers (endocarditis, myocarditis and pericarditis). This inflammation becomes apparent after a latent period of 2–3 weeks. Active inflammation of the valves may eventually lead to chronic valvular stenosis or insufficiency. These lesions involve the mitral, aortic and tricuspid valves, in that order of frequency.

Although antibodies to these antigens are found in patients with RF, it has not been proved that they are cytotoxic or even that they are directly involved in the pathogenesis of the disease. A direct toxic effect of some streptococcal product on the myocardium has not yet been excluded.

PATHOLOGY: Acute rheumatic heart disease is a pancarditis; that is, it affects all three layers of the heart (endocardium, myocardium, pericardium).

MYOCARDITIS: In severe cases of RF, a few patients may die during the earliest acute phase of the illness before the typical granulomatous inflammation develops. At this early stage, the heart tends to be dilated and shows a nonspecific myocarditis, with lymphocytes and macrophages predominating, although a few neutrophils and eosinophils may be present. Fibrinoid degeneration of collagen, in which fibers become swollen, fragmented and eosinophilic, is characteristic of this early phase.

The **Aschoff body** is the characteristic granulomatous lesion of rheumatic myocarditis (Fig. 17-29). It develops several weeks after symptoms begin. At first, it consists of a perivascular focus of swollen eosinophilic collagen surrounded by lymphocytes, plasma cells and macrophages. With time, the Aschoff body assumes a granulomatous appearance, with a fibrinoid central and a perimeter of lymphocytes, plasma cells, macrophages and giant cells. In time, it is replaced by a scarred nodule.

Anitschkow cells are unusual cells within Aschoff bodies, whose nuclei contain a central band of chromatin. These nuclei have an "owl eye" appearance in cross-section, and they resemble a caterpillar when cut longitudinally (Fig. 17-29). These cells are macrophages that are normally present in small numbers but accumulate and are prominent in certain types of inflammatory diseases of the heart. Anitschkow cells may become multinucleated, in which case they are termed **Aschoff giant cells**.

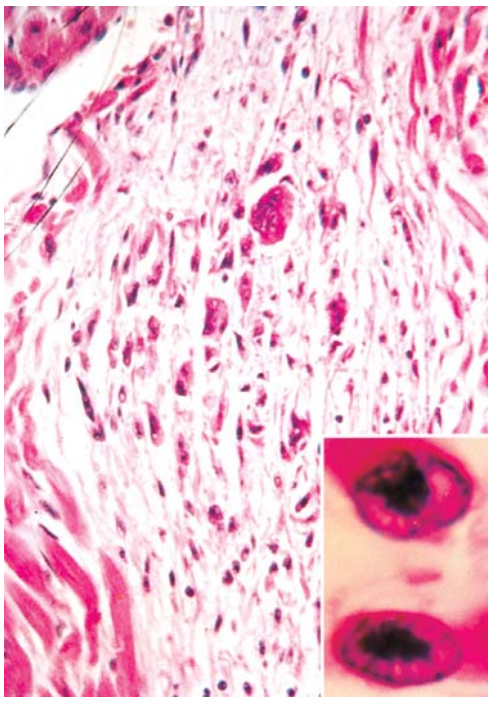

FIGURE 17-29. Acute rheumatic heart disease. An Aschoff body in the myocardial interstitium. Note collagen degeneration, lymphocytes and a multinucleated Aschoff giant cell. **Inset.** Nuclei of Anitschkow myocytes, showing "owl-eye" appearance in cross-section and "caterpillar" shape longitudinally.

PERICARDITIS: Tenacious irregular fibrin deposits are found on visceral and parietal pericardial surfaces during the acute inflammatory phase of RF. These exudates resemble the shaggy surfaces of two slices of buttered bread that have been pulled apart ("bread-and-butter pericarditis"). This pericarditis may manifest clinically as a friction rub, but it is functionally minor and only infrequently leads to constrictive pericarditis.

ENDOCARDITIS: During the acute stage of rheumatic carditis, valve leaflets become inflamed and edematous. All four valves are affected, but left-sided valves are most injured because they close under greater pressures than right-sided valves. The result is damage and focal loss of endothelium along valve leaflet closure lines. This leads to deposition of tiny nodules of fibrin, which can be recognized grossly as "verrucae" along the leaflets (so-called verrucous endocarditis of acute RF).

CLINICAL FEATURES: There is no specific test for RF. Clinically, the diagnosis is made if two major—or one major and two minor—criteria (**Jones criteria**) are met. Evidence of recent streptococcal infection increases the probability of RF.

The **major criteria** of acute RF include carditis (murmurs, cardiomegaly, pericarditis and congestive heart failure), polyarthritis, chorea, erythema marginatum and subcutaneous nodules.

The **minor criteria** are previous history of RF, arthralgia, fever, certain laboratory tests indicating an inflammatory process (e.g., increased sedimentation rate, positive test result for C-reactive protein, leukocytosis) and ECG changes.

Symptoms of RF begin 2–3 weeks after an infection with *S. pyogenes.* By then, throat cultures are usually negative. Increasing serum antibodies to group A streptococcal antigens, such as antistreptolysin O, anti-DNAase B and antihyaluronidase, provide concrete evidence of a recent infection with group A *Streptococcus.* Acute symptoms of RF usually subside within 3 months, but with severe carditis, clinical activity may continue for 6 months or more. Mortality in acute rheumatic carditis is low. The main cause of death is heart failure due to myocarditis, although valvular dysfunction may also play a role.

Recurrent attacks of RF are associated with types of group A β-hemolytic streptococci to which the patient has not been exposed previously and, thus, to which immunity has not developed. The rate of RF recurrence is related to the time between the initial episode and a subsequent streptococcal infection. In patients with a history of a recent attack of RF, recurrence rates may reach 65%, while recurrence after 10 years affects only 5% of patients.

Prompt treatment of streptococcal pharyngitis with antibiotics prevents a first attack of RF and, less often, recurrences. There is no specific treatment for acute RF, but corticosteroids and salicylates are helpful in managing the symptoms.

Chronic Rheumatic Heart Disease

PATHOLOGY: The myocardial and pericardial components of rheumatic pancarditis typically resolve without permanent sequelae. By contrast,

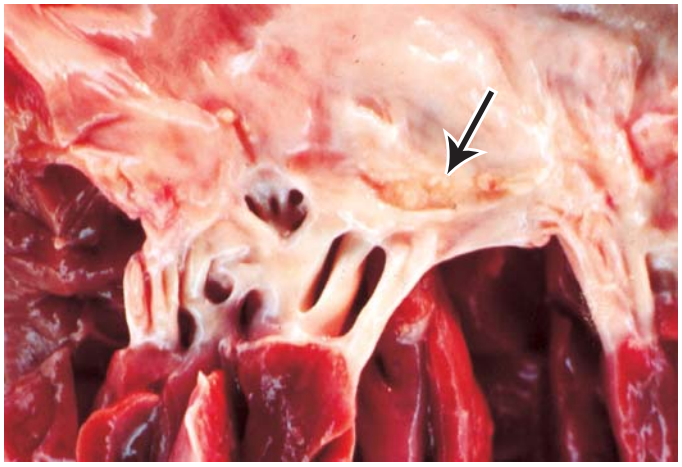

FIGURE 17-30. Chronic rheumatic valvulitis. The mitral valve leaflets are thickened and focally calcified (*arrow*), and the commissures are partially fused. The chordae tendineae are also short, thick and fused.

valvulitis due to RF often leads to long-term structural and functional changes. During the healing phase, valve leaflets develop diffuse fibrosis and become thickened, shrunken and less pliable. At the same time, healing of the verrucous lesions along the lines of closure often generates fibrous "adhesions" between leaflets, especially at the commissures (commissural fusion). The result is a stenotic valve that does not open freely because its leaflets are rigid and partially fused. Blood flow across such a valve is turbulent, which can cause even more scarring and deformation of leaflets because of chronic "wear and tear" on the valve. Severe valvular scarring may develop months or years after a single bout of acute RF. On the other hand, recurrent episodes of acute RF are common and result in repeated and progressively increasing damage to the heart valves.

The mitral valve is the most commonly and severely affected valve in chronic rheumatic disease. It snaps shut under systolic pressure and, thus, bears the greatest mechanical burden of all the valves. In chronic mitral valvulitis, valve leaflets become conspicuous, irregularly thickened and calcified, often with fusion of commissures and chordae tendineae (Fig. 17-30). In severe chronic rheumatic mitral valvular disease, valve orifices become reduced to fixed narrow slits resembling "fish mouths" when viewed from the ventricular aspect (Fig. 17-31). Stenosis is dominant functionally, but mitral valves are also regurgitant. Chronic regurgitation produces a "jet" of blood directed at the posterior aspect of the left atrium, damaging atrial endocardium and producing focal rough, wrinkled endocardium called "MacCallum patches."

The aortic valve, which snaps shut under diastolic pressure, is the second most commonly involved valve in rheumatic heart disease. Diffuse fibrous thickening of the cusps and fusion of the commissures cause aortic stenosis, which may be mild initially but which progresses because of the chronic effects of turbulent blood flow across the valve. Often, cusps become rigidly calcified as the patient ages, resulting in stenosis and insufficiency, although either lesion may predominate (Fig. 17-32). The lower pressures experienced by the right-sided valves are usually protective. In recurrent RF, however, tricuspid valves may become deformed, virtually always in association with mitral and aortic lesions. Pulmonic valves are rarely affected.

Complications of Chronic Rheumatic Heart Disease

- **Bacterial endocarditis** follows episodes of bacteremia (e.g., during dental procedures). The scarred valves of rheumatic heart disease provide an attractive environment for bacteria that would bypass a normal valve.
- **Mural thrombi** form in atrial or ventricular chambers in 40% of patients with rheumatic valvular disease. They give rise to thromboemboli, which can produce infarcts in various organs. Rarely, a large thrombus in the left atrial appendage develops a stalk and acts as a ball valve to obstruct the mitral valve orifice.
- **Congestive heart failure** complicates rheumatic disease of both mitral and aortic valves.

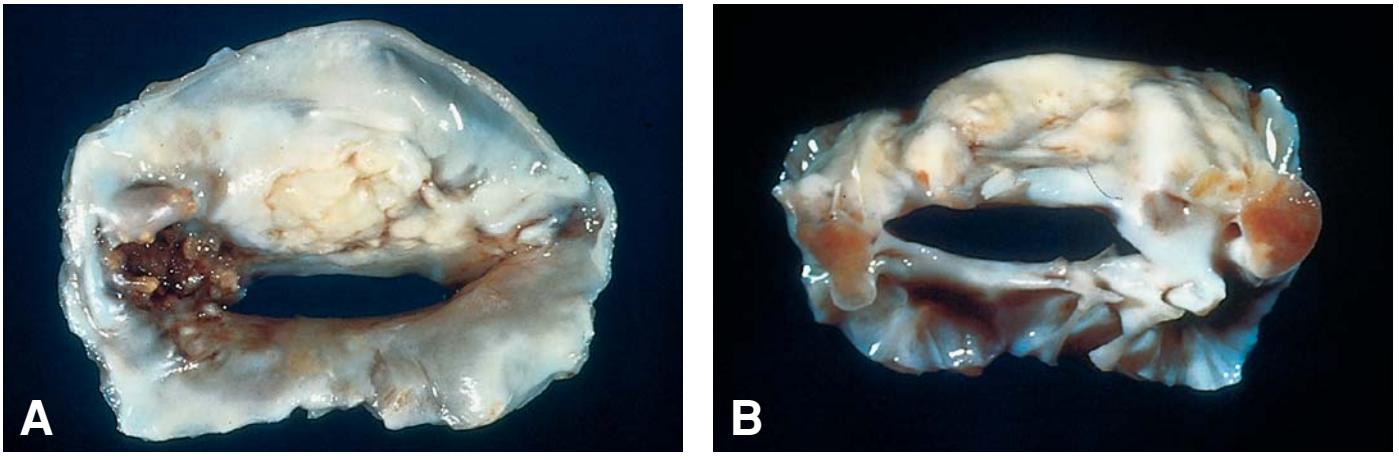

FIGURE 17-31. Chronic rheumatic valvulitis. A view of a surgically excised rheumatic mitral valve from the left atrium **(A)** and left ventricle **(B)** shows rigid, thickened and fused leaflets with a narrow orifice, creating the characteristic "fish mouth" appearance of rheumatic mitral stenosis. Note that the tips of the papillary muscles (shown in B) are directly attached to the underside of the valve leaflets, reflecting marked shortening and fusion of the chordae tendineae.

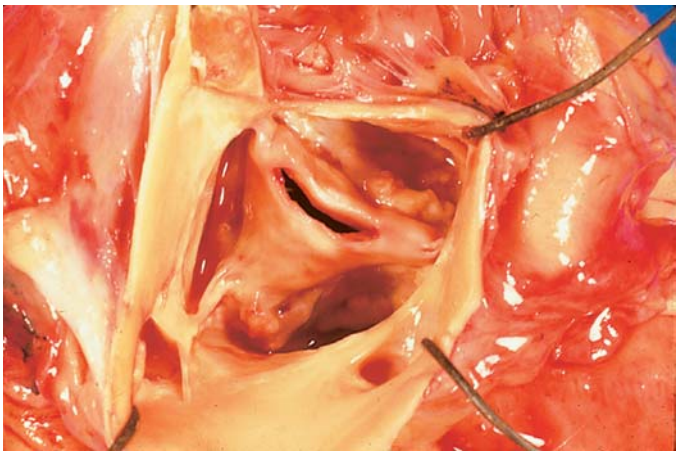

FIGURE 17-32. Chronic rheumatic aortic valvulitis. An example of severe rheumatic aortic stenosis. Three sinuses of Valsalva are recognizable, but the cusps are rigidly fibrotic and calcified, and extensive fusion of the commissures has narrowed the orifice into a fixed slit-like configuration that does not change during the cardiac cycle.

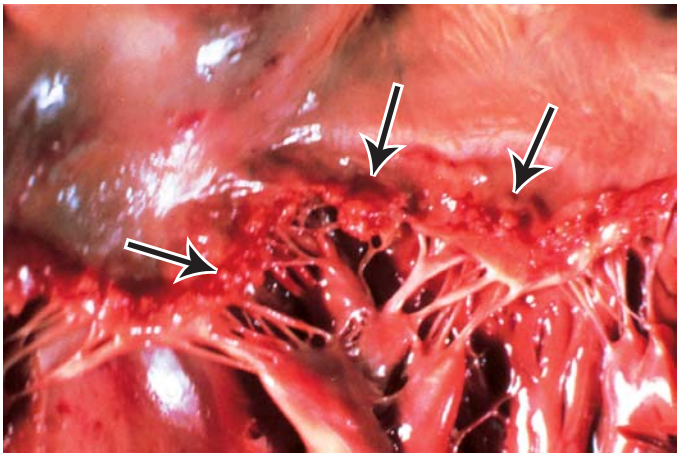

FIGURE 17-33. Libman-Sacks endocarditis. The heart of a patient who died of complications of systemic lupus erythematosus displays verrucous vegetations (*arrows*) on the leaflets of the mitral valve.

- **Adhesive pericarditis** often follows the fibrinous pericarditis of acute attacks, but rarely causes constrictive pericarditis.

Autoimmune Diseases Affect Cardiac Valves and Myocardium

Systemic Lupus Erythematosus

The heart is often involved in SLE, but cardiac symptoms are usually less prominent than other manifestations of the disease.

PATHOLOGY: The most common cardiac lesion is **fibrinous pericarditis,** usually with an effusion. **Myocarditis** in SLE, manifesting as subclinical left ventricular dysfunction, is also common and reflects the severity of the disease in other organs. Fibrinoid necrosis of small vessels and focal degeneration of interstitial tissue are seen.

Endocarditis is the most striking cardiac lesion of SLE. Verrucous vegetations, up to 4 mm, occur on endocardial surfaces and are called **Libman-Sacks endocarditis**. They occur most often on the mitral valve (Fig. 17-33), usually on atrial surfaces, close to the origin of the leaflets from the valve ring. They may also extend onto chordae tendineae and papillary muscles. Aortic valve involvement is rare. Ordinarily, *Libman-Sacks endocarditis heals without scarring and does not produce a functional deficit.*

Rheumatoid Arthritis

The heart is rarely involved in patients with rheumatoid arthritis. Characteristic rheumatoid granulomatous inflammation, with fibrinoid necrosis and palisaded lymphocytes and macrophages, may occur in the pericardium, myocardium or valves. Cardiac function remains intact.

Ankylosing Spondylitis

A characteristic aortic valve lesion develops in up to 10% of patients with long-standing ankylosing spondylitis. The aortic valve ring is dilated and its cusps are scarred and shortened. Focal inflammatory lesions occur in all layers of the aortic wall, particularly near the valve ring. Aortic regurgitation is the principal functional consequence.

Scleroderma (Progressive Systemic Sclerosis)

Cardiac involvement is second only to renal disease as a cause of death in scleroderma. The myocardium shows intimal sclerosis of small arteries, which leads to small infarcts and patchy fibrosis. As a result, congestive heart failure and arrhythmias are common. In fact, ECGs show ventricular ectopy in up to 2/3 of patients with scleroderma, and serious arrhythmias in 1/4. Cor pulmonale (due to pulmonary interstitial fibrosis) and hypertensive heart disease (caused by renal involvement) are also seen.

Polyarteritis Nodosa

The heart is affected in up to 75% of patients with polyarteritis nodosa. Necrotizing lesions in branches of the coronary arteries cause myocardial infarction, arrhythmias or heart block. Cardiac hypertrophy and failure due to renal vascular hypertension are common.

Bacterial Endocarditis Is Infection of the Cardiac Valves

Fungi, chlamydia and rickettsiae may also cause infective endocarditis, but do so uncommonly. Before the antibiotic era, bacterial endocarditis was untreatable and almost invariably fatal. The infection was classified according to its clinical course as acute or subacute endocarditis. **Acute bacterial endocarditis** was infection of normal cardiac valves by highly virulent suppurative organisms, typically *Staphylococcus aureus* and *S. pyogenes.* Affected valves were rapidly destroyed, and patients usually died within 6 weeks from acute heart failure or overwhelming sepsis.

Subacute bacterial endocarditis was less fulminant, with less virulent organisms (e.g., *Streptococcus viridans* or *Staphylococcus epidermidis*) infecting structurally abnormal valves, which typically had been deformed by rheumatic

heart disease. These patients usually survived for 6 months or more, and infectious complications were uncommon.

Antimicrobial therapy changed clinical patterns of bacterial endocarditis, and the above classical presentations are now unusual. The disease is now classified by the anatomic location and the offending organism (Table 17-6).

EPIDEMIOLOGY: Most children with bacterial endocarditis have an underlying cardiac lesion. In the past, rheumatic heart disease accounted for 1/3 of such cases. However, as incidence of RF has declined, RF is responsible for fewer than 10% of children with bacterial endocarditis. ***The most common predisposing condition for bacterial endocarditis in children currently is congenital cardiac malformations.***

Epidemiology of bacterial endocarditis has also changed in adults. Rheumatic heart disease once made up 75% of cases, but now underlies only a few. Most adults with bacterial endocarditis have no predisposing cardiac lesion. ***Mitral valve prolapse (MVP) and congenital heart disease are now the most frequent bases for bacterial endocarditis in adults.***

- In patients in whom bacterial endocarditis is superimposed on **rheumatic heart disease,** mitral valves are affected in over 85%, and aortic valves in 50%. A lone mitral valve is affected more often in women (2:1), but the ratio is reversed, 4:1, in isolated aortic endocarditis.
- **Intravenous drug abusers** inject pathogenic organisms along with illicit drugs, and bacterial endocarditis is a notorious complication. In such patients, 80% have no underlying cardiac lesion, and the tricuspid valve is involved in half of cases. The most common source of bacteria in intravenous drug abusers is the skin, with *S. aureus* causing more than half of the infections.
- **Prosthetic valves** are sites of infection in 15% of cases of endocarditis in adults, and 4% of patients with prosthetic valves have this complication. Staphylococci are again responsible for half of these infections. Most of the rest are caused by gram-negative aerobic organisms, streptococci, enterococci and fungi. Indwelling vascular catheters are another source of iatrogenic endocarditis.
- **Transient bacteremia** from any procedure may lead to infective endocarditis. Examples include dental procedures, urinary catheterization, gastrointestinal endoscopy and obstetric procedures. Antibiotic prophylaxis is recommended during such maneuvers for patients at increased risk for bacterial endocarditis (e.g., those with a history of RF or a cardiac murmur).
- **The elderly** are increasingly prone to developing endocarditis. Degenerative changes in heart valves, including calcific aortic stenosis and calcification of mitral annuli, predispose to endocarditis.
- **Diabetes** and **pregnancy** may also increase the incidence of bacterial endocarditis.

ETIOLOGIC FACTORS AND MOLECULAR PATHOGENESIS: Virulent organisms, such as *S. aureus,* can infect apparently normal valves, but the mechanism of such bacterial colonization is poorly understood. Infection of previously damaged valves by less virulent organisms has been tied to (1) hemodynamic factors, (2) formation of an initially sterile platelet–fibrin thrombus and (3) adherence properties of the microorganisms. A key feature is abnormal blood flow across a damaged valve. Lesions form on the inflow portions of valves, where high pulsatile shear stresses occur. The pressure gradient across a narrow orifice (valve or congenital defect) produces turbulent flow at the periphery and a high-velocity jet at the center, both of which tend to denude valve endothelial surfaces. This leads to focal deposition of platelets and fibrin, creating small sterile vegetations that are hospitable sites for bacterial colonization and growth. Indeed, platelet adhesion is enhanced at high shear rates, which occur at leaflet free edges. Surrounding endothelium becomes activated by the presence of platelet–fibrin thrombi and upregulates expression of adhesion molecules (vascular cell adhesion molecule-1 [VCAM-1], intracellular adhesion molecule-1 [ICAM-1] and E-selectin). These, in turn, attract inflammatory cells. Microorganisms that gain access to the circulation, as a result of dental manipulation for example, can be deposited within the vegetations. In this protected environment, there may be 10^{10} organisms per gram of tissue. Matrix metalloproteinases made by bacteria begin to destroy valves, facilitating formation of adjacent vegetations.

Factors that promote bacterial adherence to sterile vegetations are believed to be important in the pathogenesis of endocarditis. Cell-associated and circulating fibronectin both bind to surface molecules of the bacteria, facilitating

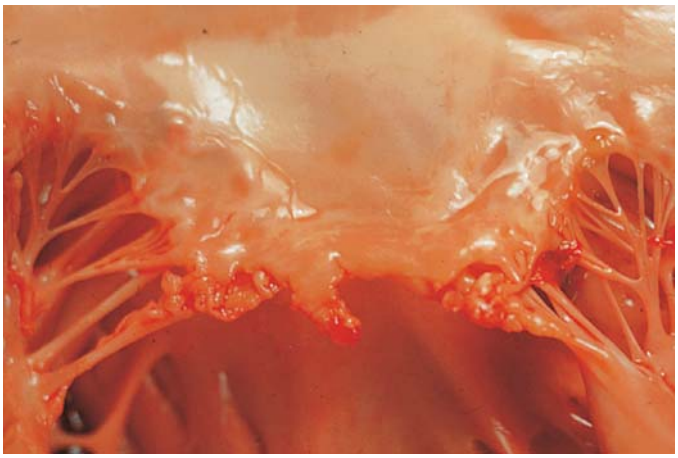

FIGURE 17-34. Bacterial endocarditis. The mitral valve shows destructive vegetations, which have eroded through the free margins of the valve leaflets.

adhesion of fibrin, collagen and cells. Some microorganisms produce extracellular polysaccharides, which also function as adhesion factors.

PATHOLOGY: Bacterial endocarditis most commonly involves the left-sided heart valves (mitral, aortic or both). The most common congenital heart lesions that underlie bacterial endocarditis are PDA, tetralogy of Fallot, VSD and bicuspid aortic valve, which is an increasingly recognized risk factor, especially in men over 60. ***As a rule, the vegetations form on the upstream sides of the valves (i.e., the atrial side of atrioventricular valves and the ventricular side of semilunar valves), often at points where leaflets or cusps close*** (Fig. 17-34). Vegetations consist of platelets, fibrin, cell debris and masses of organisms. Underlying valve tissue is edematous and inflamed, and may eventually become so damaged that a leaflet perforates, causing regurgitation. Lesions vary from small, superficial deposits to bulky, exuberant vegetations. The infective process may spread locally to involve valve rings or adjacent mural endocardium and chordae tendineae.

Infected thromboemboli travel to multiple systemic sites, causing infarcts or abscesses in many organs, including the brain, kidneys, intestine and spleen.

Focal segmental glomerulonephritis may complicate infective endocarditis (see Chapter 22). It results from immune complex deposition in glomeruli, producing a patchy hemorrhagic appearance—so-called flea-bitten kidneys.

CLINICAL FEATURES: Many patients show early symptoms of bacterial endocarditis within a week of the bacteremic episode, and almost all are symptomatic within 2 weeks. Nonspecific symptoms—low-grade fever, fatigue, anorexia, weight loss—predominate at first. Heart murmurs develop almost invariably and often change during the course of the disease. In cases lasting more than 6 weeks, splenomegaly, petechiae and clubbing of the fingers are frequent. In 1/3 of patients, systemic emboli are recognized at some time during the illness. One third of patients show some neurologic dysfunction, owing to the frequency of cerebral emboli. Mycotic aneurysms of cerebral vessels, brain abscesses and intracerebral bleeding are observed. Pulmonary emboli typify tricuspid valve endocarditis in drug addicts.

Antibacterial therapy is effective in limiting the morbidity and mortality of bacterial endocarditis. Most patients defervesce within a week of instituting such therapy. However, prognosis depends to some extent on the offending organism and the stage at which infection is treated. ***A third of cases of* S. aureus *endocarditis are still fatal.*** Surgical replacement of a valve destroyed by endocarditis is risky and carries high surgical mortality as long as infection is active. ***The most common serious complication of bacterial endocarditis is congestive heart failure, usually due to valvular destruction, and portending a grim prognosis.*** Myocardial abscesses and infarction due to coronary artery emboli may contribute to heart failure.

Nonbacterial Thrombotic Endocarditis Is a Complication of Wasting Diseases

Nonbacterial thrombotic endocarditis (NBTE), also known as marantic endocarditis, entails sterile vegetations on apparently normal cardiac valves, almost always in association with cancer or some other wasting disease. It affects mitral (Fig. 17-35) and aortic valves equally often. NBTE resembles infective endocarditis grossly, but it does not destroy affected valves and lacks both inflammation and microorganisms.

The cause of NBTE is poorly understood. It is seen commonly as a paraneoplastic condition, usually complicating adenocarcinomas (particularly of pancreas and lung) and hematologic malignancies. NBTE may also occur in disseminated intravascular coagulation or accompany debilitating nonneoplastic diseases, accounting for the term "marantic endocarditis" (from the Greek, *marantikos,* "wasting away"). It may reflect increased blood coagulability or immune complex deposition. Lacking bacteria, the vegetations remain small and there is no valve destruction. The main danger posed by NBTE is distant embolization, clinically presenting as infarcts of many organs, but this is unusual and NBTE is often an incidental finding at autopsy.

Calcific Aortic Stenosis Reflects Chronic Damage to the Valve

Calcific aortic stenosis is narrowing of the aortic valve orifice due to calcium deposition in the valve cusps and ring.

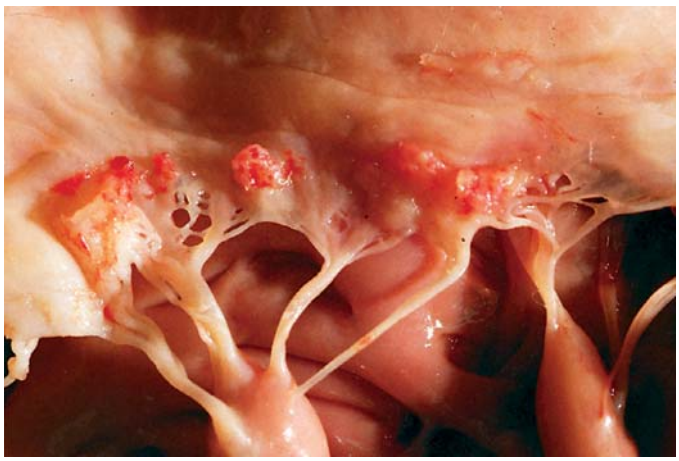

FIGURE 17-35. Marantic endocarditis. Sterile platelet–fibrin vegetations are seen on the leaflets of a structurally normal mitral valve.

ETIOLOGIC FACTORS AND PATHOLOGY: Calcific aortic stenosis has three main causes.

- **Rheumatic aortic valve disease** is characterized by diffuse fibrous thickening and scarring of aortic cusps, commissural fusion and calcium deposition, all of which reduce the valve orifice and limit valve mobility (Fig. 17-32). Rheumatic aortic stenosis almost never occurs in isolation; it accompanies rheumatic mitral valve disease. Now that acute RF has become so rare in the United States and most elderly patients with rheumatic valve disease have either undergone valve replacement or died, calcific aortic stenosis is usually attributed to other causes.
- **Degenerative (senile) calcific stenosis** develops in the elderly as a degenerative process in a tricuspid aortic valve. Valve cusps become rigidly calcified, but commissural fusion (Fig. 17-36), which is a hallmark of rheumatic aortic valves, is not seen. The mitral valve is usually normal in patients with senile calcific aortic stenosis, although the mitral annulus may also be calcified.
- **Congenital bicuspid aortic stenosis** often develops with age (Fig. 17-37).
- **Calcific aortic stenosis** in both congenitally malformed valves and normal ones is probably related to cumulative effects of years of turbulent blood flow around the valve. Thus, although a bicuspid valve is not inherently stenotic, its orifice is elliptical rather than round, and flow across the valve is more turbulent than with a tricuspid aortic valve. Increasing cusp rigidity eventually produces functional derangements, typically in patients over age 60.

In any form of calcific aortic stenosis, calcification produces nodules restricted to the base and lower half of the cusps, and rarely involves the free margins. Without rheumatic scarring, commissures are not fused and three distinct cusps are evident.

Aortic valve calcification is not a purely passive process in which devitalized tissue becomes mineralized, as the term "dystrophic calcification" seems to imply. In fact, valvular calcification is an active process involving modulation of valvular interstitial cells to an osteoblastic phenotype and new gene expression resulting in cell-mediated mineralization of the extracellular matrix. Many of the mechanisms and risk factors associated with valvular calcification are similar to those for atherosclerosis. Mechanical forces promote accumulation of LDL particles and other factors, leading to inflammation, activation and transformation of valvular interstitial cells, remodeling of extracellular matrix and secretion of osteogenic proteins such as bone morphogenic protein-2 and other noncollagenous matrix proteins. Despite these pathogenetic similarities to atherosclerosis, effective prevention of the latter, as with statins, does not prevent the development of calcific aortic stenosis.

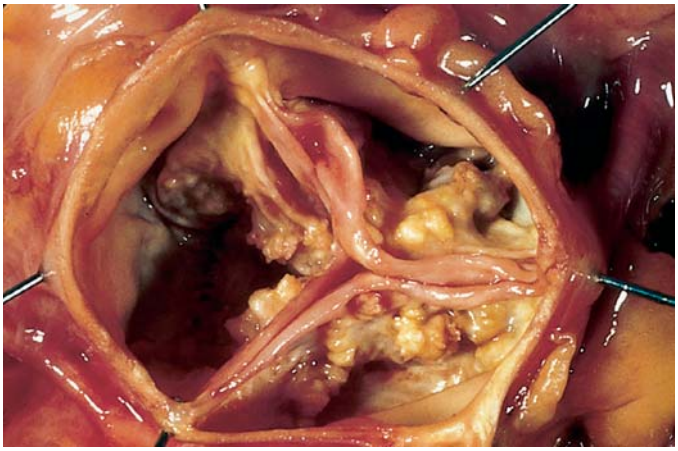

FIGURE 17-36. Calcific aortic stenosis in a three-cuspid aortic valve in an elderly person. The leaflets are heavily calcified, but there is no commissural fusion (compare with Fig. 17-32).

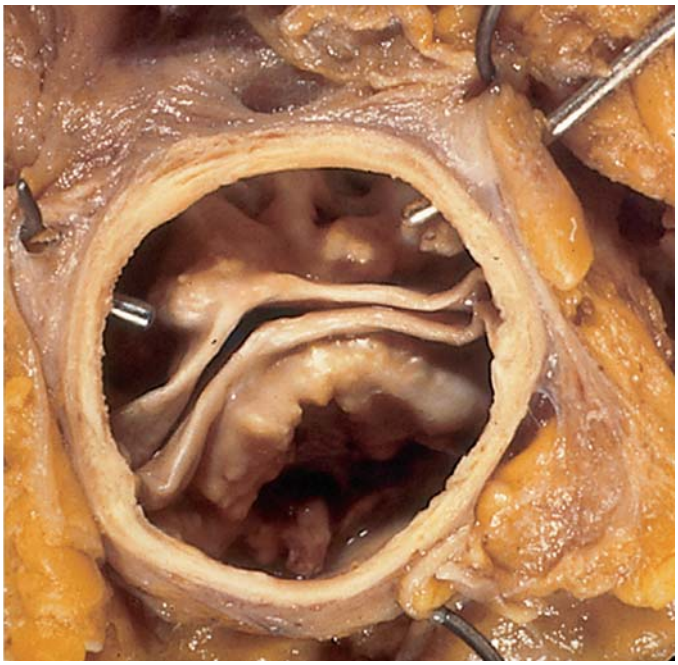

FIGURE 17-37. Calcific aortic stenosis of a congenitally bicuspid aortic valve. The two leaflets are heavily calcified, but there is no commissural fusion. Probes show the openings of the coronary ostia.

CLINICAL FEATURES: Severe aortic stenosis causes striking concentric left ventricular hypertrophy. Eventually, the ventricle dilates and fails. Surgical valve replacement is highly successful (5-year survival rate of 85%), if done before ventricular dysfunction is irreversible. The hypertrophic left ventricle then returns to normal size.

Mitral Valve Annulus Calcification Is Usually Asymptomatic

Calcification of the mitral valve annulus occurs commonly in the elderly and is usually without functional significance, although it often produces a murmur. However, if it is severe enough to interfere with posterior mitral leaflet excursion during systole, mitral regurgitation occurs. Unlike calcification in RF-damaged valves, valve leaflets are not deformed in mitral valve annulus calcification in the elderly, and calcification affects the annulus most, rather than the leaflets. About 40% of women older than 90 have this lesion, compared to only 15% of men. Calcification of the mitral valve annulus is aggravated if the patient has aortic stenosis, hypertension or diabetes.

Calcific deposits transform the mitral ring into a rigid, curved bar up to 2 cm in diameter, which may be evident

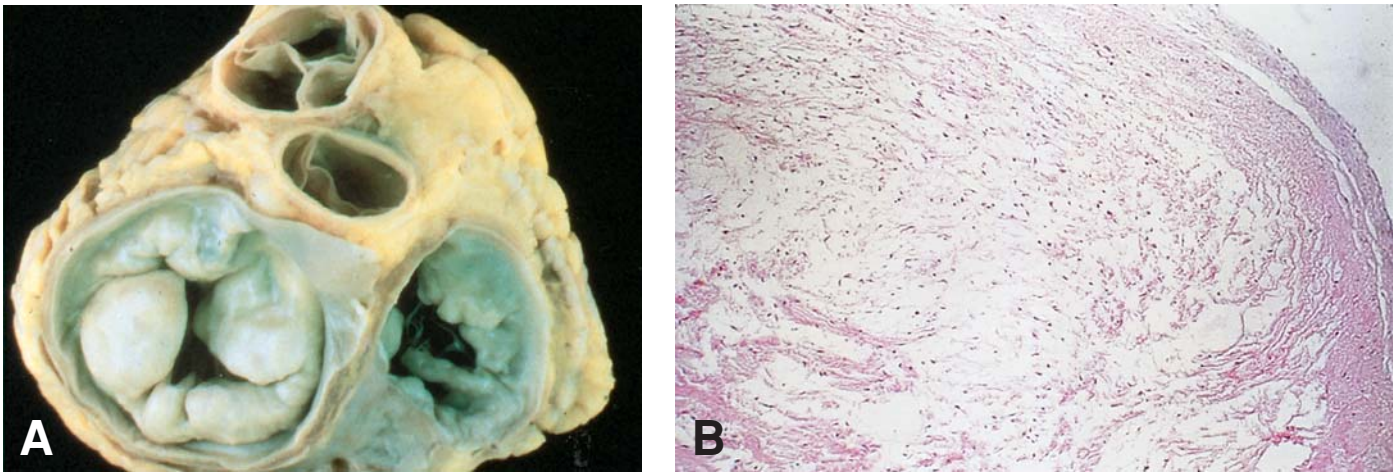

FIGURE 17-38. Mitral valve prolapse. A. A view of the mitral valve (*left*) from the left atrium shows redundant and deformed leaflets, which billow into the left atrial cavity. **B.** A microscopic section of one of the mitral valve leaflets reveals conspicuous myxomatous connective tissue in the center of the leaflet.

radiologically. Amorphous masses of calcified material first develop in the connective tissue of the valve ring, but, with time, extend into the base of the leaflets and eventually to the ventricular septum.

Mitral Valve Prolapse Is the Most Common Indication for Valve Repair or Replacement

In MVP, mitral valve leaflets become enlarged and redundant. Chordae tendineae are thinned and elongated, so that the leaflets billow and prolapse into the left atrium during systole (Fig. 17-38A). Also called "floppy mitral valve syndrome," MVP is the most common cause of mitral regurgitation that requires surgical valve repair or replacement. Up to 5% of adults may show echocardiographic evidence of MVP, although most will not have severe enough regurgitation to require surgery.

MOLECULAR PATHOGENESIS: Many cases of MVP appear to be transmitted as an autosomal dominant trait. Three different loci on chromosomes 16, 11 and 13 are associated with MVP, but no specific gene mutations have been identified. Prolapsed mitral valves accumulate striking amounts of myxomatous connective tissue in the center of the valve leaflet (Fig. 17-38B). Proteoglycans in the valve are increased, and electron microscopy shows fragmentation of collagen fibrils. Presumably, these changes reflect a molecular defect in the extracellular matrix that allows leaflets and chordae to enlarge and stretch under the high-pressure conditions they experience during the cardiac cycle. MVP is usually an isolated finding, but is particularly prevalent in patients with Marfan syndrome, Ehlers-Danlos syndrome, osteogenic imperfecta and other collagen-related disorders. This association with inherited connective tissue disorders suggests an abnormality of connective tissue in the pathogenesis of myxomatous degeneration, but thus far, no abnormalities in fibrillar collagen genes or TGF-β signaling have been identified. Pectus excavatum, scoliosis and loss of kyphosis of the thoracic spine are common in patients with MVP, but it is not known how or if these bony abnormalities are genetically linked to MVP.

The risk of sudden death in patients with MVP, presumably due to ventricular tachyarrhythmias, is twice that in the general population. Repair of a regurgitant floppy mitral valve lowers this risk. The mechanisms are not well understood, but the risk appears to depend primarily on the degree of mitral regurgitation, perhaps related to ventricular remodeling associated with volume overload.

PATHOLOGY: Mitral valve leaflets are redundant and deformed (Fig. 17-38A). On cross-section they have a gelatinous appearance and slippery texture, owing to accumulation of acid mucopolysaccharides (proteoglycans). Myxomatous degeneration also affects the annulus and chordae tendineae, increasing prolapse and regurgitation. Damage to chordae may be so severe that they break. Rupture of multiple chordae can yield a flail mitral valve that is totally incompetent. Although the mitral valve is usually the only valve affected, myxomatous degeneration can occur in other valves, especially in patients with Marfan syndrome, 90% of whom have clinical evidence of MVP.

CLINICAL FEATURES: Most patients with MVP are asymptomatic. Clinical recognition of MVP is based on classical auscultatory findings: a mid- to late systolic click, caused by the snap of the redundant leaflets as they prolapse into the left atrium. A late systolic murmur is present if regurgitation is significant. Endocarditis, both infective and nonbacterial, may develop as a serious complication, and cerebral emboli are common. Significant mitral regurgitation develops in 15% of patients after 10–15 years of MVP, after which mitral valve repair or replacement is indicated.

Papillary Muscle Dysfunction May Cause Mitral Regurgitation

Left ventricular papillary muscle dysfunction is usually due to ischemia. These muscles are especially vulnerable to ischemic injury as they are supplied by terminal branches of intramyocardial coronary arteries. Any reduction in coronary blood flow thus preferentially interferes with papillary muscle function. Brief periods of ischemia (e.g., during

episodes of angina pectoris) can cause transient papillary muscle dysfunction (stunning) and temporary mitral regurgitation. Permanent mitral regurgitation may be due to myocardial infarction and subsequent scarring of papillary muscles. One third of patients being evaluated for coronary artery bypass surgery show evidence of "ischemic mitral regurgitation." Papillary muscle dysfunction may also be associated with a healed myocardial infarct, in which impaired myocardial contractility at the base of a papillary muscle impedes its function. Rarely, patients may suddenly develop life-threatening mitral regurgitation after rupture of an acutely infarcted papillary muscle.

Carcinoid Heart Disease Affects Right-Sided Valves

Carcinoid heart disease is an unusual condition that uniquely affects the right side of the heart, leading to tricuspid regurgitation and pulmonary stenosis. It occurs in people with carcinoid tumors, usually of the small intestine, after they have spread to the liver.

PATHOPHYSIOLOGY: The pathogenesis of carcinoid heart disease is not fully understood, but the valvular and endocardial lesions are thought to be caused by high concentrations of serotonin or other vasoactive amines and peptides secreted by the tumor in the liver. These moieties are metabolized in the lung, so carcinoid heart disease affects the right side of the heart almost exclusively. There are reports of left-sided involvement in patients with atrial or ventricular septal defects.

During the 1990s, reports surfaced of mitral and aortic valve disease in patients taking the appetite-suppressing drugs fenfluramine-phentermine ("fen-phen"). Pathologic features of those valve lesions were strikingly similar to those seen in carcinoid heart disease, except that they developed on left-sided valves. Since then, other anorexigenic drugs and ergot alkaloid drugs such as methysergide and ergotamine used to treat migraine headaches have also been linked to this type of valve disease. Since these drugs interfere with serotonin metabolism and signaling, the pathogenesis of drug-related and carcinoid valve disease is similar.

PATHOLOGY: The cardiac lesions are plaque-like deposits of dense, pearly gray, fibrous tissue on the tricuspid (Fig. 17-39) and pulmonary valves and on the endocardial surface of the right ventricle. These patches appear "tacked on" to valve leaflets, without associated inflammation or apparent damage to underlying valve structures. However, leaflets become deformed, and their surface area reduced. As a result, tricuspid leaflets become "stuck down" onto adjacent right ventricular mural endocardium, resulting in tricuspid insufficiency or stenosis. Shrinkage of the pulmonary valve and its annulus leads to pulmonary stenosis.

FIGURE 17-39. Carcinoid heart disease. Pearly white deposits are seen on the tricuspid valve leaflets and adjacent endocardium. Although the valve leaflets have not been destroyed, they have become deformed and "stuck down" on the ventricular endocardium, which usually produces tricuspid regurgitation.

MYOCARDITIS

Myocarditis is inflammation of the myocardium associated with myocyte necrosis and degeneration. This definition specifically excludes ischemic heart disease. The true incidence of myocarditis is difficult to establish because many cases are asymptomatic. It can occur at any age but is most common in children 1–10 years old. It is one of the few heart diseases that can cause acute heart failure in previously healthy children, adolescents or young adults. Severe myocarditis can cause arrhythmias and even sudden cardiac death.

Most Cases of Viral Myocarditis Have No Demonstrable Cause

Viral etiology is generally suspected, but the evidence is usually circumstantial unless polymerase chain reaction (PCR) studies identify viral genomes in heart biopsies. The most common viral causes of myocarditis are listed in Table 17-7.

TABLE 17-7
CAUSES OF MYOCARDITIS

Idiopathic
Infectious
• Viral: Coxsackievirus, adenovirus, echovirus, influenza virus, human immunodeficiency virus and many others
• Rickettsial: Typhus, Rocky Mountain spotted fever
• Bacterial: Diphtheria, staphylococcal, streptococcal, meningococcal, *Borrelia* (Lyme disease) and leptospiral infection
• Fungi and protozoan parasites: Chagas disease, toxoplasmosis, aspergillosis, cryptococcal and candidal infection
• Metazoan parasites: *Echinococcus, Trichina*
Noninfectious
• Hypersensitivity and immunologically related diseases: Rheumatic fever, systemic lupus erythematosus, scleroderma, drug reaction (e.g., to penicillin or sulfonamide) and rheumatoid arthritis
• Radiation
• Miscellaneous: Sarcoidosis, uremia

MOLECULAR PATHOGENESIS: The pathogenesis of viral myocarditis involves direct viral cytotoxicity and cell-mediated immune reactions against infected myocytes. In animal models, inoculation of a cardiotropic virus is followed shortly by viral replication in the myocardium. There are only scattered foci of acute myocyte necrosis with little, if any, inflammation, and there is little evidence of functional impairment. Over the next few days, mononuclear cells, principally T lymphocytes and macrophages, infiltrate the myocardium extensively. At the point of maximum inflammation, signs of heart failure develop, although viral cultures of blood and myocardium are negative. This finding is consistent with the observation that patients with symptomatic myocarditis generally have negative viral cultures, although viral nucleic acid sequences can still be detected by PCR.

The most common viruses to infect the heart, coxsackievirus and adenovirus, both enter cardiac myocytes after binding the same cell surface receptor, the coxsackie-adenovirus receptor (CAR). Deletion of this molecule in mice prevents viral infection. CAR belongs to the family of intercellular adhesion molecules. It is especially abundant in children, which may explain why viral myocarditis is so common in childhood. Once inside a myocyte, coxsackieviruses produce proteases, such as protease 2A, which play a role in viral replication. These proteases may impede myocardial function. They also cleave myocyte proteins such as dystrophin, which may be involved in virus exiting from myocytes (intracellular viral load is higher if dystrophin is absent).

Cardiac myocytes contain powerful innate antiviral defenses mediated by Janus kinase (JAK) and STAT pathways activated by interferon (IFN)-α/β, IFN-γ and interleukin-6 (IL-6). However, these actions can be inhibited by suppressors of cytokine signaling (SOCS), proteins that limit potentially deleterious actions of cytokine signaling in cardiac myocytes. Levels of SOCS profoundly affect susceptibility to coxsackievirus infection. Thus, the highly variable clinical and pathologic manifestations of viral myocarditis depend on the dynamic interplay between mechanisms that determine viral entry, replication and release, and immune mechanisms (innate and T-cell mediated) of host responsiveness.

PATHOLOGY: The hearts of patients with myocarditis who develop clinical heart failure during the active inflammatory phase show biventricular dilation and generalized myocardial hypokinesis. At autopsy, such hearts are flabby and dilated. Histologic features of viral myocarditis vary with the clinical disease severity, but with few exceptions, microscopic features are nonspecific and indistinguishable from toxic myocarditis. Most cases show patchy or diffuse interstitial, predominantly mononuclear, inflammatory infiltrates, mainly of T lymphocytes and macrophages (Fig. 17-40). Multinucleated giant cells may also be present. The inflammatory cells often surround individual myocytes, and focal myocyte necrosis is seen. During the resolving phase, fibroblasts proliferate and interstitial collagen is deposited. Neutrophils are uncommon in viral myocarditis. However, if necrosis is extensive, the histology may resemble that of an infarct—a neutrophilic infiltrate followed by organization and repair. Most viruses that cause myocarditis also cause pericarditis.

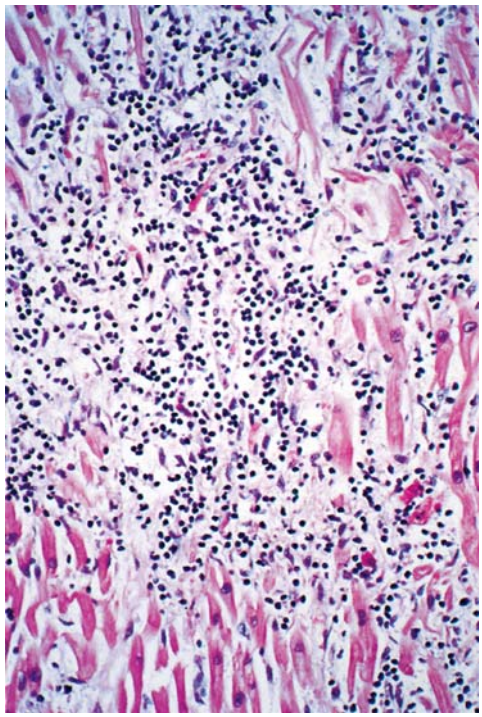

FIGURE 17-40. Viral myocarditis. The myocardial fibers are disrupted by a prominent interstitial infiltrate of lymphocytes and macrophages.

CLINICAL FEATURES: Many people with viral myocarditis have no symptoms. When symptoms do occur, they usually start a few weeks after infection. Most patients recover from acute myocarditis, although a few die of congestive heart failure or arrhythmias. The disease may be unusually severe in infants and pregnant women. Despite resolution of the active inflammatory phase of viral myocarditis, subtle functional impairment may persist for years and progression to overt cardiomyopathy is well documented. There is no specific treatment for viral myocarditis; supportive measures are the rule. Antiviral and immunomodulatory therapies are not useful.

MYOCARDITIS IN ACQUIRED IMMUNODEFICIENCY SYNDROME: A significant number of patients with AIDS have clinical or pathologic evidence of cardiac disease (pericardial effusions, myocarditis, endocarditis or cardiomyopathy). They are prone to an unusually high incidence of viral myocarditis, which largely reflects cardiotropic viruses, such as coxsackievirus and adenovirus. Human immunodeficiency virus type 1 (HIV-1) infection of cardiac myocytes appears to play a minor role.

Nonviral Transmissible Agents May Cause Myocarditis

Other microorganisms that gain access to the bloodstream can infect the heart. Among these, brucellosis, meningococcemia and psittacosis (see Chapter 9) often lead to infectious myocarditis. Some bacteria (e.g., diphtheria) produce cardiotoxins, which may cause fatal myocarditis. The most common cause of myocarditis in South America is a protozoan, *Trypanosoma cruzi*, the agent of Chagas disease (see below, Chapter 9).

- **Bacterial infection** of the myocardium is characterized by multiple foci of a mixed inflammatory infiltrate, with

neutrophils predominant. Microabscesses occur when septic emboli lodge in the coronary circulation, often secondary to infective endocarditis.

- **Rickettsial diseases** often cause widespread vasculitis, which affects small coronary blood vessels.
- **Fungal infection** of the myocardium typically occurs in immunocompromised patients, although the heart is relatively resistant to fungal infection.
- **Toxoplasmosis** can involve the myocardium in immunosuppressed patients; these intracellular parasites proliferate in cardiac myocytes and elicit a focal mixed inflammatory response, with neutrophils and eosinophils.
- **Chagas disease** is associated with proliferation of parasites within cardiac myocytes and a mixed inflammatory cell infiltrate, composed principally of lymphocytes, plasma cells and macrophages.

Granulomatous Myocarditis May Be Caused by Microorganisms or Immunologically Mediated Injury

Granulomatous myocarditis, with myocyte necrosis, occurs in a variety of diseases. Microorganisms associated with granulomatous myocarditis include *Mycobacteria* and some types of fungi. Immunologically mediated injury of the myocardium, for example, rheumatic myocarditis (Fig. 17-29) and sarcoidosis (see Fig. 17-46), may also cause granulomatous myocarditis.

Hypersensitivity Myocarditis Is a Reaction to Drugs

PATHOLOGY: In hypersensitivity myocarditis, the inflammation is interstitial and perivascular and is often confined to the myocardium without affecting other organs. The inflammatory infiltrate in hypersensitivity myocarditis resembles that in viral myocarditis but tends to have numerous eosinophils, in addition to lymphocytes and plasma cells. Another typical feature is the virtual absence of myocyte necrosis, even when the infiltrate is intense.

CLINICAL FEATURES: Hypersensitivity myocarditis is usually clinically silent. The diagnosis is often made as an incidental finding at autopsy. However, it may produce chest pain and ECG changes resembling acute myocardial ischemia. Occasionally, hypersensitivity myocarditis causes fatal ventricular arrhythmias. When the disease causes symptoms, treatment consists of discontinuing the offending drug and administering corticosteroids or immunosuppressive agents.

Giant Cell Myocarditis Is Usually Fatal

Giant cell myocarditis is a rare, highly aggressive disease characterized by intense inflammation, extensive areas of myocyte necrosis and many multinucleated giant cells derived from macrophages. Its cause is unknown, but it sometimes occurs in patients with SLE, hyperthyroidism or thymoma. An autoimmune etiology has been suggested, but there is no persuasive evidence for this theory.

Giant cell myocarditis is usually a rapidly fatal disease of adults in the third to fifth decades, although it also occurs in adolescents. Patients die of congestive heart failure or suddenly from arrhythmias. At autopsy, the heart is flabby and dilated and may contain mural thrombi. Prominent giant cells, lymphoid cells and macrophages are present at the margins of serpiginous areas of myocardial necrosis. Although giant cells are many, there are no granulomas. A few patients may recover, but the only effective treatment for most is cardiac transplantation. However, giant cell myocarditis may recur in transplanted hearts in 1/4 of cases.

METABOLIC DISEASES OF THE HEART

Hyperthyroidism Causes High-Output Failure

Thyroid hormone has direct inotropic and chronotropic effects on the heart: (1) it increases activity of the sarcolemmal sodium-potassium pump (Na^+/K^+-adenosine triphosphatase [ATPase]); (2) it enhances synthesis of a myosin isoform with rapid ATPase activity and reduces production of a slower isoform; and (3) it upregulates expression of SERCA and exerts direct effects on voltage-gated Ca^{2+} channels in the sarcolemma, thus facilitating contractility. Hyperthyroidism therefore causes tachycardia and increases cardiac workload, owing to decreased peripheral resistance and increased cardiac output. It may eventually lead to angina pectoris, high-output failure and/or arrhythmias (atrial fibrillation, most commonly).

Hypothyroid Heart Disease Diminishes Cardiac Output

Patients with severe hypothyroidism (**myxedema**) have low cardiac output, reduced heart rate and poor myocardial contractility—the opposite changes of those seen in hyperthyroidism. There may be a pericardial effusion created by increased capillary permeability and leakage of fluid and protein into the pericardial cavity. Pulse pressure is low because of higher peripheral resistance and lower blood volume.

The hearts of patients with myxedema are flabby and dilated, and the myocardium shows myofiber swelling. Basophilic (mucinous) degeneration is common. Interstitial fibrosis may also be present. Despite these changes, myxedema does not cause congestive heart failure in the absence of other cardiac disorders.

Thiamine Deficiency (Beriberi) Heart Disease Resembles Hyperthyroidism

Beriberi heart disease develops in people who eat insufficient vitamin B_1 (thiamine) for at least 3 months (see Chapter 8). It is seen in parts of Asia where the diet consists largely of shelled rice. In the United States, thiamine deficiency is occasionally seen in alcoholics or neglected people. Beriberi heart disease results in decreased peripheral vascular resistance and increased cardiac output, thus resembling hyperthyroidism with high-output failure. Interestingly, heart failure may develop so abruptly that patients die within 2 days of the onset of symptoms. At autopsy, the heart is dilated and shows only nonspecific microscopic changes.

CARDIOMYOPATHY

Cardiomyopathies are primary diseases of the myocardium exclusive of damage caused by extrinsic factors. Usually,

primary cardiomyopathies are divided into the major clinicopathologic groups of **dilated cardiomyopathy** (DCM), **hypertrophic cardiomyopathy** (HCM), **arrhythmogenic cardiomyopathy** (AC) and **restrictive cardiomyopathy** (RCM). DCM is most common and is a leading indication for heart transplantation. It is characterized by biventricular dilation, impaired contractility and eventually congestive heart failure. DCM can develop after a large number of known insults that injure cardiac myocytes directly **(secondary DCM),** or it may be idiopathic **(primary DCM)**.

In Idiopathic Dilated Cardiomyopathy Contractility Is Impaired

MOLECULAR PATHOGENESIS: Many etiologies have been implicated in idiopathic DCM. Most cases probably represent interplay between genetic, epigenetic and environmental factors.

Genetic factors play an important role in the pathogenesis of DCM. At least 1/3 of DCM patients inherited the disease as a single-gene disorder in a Mendelian pattern. The proportion may be even greater, as incomplete penetrance often makes it difficult to identify early or latent disease in family members. Most familial cases seem to be transmitted as autosomal dominant traits, but autosomal recessive, X-linked recessive and mitochondrial inheritance patterns have all been described (Table 17-8).

Mutations in more than 50 genes have been linked to DCM. Several occur in genes encoding cytoskeletal proteins such as lamin A/C, desmin and metavinculin. Others occur in genes such as δ-sarcoglycan and dystrophin, which are involved in anchoring the cytoskeleton and the sarcolemma to the extracellular matrix (Table 17-8). ***This has led to the hypothesis that defects in force transmission lead to development of a dilated, poorly contracting heart*** (Fig. 17-41). However, 35%–45% of genetic causes of DCM may be related to mutations in genes encoding sarcomeric proteins such as

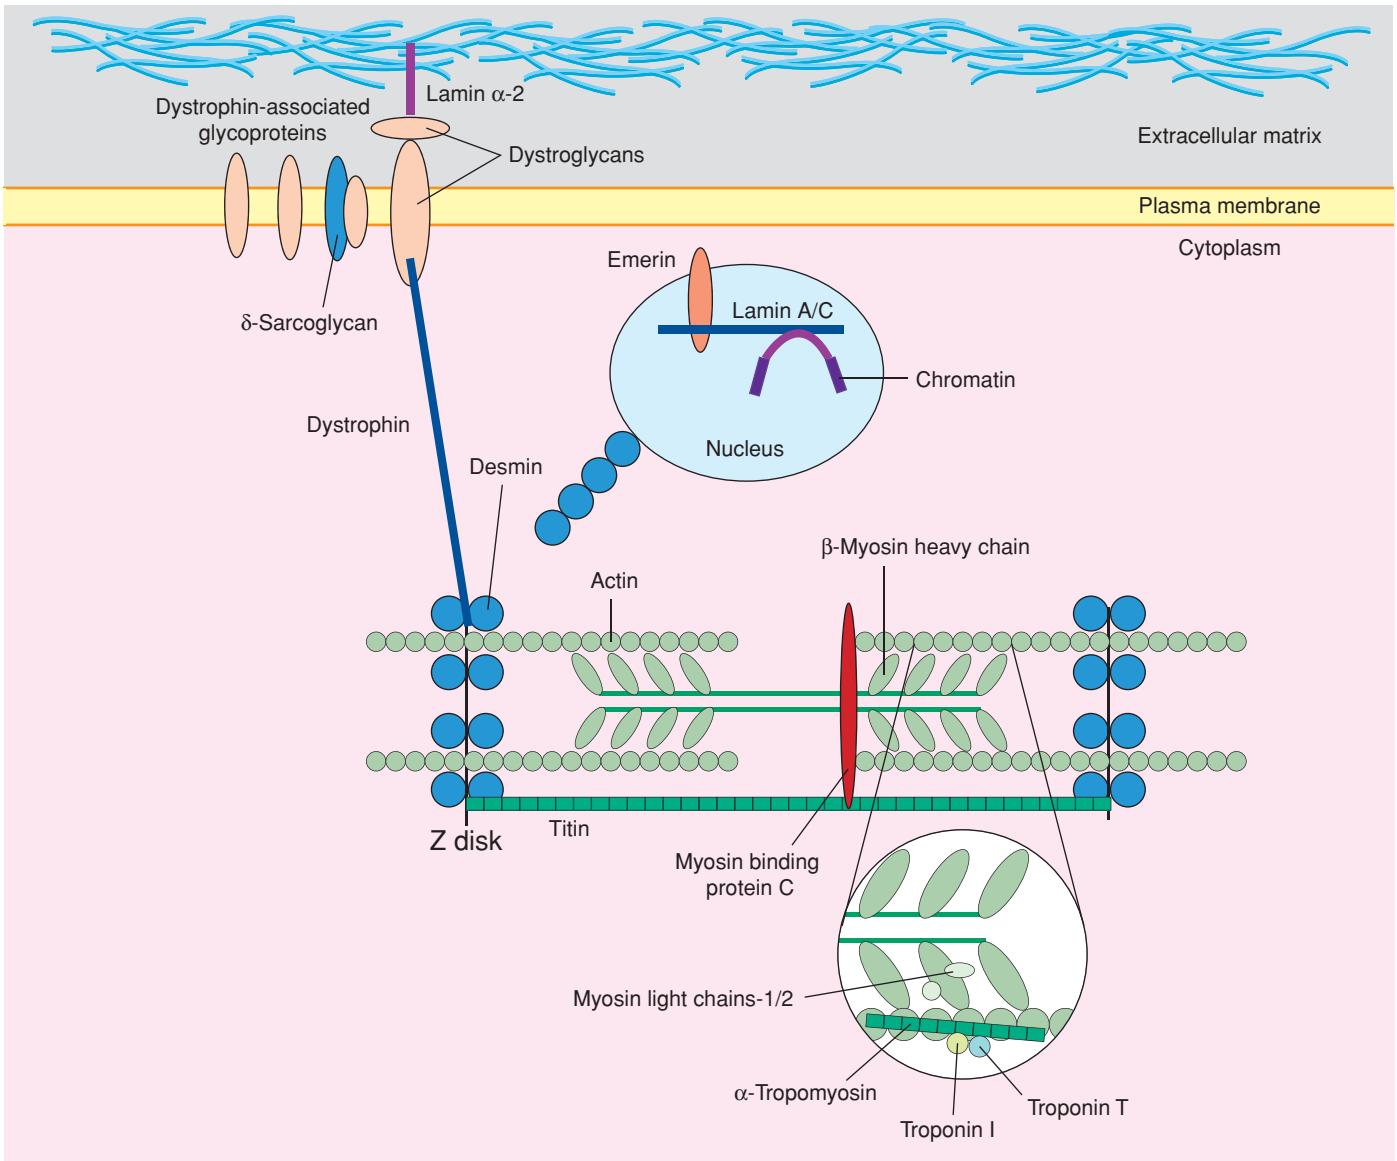

FIGURE 17-41. Subcellular distribution and molecular interactions of mutant proteins implicated in the pathogenesis of dilated and hypertrophic cardiomyopathy. The specific mutations responsible for each type are provided in Tables 17-8 and 17-9.

TABLE 17-8
GENE DEFECTS ASSOCIATED WITH DILATED CARDIOMYOPATHY (DCM)

Gene	Chromosome Locus	OMIM[a]	Gene Product	Frequency	Related Disorders
Autosomal Dominant					
TTN	2q31	188840	Titin	20%–25%	Hypertrophic cardiomyopathy (HCM)
LMNA	1q21.2	150330	Lamin A/C	4%–8%	Lipodystrophy, Charcot-Marie-Tooth, Emery-Dreifuss muscular dystrophy, Hutchinson-Gilford progeria syndrome, limb girdle muscular dystrophy (LGMD)
MYH7	14q12	160760	β-Myosin heavy chain	4%–6%	Laing distal myopathy, HCM
TNNT2	1q32	191045	Cardiac troponin T	3%	HCM
SCN5A	3p21	600163	Sodium channel	2%–3%	Long QT syndrome, Brugada syndrome, idiopathic ventricular fibrillation, sick sinus syndrome, cardiac conduction system disease
MYH6	14q12	160710	α-Myosin heavy chain	? 2%–3%	HCM, dominantly inherited atrial septal defect
DES	2q35	125660	Desmin	<1%–1%	Desminopathy, arrhythmogenic cardiomyopathy
VCL	10q22.1–23	193065	Metavinculin	<1%–1%	HCM
LDB3	10q22.2–23.3	605906	LIM domain-binding 3	<1%–1%	HCM
TCAP	17q12	604488	Titin-cap or telethonin	<1%–1%	LGMD, HCM
PSEN1/PSEN2	14q24.3/1q31–q42	104311/600759	Presenilin 1/2	<1%–1%	Alzheimer disease
ACTC	15q14	102540	Cardiac actin	<1%	HCM
TPM1	15q22.1	191010	α-Tropomyosin 1	<1%	HCM
SGCD	5q33–34	601411	δ-Sarcoglycan	<1%	Delta sarcoglycanopathy (LGMD)
CSRP3	11p15.1	600824	Muscle LIM protein	<1%	HCM
ACTN2	1q42–q43	102573	α-Actinin-2	<1%	HCM

[a]OMIM is Online Mendelian Inheritance in Man, http://www.ncbi.nlm.nih.gov/sites/entrez?db=omim, where additional information for each gene can be found.

actin, titin, troponin T and β- or α-myosin heavy chains. Mutations (mainly truncations) in the giant sarcomeric protein titin, which has 35,000 amino acids, may alone account for up to 25% of genetic causes.

Interestingly, some sarcomeric protein mutations may produce either DCM or HCM phenotypes, perhaps depending on whether they produce a defect in force generation (HCM) or force transmission. For example, actin mutations associated with HCM have been localized to a portion of the molecule near a myosin-binding site, which could impair sarcomeric function. By contrast, DCM-associated mutations in actin are within the region that binds to the dystrophin–sarcoglycan

complex (Fig. 17-41). While the force transmission hypothesis is appealing, it may not account for other mutations linked to DCM such as those involving the cardiac sodium channel or presenilin, both of which have also been implicated in other types of diseases (Table 17-8). As the list of genetic factors expands, so too does the breadth of potential molecular mechanisms and insights into genotype–phenotype relationships. For example, mutations in genes encoding proteins of the cytoskeleton and sarcomere tend to produce phenotypes dominated by contractile dysfunction and heart failure, while mutations in genes for desmosomal proteins, lamin A/C and the cardiac sodium channel protein Nav1.5 lead to a more arrhythmogenic DCM picture.

Viral myocarditis may eventually lead to DCM, but how this would develop is not clear. Once they have infected cardiac myocytes, viruses can harness the host ubiquitin/proteasomal system and autophagy machinery to facilitate their replication. Ongoing interactions between viruses and these host systems can impair normal host protein turnover kinetics and promote oxidative stress. This could, in turn, lead to abnormal regulation of contractile proteins and promote apoptosis and autophagic cell death with the eventual emergence of a clinical phenotype of ventricular remodeling and failure. Indeed, persistence of viral genomes in the heart detected by PCR is associated with progressive impairment of left ventricular function, whereas spontaneous viral elimination is associated with improved function.

Immunologic abnormalities, both cellular and humoral, have been recognized in both myocarditis and idiopathic DCM. Autoantibodies have been identified against several cardiac antigens, including a variety of mitochondrial antigens, cardiac myosin and β-adrenergic receptors. However, as in many cases of autoimmune disease, a pathogenic role for immune mechanisms remains to be proven: circulating autoantibodies may be the result of myocardial injury, rather than its cause.

PATHOLOGY: The pathology of DCM is generally nonspecific, and is similar whatever its genesis. At autopsy, the heart is invariably enlarged, with conspicuous left and right ventricular hypertrophy. Heart weight may be tripled (>900 g). As a rule, all chambers of the heart are dilated, though the ventricles are more severely affected than are the atria (Fig. 17-42). At end stage, left ventricular dilation is usually so severe that the left ventricle wall appears to be of normal thickness or even thinned. The myocardium is flabby and pale, sometimes with small subendocardial scars. The left ventricle endocardium tends to be thickened, especially at the apex. Adherent mural thrombi are often present in this area.

DCM is characterized by atrophic and hypertrophic myocardial fibers. Cardiac myocytes, especially in the subendocardium, often show advanced degenerative changes characterized by myofibrillar loss (myocytolysis), an effect that gives cells a vacant, vacuolated appearance. Interstitial and perivascular fibrosis of myocardium is evident, also most prominently in the subendocardial zone. Scattered chronic inflammatory cells may be present, but are not conspicuous. Electron microscopy typically shows loss of sarcomeres and an apparent increase in mitochondria.

CLINICAL FEATURES: The clinical courses of idiopathic and secondary DCM are comparable. Both begin insidiously with compensatory ventricular hypertrophy and asymptomatic left ventricular dilation. Exercise intolerance usually progresses relentlessly to frank congestive heart failure and 75% of patients die within 5 years of the onset of symptoms. Half of all deaths in DCM patients are sudden and are attributed to ventricular arrhythmias. Abnormalities in intracellular Ca^{2+} handling and certain repolarizing (K^+) currents are common features in all forms of heart failure. They tend to prolong QT intervals and increase the likelihood of arrhythmias initiated by triggered activity. Supportive treatment is useful, but cardiac transplantation or a ventricular assist device is eventually necessary.

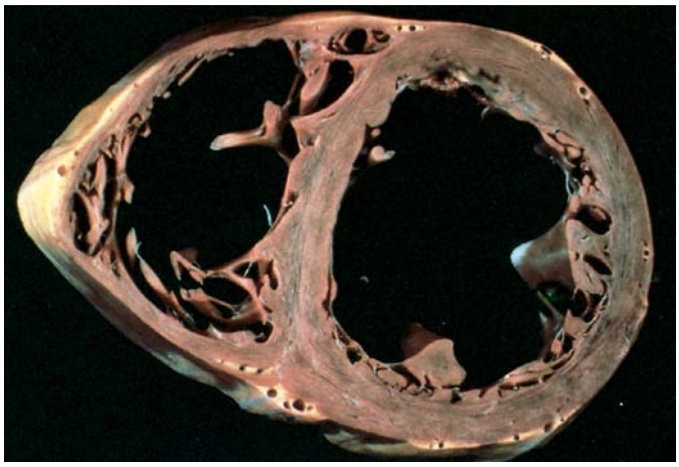

FIGURE 17-42. Idiopathic dilated cardiomyopathy. A transverse section of the enlarged heart reveals conspicuous dilation of both ventricles. Although the ventricular wall appears thinned, the increased mass of the heart indicates considerable hypertrophy.

Over 100 Diseases May Cause Clinical Features of Secondary Dilated Cardiomyopathy

Thus, secondary DCM is best viewed as a final common pathway for virtually any toxic, metabolic or infectious disorder that directly injures cardiac myocytes. In this context, alcohol abuse, hypertension, pregnancy and viral myocarditis predispose to secondary DCM. Diabetes mellitus and cigarette smoking are also associated with an increased incidence of DCM.

Toxic Cardiomyopathy

Many chemicals and drugs cause myocardial injury, but only a few of the more important chemicals are discussed here.

ETHANOL: Alcohol is the single most common identifiable cause of DCM in the United States and Europe. Ethanol abuse can lead to chronic, progressive cardiac dysfunction, which may be fatal. The disorder is more common in men, because alcoholism is more frequent in men. The typical patient is between 30 and 55 years old and has been drinking heavily for at least 10 years.

MOLECULAR PATHOGENESIS: The pathogenesis of alcoholic cardiomyopathy is obscure. In experimental animals, the presence of ethanol exerts a negative inotropic effect (decreased contractile strength) on cardiac muscle, impairs calcium flux, inhibits

protein synthesis and produces oxidative stress. Moreover, adducts of ethanol, metabolic products such as acetaldehyde and fatty acid ethyl esters impair cardiac myocyte function. Yet all of these effects are entirely reversible if ethanol is discontinued. Since the development of human alcoholic cardiomyopathy requires more than 10 years of alcohol abuse and is related to the total lifetime dose of alcohol, the role of reversible changes is questionable. Alcohol abuse increases the rate of apoptosis in human cardiac myocytes, and inhibitory effects on certain types of progenitor cells have been shown. Whether alcoholic cardiomyopathy represents an imbalance between apoptosis and replacement of cardiac myocytes, as has been claimed for biological aging (see Chapter 10), is a subject for further study.

COBALT: The cardiac toxicity of cobalt is discussed in Chapter 8.

CATECHOLAMINES: In high concentrations, catecholamines can cause focal myocyte necrosis (contraction band necrosis). Toxic myocarditis may occur in patients with pheochromocytomas or who require high doses of inotropic drugs to maintain blood pressure and in accident victims who sustain massive head trauma. Multiple mechanisms contribute to myocardial injury, but the most important is enhanced calcium flux into myocytes. Focal ischemia caused by platelet aggregation and microvascular constriction may also contribute. Catecholamine toxicity has been implicated in Takotsubo cardiomyopathy, also known as apical ballooning cardiomyopathy or stress-induced cardiomyopathy, which is characterized by the abrupt onset of transient left ventricular dysfunction with apical dilation, often brought on by severe emotional or physical stress.

ANTHRACYCLINES: Doxorubicin (Adriamycin) and other anthracycline drugs are potent chemotherapeutic agents whose usefulness is limited by cumulative, dose-dependent, cardiac toxicity. The clinical major effect is poor myocyte contractility due to chronic, irreversible degeneration of cardiac myocytes. The histopathology of this disorder includes vacuolization and loss of myofibrils. Myocyte necrosis is rare, but once severe degeneration occurs, intractable congestive heart failure develops and the prognosis is grim.

PATHOPHYSIOLOGY: DCM begins to appear in patients who receive a cumulative dose of more than 500 mg doxorubicin per m^2, and 35% of those receiving more than 550 mg/m^2 develop cardiomyopathy. The mechanism by which anthracyclines damage the heart appears related mainly to formation of ROS through redox cycling of aglycone metabolites and anthracycline–iron complexes. Although the heart is relatively resistant to radiation injury, anthracyclines and radiation act synergistically. Thus, a patient who has received radiotherapy to the mediastinum is likely to develop anthracycline toxicity at a lower dose than someone who was never irradiated. As detailed below, DCM due to anthracyclines is only one example of long-term cardiovascular complications in patients who have survived cancer therapies.

CYCLOPHOSPHAMIDE: This alkylating agent is often used in high doses before bone marrow transplantation. It does not cause classical DCM but can cause pericarditis and occasionally massive hemorrhagic myocarditis. The latter is thought to be secondary to endothelial injury and thrombocytopenia.

COCAINE: Cocaine use is often associated with chest pain and palpitations. True DCM is an unusual complication of cocaine abuse, but myocarditis, focal necrosis and thickening of intramyocardial coronary arteries have been reported. Myocardial ischemia or infarction associated with cocaine use has been attributed to coronary vasoconstriction in the face of increased myocardial oxygen demand. Sudden death due to spontaneous ventricular tachyarrhythmias is well documented. Cocaine-induced arrhythmias may be due to drug-related vasoconstriction, sympathomimetic activity, hypersensitivity responses and direct toxicity.

Cardiomyopathy of Pregnancy

A unique form of DCM develops in the last trimester of pregnancy or the first 6 months after delivery. The disorder is relatively uncommon in the United States, but in some areas in Africa, it occurs in as many as 1% of pregnant women. Risk of cardiomyopathy of pregnancy is greatest in black, multiparous women older than 30 years. Some patients exhibit inflammatory cells in heart biopsies taken during the symptomatic phase of the illness, consistent with the hypothesis that disordered immunity may underlie development of DCM in this setting.

Unlike most other varieties of DCM, half of women with cardiomyopathy of pregnancy spontaneously recover normal cardiac function. In the other half, left ventricular dysfunction persists or becomes overt congestive heart failure, leading to early death. In patients who survive, subsequent pregnancies pose a high risk of recurrence and maternal mortality.

PATHOPHYSIOLOGY: Overproduction of prolactin has been implicated in cardiomyopathy of pregnancy. In normal pregnancy, prolactin increases blood volume, decreases blood pressure and diminishes renal excretion of water and salts. Patients with peripartum cardiomyopathy have increased blood levels of a biologically active proteolytic fragment of prolactin. Small clinical studies using the prolactin secretion inhibitor bromocriptine have shown promising results.

In Hypertrophic Cardiomyopathy Cardiac Hypertrophy Is Out of Proportion to Hemodynamic Load

HCM develops for no apparent physiologic reason, is probably genetically determined in most patients and is an autosomal dominant trait in half of patients. Many people with no family history probably have spontaneous mutations or a mild form of disease that is hard to detect. The prevalence of HCM in the United States is about 1 in 500.

MOLECULAR PATHOGENESIS: The clinical picture of HCM is typically caused by dominant mutations in genes encoding proteins of the sarcomere (Table 17-9). Roughly 80% of HCM cases for which a genetic basis is identified involve mutations in one of two

genes: those encoding β-myosin heavy chain and myosin-binding protein C. Mutations in genes for cardiac troponin T, cardiac troponin I and α-tropomyosin-1 (components of the troponin complex) account for most remaining cases. However, like DCM, there is marked allelic heterogeneity in HCM such that most mutations occur "privately" or at frequencies of less than 1%. Thus, hundreds of different mutations, mostly missense, have been identified. In addition, mutations in several nonsarcomeric protein genes have rarely been linked to the clinical phenotype of HCM. As noted in the discussion of DCM, different mutations in the same gene can give rise to diverse clinical phenotypes of DCM or HCM.

The mechanistic link between the mutations and the resultant clinical and pathologic phenotypes of HCM is poorly understood. In general, it is thought that the mutant protein is incorporated into the sarcomere, where it acts in a dominant-negative fashion to cause a loss of sarcomeric function. ***This proposed mechanism has led to the hypothesis that HCM is related to defects in force generation due to altered sarcomeric function.*** Hypertrophy may then be a compensatory response. Other mutations (e.g., involving myosin light-chain or α-tropomyosin-1 genes) may actually enhance contractility and thus lead to hypertrophy. Still others (e.g., mutations in the myosin-binding protein C gene) may produce proteins that do not become incorporated into sarcomeres. These might lead to hypertrophy because a functional protein is missing, rather than by a dominant-negative effect.

Because of the risk of sudden death in HCM, there have been many attempts to use genetics to help stratify risk. Overall, results have been disappointing, although some correlations have been recognized. For example, selected mutations in β-myosin heavy-chain and troponin T genes involve a high likelihood of sudden death. In the case of the

β-myosin heavy-chain mutations, the risk of sudden death correlates with the amount of hypertrophy, whereas troponin T mutations, which are also linked to sudden death, produce minimal or no hypertrophy. HCM in patients with myosin-binding protein C mutations is usually benign clinically, and is associated with slowly progressive hypertrophy developing late in life. A few patients (2%–5%) have mutations in two genes and generally show earlier onset and a more severe clinical phenotype.

PATHOLOGY: The heart in HCM is always enlarged, but the extent of hypertrophy varies in different genetic forms. The left ventricular wall is thick, and its cavity is small, sometimes only a slit. Papillary muscles and trabeculae carneae are prominent and encroach on the lumen. More than half of cases exhibit asymmetric hypertrophy of the interventricular septum, with a ratio of septum to left ventricular free wall thickness greater than 1.5 (Fig. 17-43A). In some rare genetic forms of HCM, only the apical portion of the left ventricle or the papillary muscles may be selectively hypertrophied. Often, the thickened, hypertrophied interventricular septum bulges into the left ventricular outflow tract early in ventricular systole, obstructing the aortic outflow tract. In this situation, an endocardial mural plaque is typically seen in the outflow tract, corresponding to the contact point where the anterior mitral valve leaflet impinges on the septal wall of the outflow tract during systole. Both atria are commonly dilated.

The most notable histologic feature of HCM is **myofiber disarray,** which is most extensive in the interventricular septum. Instead of the usual parallel arrangement of myocytes into muscle bundles, myofiber disarray is characterized by oblique and often perpendicular orientations of adjacent hypertrophic myocytes (Fig. 17-43B). By electron microscopy, myofibrils and myofilaments within individual myocytes are also disorganized. Such structural disarrangements may be present in infants with congenital heart defects and in several other settings, but they are always extensive in HCM and are not as widespread in other situations. Interstitial cells are usually hyperplastic, and intramural coronary arteries may be thick and cellular (Fig. 17-43C).

CLINICAL FEATURES: Many patients with HCM have few, if any, symptoms, and the diagnosis is commonly made during screening of the family with an affected member. Despite a lack of symptoms, such people may be at risk for sudden death, particularly during severe exertion. In fact, unsuspected HCM is commonly found at autopsy in young competitive athletes who die suddenly (see Fig. 17-47). Clinical recognition of HCM can occur at any age, often in the third to fifth decades of life, but it also is encountered in the elderly (mainly in people with myosin-binding protein C mutations). Some patients with HCM are incapacitated by cardiac symptoms, of which dyspnea, angina pectoris and syncope are most common. The clinical course tends to remain stable for many years, although eventually the disease can progress to congestive heart failure. In 10% of patients, DCM supervenes.

Despite the fact that mutant proteins impair the sarcomere, contractile function in HCM tends to be hyperdynamic.

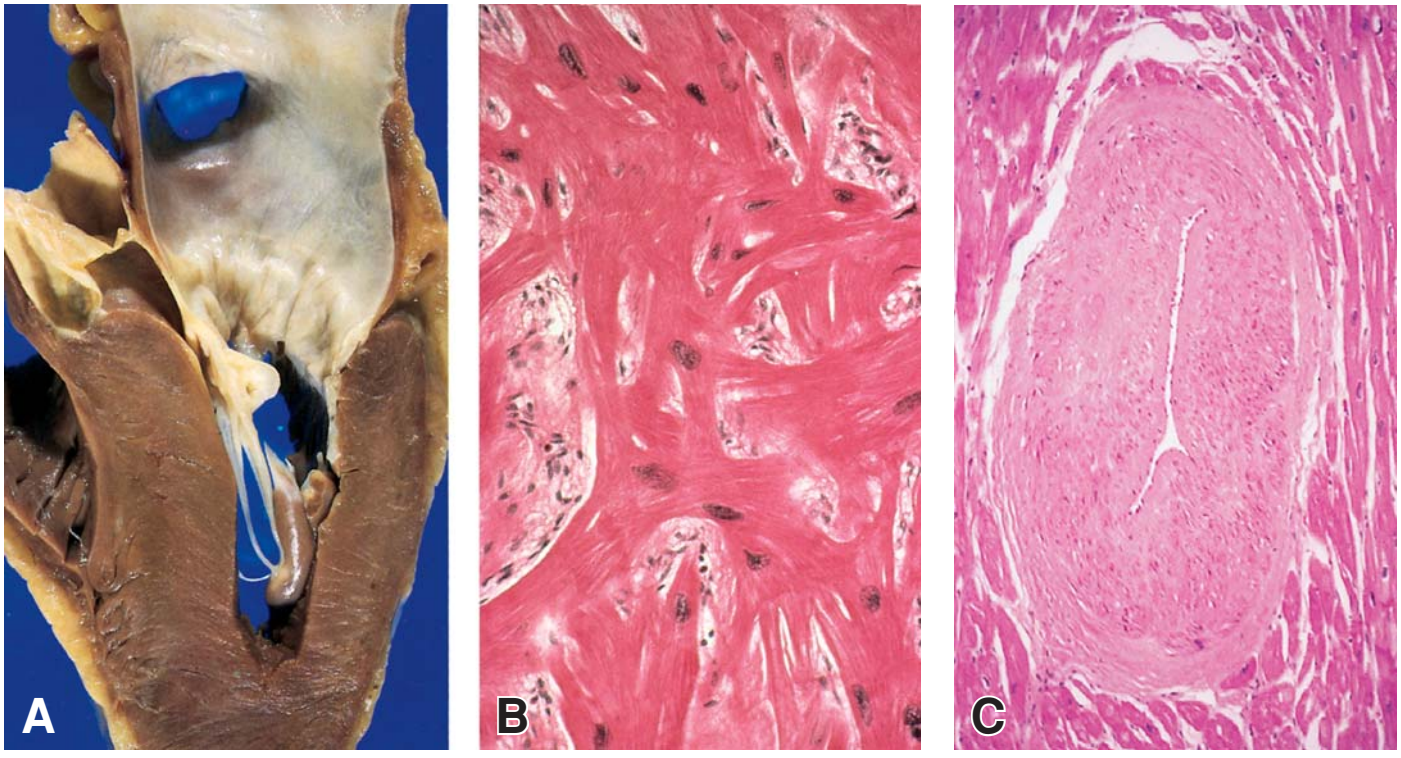

FIGURE 17-43. Hypertrophic cardiomyopathy (HCM). A. The heart has been opened to show striking asymmetric left ventricular hypertrophy. The interventricular septum is thicker than the free wall of the left ventricle and impinges on the outflow tract such that it contacts the underside of the anterior mitral valve leaflet. The left atrium is markedly enlarged. **B.** A section of the myocardium shows the characteristic myofiber disarray and hyperplasia of interstitial cells. **C.** A small intramural coronary artery shows a thickened, hypercellular media. This type of remodeling of coronary vessels could contribute to development of angina-like symptoms in some patients with HCM.

Ejection fractions are typically very high and most of the stroke volume is ejected during early systole. The most prominent dysfunctional aspect of HCM is decreased left ventricular compliance (diastolic dysfunction), which results in increased end-diastolic pressure. Mitral regurgitation is also seen in many such patients, leading to the atrial dilation commonly seen in HCM (note the enlarged left atrium in Fig. 17-43). In 1/4 of patients, functional obstruction of the left ventricular outflow tract occurs near the end of systole, resulting in a pressure gradient between the apex and the subvalvular region of the left ventricle.

HCM responds paradoxically to pharmacologic interventions. Heart failure from other causes is typically treated with cardiac glycosides to increase myocardial contractility and with diuretics to reduce intravascular volume. These drugs aggravate symptoms of HCM. Rather, HCM is treated with β-adrenergic blockers and Ca^{2+} channel blockers, which reduce contractility, decrease outflow tract obstruction and may improve left ventricular relaxation during diastole. Surgical removal of part of the hypertrophic septum or injection of ethanol into a septal artery to cause localized infarction may relieve symptoms of obstruction, but the risk of sudden death remains.

Arrhythmogenic Cardiomyopathy Is a Disease of the Desmosome with a High Risk of Sudden Death

Arrhythmogenic cardiomyopathy (AC) is a highly arrhythmogenic form of human heart disease. First described as a right ventricular disease (arrhythmogenic right ventricular cardiomyopathy, or ARVC), AC is now recognized to include biventricular and left dominant forms, which may be misdiagnosed as dilated cardiomyopathy or myocarditis. It affects roughly 1 in 5000 individuals and occurs most commonly in Mediterranean countries where it is a leading cause of sudden death in young people (under 35 years of age).

MOLECULAR PATHOGENESIS AND PATHOLOGY: AC is associated with serious arrhythmias and/or sudden death, which may occur early in the disease before significant structural remodeling and contractile dysfunction develop. The classical form (ARVC) affects the right ventricular free wall. The characteristic pathologic features are degeneration of cardiac myocytes and replacement by fat and fibrous tissue (Fig. 17-44), but the extent of this change can be quite variable and it is not necessarily conspicuous in patients who die suddenly.

AC is a familial disease, usually inherited in an autosomal dominant pattern. Its true incidence is probably underestimated because of variable penetrance, age-related progression and large phenotypic variation. The diagnosis can be difficult to make and requires analysis of various clinical criteria, which, although relatively specific, are not very sensitive. Mutations in genes encoding proteins in desmosomes, cell–cell adhesion organelles, can be identified in more than half of individuals who fulfill these criteria. These include genes for desmosomal adhesion molecules such as desmoglein-2 and intracellular desmosomal proteins including plakoglobin, desmoplakin and plakophilin-2, which form a complex that links the adhesion molecules to the desmin cytoskeleton in cardiac myocytes. Mutations in the gene for plakophilin-2 are most commonly seen in classical ARVC, whereas mutations in the gene for desmoplakin are often associated with biventricular or left-sided forms of AC. Desmosomes are particularly abundant in heart and skin, two organs that experience the greatest mechanical burden, and mutations in desmosomal genes generally give rise to cutaneous and/or cardiac disease depending on the tissue-specific expression pattern of the mutant isoform. The mechanism by which desmosome mutations cause AC is unresolved, but increasing evidence implicates deranged Wnt signaling pathways and abnormal responses to mechanical stimulation of the heart during exercise.

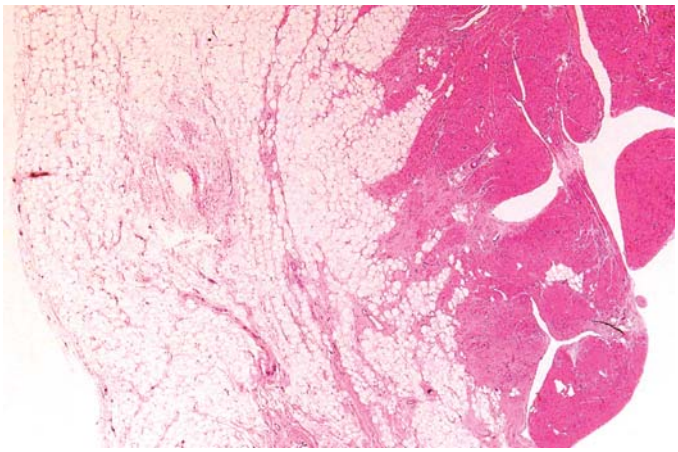

FIGURE 17-44. Arrhythmogenic cardiomyopathy. This section of the right ventricular free wall from a patient with classical arrhythmogenic right ventricular cardiomyopathy shows that much of the myocardium has been replaced by mature adipose tissue and fibrosis such that only subendocardial muscle bundles remain.

Restrictive Cardiomyopathy Impairs Diastolic Function

Restrictive cardiomyopathy describes a group of diseases in which myocardial or endocardial abnormalities limit diastolic filling while contractile function is normal. It is the least common category of cardiomyopathy in Western countries, but in some less developed areas (e.g., equatorial Africa, South America and Asia), endomyocardial diseases due to parasitic infections lead to many cases of restrictive cardiomyopathy.

ETIOLOGIC FACTORS AND PATHOLOGY: Restrictive cardiomyopathy is caused by (1) interstitial infiltration of amyloid, metastatic carcinoma or sarcoid granulomas; (2) endomyocardial disease characterized by marked fibrotic thickening of the endocardium; (3) genetic and storage diseases, including hemochromatosis and desmin-related cardiomyopathies; and (4) markedly increased interstitial fibrous tissue. The pathophysiologic consequence is a preload-dependent state, characterized by defective diastolic compliance, restricted ventricular filling, increased end-diastolic pressure, atrial dilation and venous congestion. In many respects, these hemodynamic changes are similar to the consequences of constrictive pericarditis. Many cases of restrictive cardiomyopathy are classified as idiopathic, with interstitial fibrosis as the only histologic abnormality.

The disease almost invariably progresses to congestive heart failure, and only 10% of the patients survive for 10 years.

Amyloidosis

The heart is affected in most forms of generalized amyloidosis (see Chapter 15). In fact, restrictive cardiomyopathy is the most common cause of death in the AL amyloidosis of plasma cell dyscrasias.

PATHOLOGY: Amyloid infiltration of the heart results in cardiac enlargement without ventricular dilation. The gross appearance of the heart may resemble that seen in hypertrophic cardiomyopathy. Ventricular walls are typically thickened, firm and rubbery. Amyloid accumulation is most prominent in interstitial, perivascular and endocardial regions (Fig. 17-45). Endocardial involvement is common in the atria, where nodular endocardial deposits often impart a granular appearance and gritty texture to the endocardial surface. Amyloid deposits also can thicken cardiac valves. In rare cases, amyloid in the walls of intramural coronary arteries narrows their lumens and causes ischemic injury.

CLINICAL FEATURES: Cardiac amyloidosis is most often a restrictive cardiomyopathy, with progressive diastolic and eventually systolic dysfunction. Infiltration of the conduction system can result in varying degrees of heart block and ventricular tachyarrhythmias. Echocardiography shows concentric ventricular thickening with right ventricular involvement and, usually, near-normal ejection fraction. Atrial enlargement, due to the noncompliant ventricular walls, is often seen. Low voltage of the QRS complex is a characteristic feature of the electrocardiogram.

The outlook for patients with symptomatic cardiac amyloidosis is grim: most survive less than 1 year. However, some patients have experienced more prolonged survival following successful treatment of their underlying plasma cell dyscrasia with chemotherapy or bone marrow transplantation. Durable remissions with bortezomib, a proteasome inhibitor used in multiple myeloma, have also been reported.

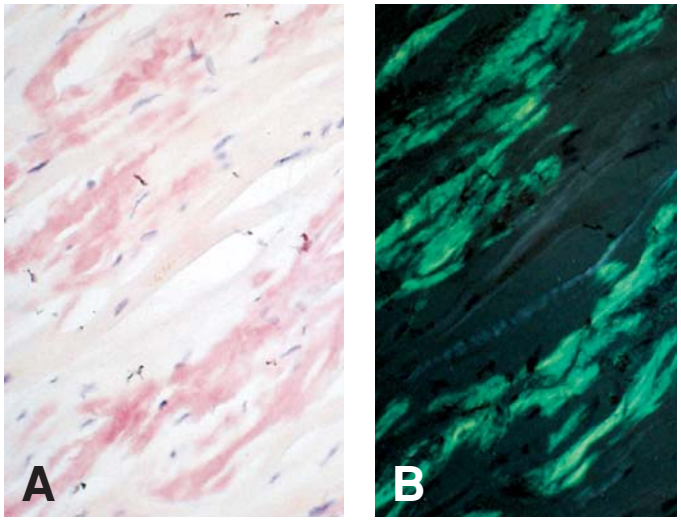

FIGURE 17-45. Cardiac amyloidosis. A. A section of myocardium stained with Congo red shows interstitial, pink-staining deposits of amyloid. **B.** Under polarized light, the same section displays the characteristic green birefringence of amyloid fibrils.

SENILE CARDIAC AMYLOIDOSIS: In senile cardiac amyloidosis, a protein related to prealbumin (transthyretin) is deposited in the hearts of elderly people (see Chapter 15). The disorder may be present to some extent in up to 25% of patients 80 years old or older. It involves not only the heart (atria and ventricles) but also, in many cases, the lungs and rectum as well. Amyloid deposits also may be found in blood vessel walls in many organs, but virtually never in renal glomeruli. Senile cardiac amyloidosis is usually an incidental finding at autopsy, and rarely is functionally significant. Even if amyloid deposits are extensive and there is symptomatic congestive heart failure, progression of the disease is much slower than that in AL amyloidosis.

Two additional forms of isolated cardiovascular amyloidosis are common in the elderly: **senile aortic amyloidosis** and **isolated atrial amyloidosis**. Neither of these forms of amyloid contains prealbumin or closely related proteins.

Desmin-Related Cardiomyopathies

Desmin is the intermediate filament protein in cardiac, striated and smooth muscle. Desmin filaments bind to desmosomes at intercalated disks and span the length of the cardiac myocyte by binding to Z disks of sarcomeres and other intracellular organelles.

MOLECULAR PATHOGENESIS AND PATHOLOGY: Many mutations in desmin are known in patients with skeletal and cardiomyopathies; most are inherited as autosomal dominant traits. The heart disease usually manifests as a restrictive cardiomyopathy, with ventricular wall thickening, loss of ventricular compliance and diastolic dysfunction. Yet, some desmin-related cardiomyopathies resemble AC or DCM, presumably related to altered molecular interactions between desmin and components of desmosomes and the cytoskeleton, In many forms, the mutant protein is expressed and apparently interferes with normal desmin filament production. Large intracellular aggregates of refractile material can be seen by light microscopy, which are tangled masses of misfolded desmin filaments.

Endomyocardial Disease

Endomyocardial disease (EMD) consists of two geographically separate disorders.

ENDOMYOCARDIAL FIBROSIS: This disorder is particularly common in equatorial Africa, where it accounts for 10%–20% of deaths from heart disease. It also occurs occasionally in other tropical and subtropical regions of the world. While it is most common in children and young adults, endomyocardial fibrosis may occur in people up to age 70. It leads to progressive myocardial failure and has a poor prognosis, although some patients survive for as long as 12 years.

EOSINOPHILIC ENDOMYOCARDIAL DISEASE (LÖFFLER ENDOCARDITIS): This is a cardiac disorder of temperate regions characterized by hypereosinophilia (up to 50,000/μL). It usually occurs in men in the fifth decade and is often accompanied by rash. Löffler endocarditis typically progresses to congestive heart failure and death, although corticosteroids may improve survival.

ETIOLOGIC FACTORS: Endomyocardial fibrosis and Löffler endocarditis are variants of the same basic disease. ***EMD probably results from myocardial injury caused by eosinophils, possibly mediated by cardiotoxic granule components.*** In the tropics, transient high blood eosinophil counts often result from parasitic infestations; in temperate climates, idiopathic hypereosinophilia is often persistent.

EMD can be divided into three stages:

1. The necrotic stage occurs within the first few months of the illness and is characterized by an intense eosinophilic infiltrate of the inner myocardial layers, usually of both ventricles. The infiltrate is perivascular and interstitial, and there is evidence of vascular injury and myocyte necrosis. This stage lasts for several months, usually without significant functional impairment.
2. The thrombotic stage develops about a year later. Mural thrombi attach to injured, slightly thickened endocardium. At this time, the myocardium is no longer inflamed but shows early hypertrophy. Emboli may occur at this time.
3. The fibrotic stage is the chronic phase of EMD, with conspicuous fibrotic endocardial thickening and marked fibrosis. This decreases compliance and causes diastolic dysfunction. Posterior valve leaflets may adhere to the endocardium, causing mitral—or on the right side, tricuspid—regurgitation.

PATHOLOGY: At autopsy, a grayish white thickened endocardium extends from the apex of the left ventricle over the posterior papillary muscle to the posterior leaflet of the mitral valve and for a short distance into the left outflow tract. Endocardial fibrosis involves the inner 1/3 to 1/2 of the ventricle wall. Mural thrombi in various stages of organization may be present. When the right ventricle is involved, the entire cavity may show endocardial thickening, which may extend to the epicardium. The fibrotic endocardium contains only a few elastic fibers. Myofibers trapped within the collagenous tissue display nonspecific degenerative changes.

Storage Diseases

Lysosomal storage diseases are detailed in Chapter 6. Only the cardiac manifestations are reviewed here.

GLYCOGEN STORAGE DISEASES: Of the various forms of glycogen storage disease, types II (Pompe disease), III (Cori disease) and IV (Andersen disease) affect the heart. Pompe disease is the most common and severe. Infants with this condition have markedly enlarged hearts (up to seven times normal), and 20% have endocardial fibroelastosis. Myocytes are vacuolated owing to large amounts of stored glycogen. These patients show a restrictive type of cardiomyopathy and usually die of cardiac failure.

MUCOPOLYSACCHARIDOSES: Several of the mucopolysaccharidoses involve the heart. Cardiac disease results from lysosomal accumulation of mucopolysaccharides (glycosaminoglycans) in various cells. In general, pseudohypertrophy of the ventricles develops and contractility gradually diminishes. The coronary arteries may be narrowed by intimal and medial thickening. In Hurler and Hunter syndromes, myocardial infarction is common. Valve leaflets may be thickened, thus causing progressive valvular dysfunction, manifested as aortic stenosis (Scheie syndrome) or mitral regurgitation (Hurler, Morquio syndromes). Cor pulmonale may result from pulmonary hypertension related to narrowing of the airways.

SPHINGOLIPIDOSES: In **Fabry disease,** glycosphingolipid accumulation in the heart may cause functional and pathologic changes like those in the mucopolysaccharidoses. Fabry disease produces gross and microscopic changes that mimic HCM, but the characteristic vacuolated appearance of cardiac myocytes is an important clue of an underlying storage disease. **Gaucher disease** only rarely involves the heart but may feature left ventricular interstitial infiltration by cerebroside-laden macrophages, impaired left ventricular compliance and cardiac output.

HEMOCHROMATOSIS: This multiorgan disease is associated with excessive iron deposition in many tissues (see Chapter 20). The degree of iron deposition in the heart varies and only roughly correlates with that in other organs. Cardiac involvement has features of both dilated and restrictive cardiomyopathy, with systolic and diastolic impairment. ***Congestive heart failure occurs in up to 1/3 of patients.***

At autopsy, the heart is dilated; ventricular walls are thickened. The myocardium reflects iron deposition in cardiac myocytes. Interstitial fibrosis is invariable, but its extent does not correlate well with the extent of iron accumulation. The severity of myocardial dysfunction seems to be proportional to the quantity of iron deposited.

Sarcoidosis

Sarcoidosis is a generalized granulomatous disease that may involve the heart (see Chapter 18). One quarter of cases show some granulomas in the heart at autopsy, but fewer than 5% of patients with this condition have cardiac symptoms. Sarcoid heart disease is seen clinically as a mixed pattern of dilated and restrictive cardiomyopathy. Sarcoid granulomas often cause extensive myocardial damage, preferentially involving the base of the interventricular septum. Because this region contains major components of the atrioventricular conduction system, bundle branch blocks or complete heart block is common. More serious life-threatening arrhythmias and sudden death are frequent. Microscopic examination of the heart in severe cases of sarcoid heart disease reveals infiltration of the myocardium by noncaseating granulomas, massive destruction of myocytes and replacement by interstitial fibrosis (Fig. 17-46).

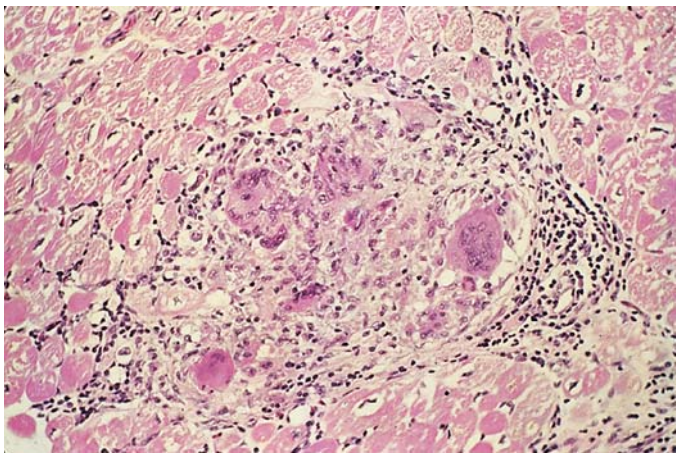

FIGURE 17-46. Cardiac sarcoidosis. The myocardium is infiltrated by noncaseating granulomas, with prominent giant cells. There is considerable destruction of cardiac myocytes with fibrosis.

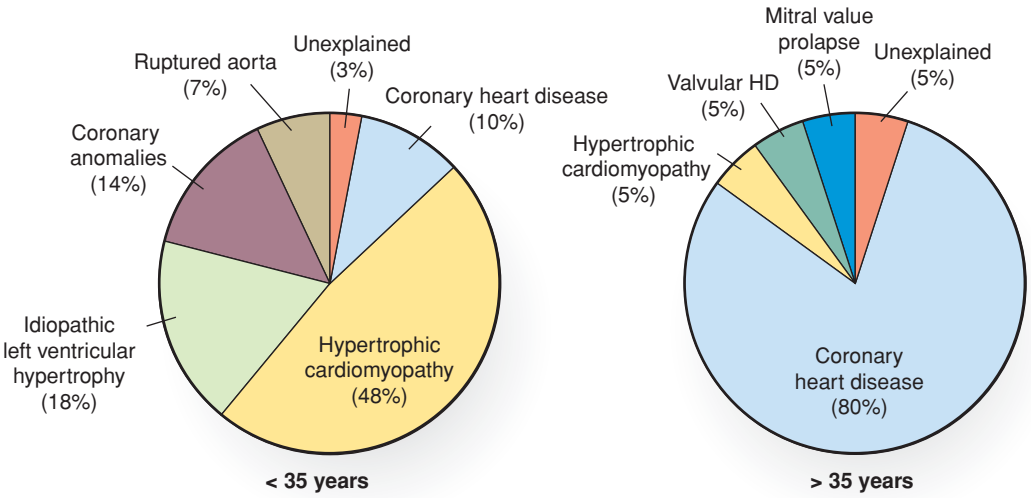

FIGURE 17-47. Different causes of sudden cardiac death in young and older adult competitive athletes. *HD* = heart disease.

SUDDEN CARDIAC DEATH

Over 300,000 people in the United States die suddenly each year. Most of these deaths are caused by spontaneous lethal ventricular tachyarrhythmias—ventricular tachycardia and ventricular fibrillation—in patients with some type of heart disease. Many sudden deaths occur out of the hospital in apparently healthy individuals who have coronary artery disease at autopsy but may have had little clinical evidence of it during life.

Common causes of sudden cardiac death differ in young and old individuals. This has been studied most thoroughly in competitive athletes (Fig. 17-47). In subjects younger than 35, HCM, idiopathic left ventricular hypertrophy (presumably reflecting genetic forms of heart muscle disease in at least some) and congenital coronary anomalies account for over 75% of sudden deaths. In Italy and other Mediterranean countries, arrhythmogenic cardiomyopathy is a leading cause of sudden death in young people. ***However, in economically developed nations, coronary artery disease is responsible for most sudden deaths in middle-aged and older adults.***

PATHOLOGY: The surface ECG may occasionally indicate a specific pathologic structure that can be implicated in causing sudden death, such as an accessory atrioventricular connection in Wolff-Parkinson-White syndrome or a lesion that disrupts a discrete component of the ventricular conduction system causing new bundle branch block. ***However, lethal arrhythmias usually arise from pathologic changes affecting conduction in the working ventricular myocardium.*** At autopsy, hearts of sudden death victims typically exhibit myocardial alterations that create "anatomic substrates of arrhythmias." These changes may be localized (e.g., healed myocardial infarcts or left ventricular aneurysms) or diffuse (e.g., variable degrees of cardiac myocyte hypertrophy and interstitial fibrosis). Spontaneous development of a lethal cardiac arrhythmia may be regarded as a stochastic event arising from complex interactions between relatively fixed anatomic substrates and acute, transient triggering events such as acute ischemia, neurohormonal activation, changes in electrolytes or other stresses. Many patients have potential arrhythmia substrates in their hearts. In most cases, they may be necessary but they are not sufficient for arrhythmogenesis. Arrhythmias are most likely when acute electrophysiologic changes (triggers) are superimposed on an existing substrate of remodeled myocardium with characteristic conduction abnormalities. Indeed, most often sudden death involves acute ischemia (a transient triggering event) in an area of the heart containing a healed infarct (a common anatomic substrate).

Sudden Cardiac Death Occurs in Patients with Structurally Normal Hearts, but This Is Rare

Some (perhaps many) of such patients have "channelopathies," genetic diseases in which mutations in genes for Na^+, K^+ and Ca^{2+} channel proteins are responsible for sudden death syndromes (see Chapter 1). Although these syndromes are rare, they have provided valuable insights into molecular mechanisms of lethal arrhythmias.

MOLECULAR PATHOGENESIS:
LONG QT SYNDROME: This condition is defined by prolonged QT intervals and T-wave abnormalities on the surface ECG and a history of syncope, ventricular arrhythmias or sudden, unexpected death. More than 10 different types of congenital long QT syndrome have been defined. Most are caused by loss-of-function mutations in genes encoding proteins that form various K^+ channels. The loss of function prolongs repolarization of the cardiac action potential (thus increasing QT intervals on surface ECGs) and promotes arrhythmias by increasing the likelihood of after-depolarizations. Long QT syndrome can also be caused by gain-of-function mutations in *SCN5A*, the gene encoding the cardiac Na^+ channel protein. These mutations prolong QT intervals by allowing leakage of depolarizing current during repolarization. Mutations in proteins responsible for ion channel trafficking or scaffolding, such as ankyrin B and caveolin-3, are also implicated in long QT syndrome. Arrhythmias occur in long QT syndrome because the mutated ion channels are normally distributed in the heart in a spatially heterogeneous fashion. The functional defect caused by the mutation creates ionic gradients that promote abnormal electrical impulse formation (after-depolarizations) and abnormal impulse conduction, conditions conducive to development of ventricular tachycardias.

BRUGADA SYNDROME: This is an autosomal dominant disease in a structurally normal heart with characteristic ST-segment elevation in right precordial leads, right bundle branch block and susceptibility to life-threatening arrhythmias. Loss-of-function mutations in *SCN5A* are identified in approximately 25% of cases.

CATECHOLAMINERGIC POLYMORPHIC VENTRICULAR TACHYCARDIA: In this condition, arrhythmias and sudden death occur in response to catecholamine surges associated with exercise or emotional stress. Mutations in genes encoding proteins that regulate intracellular Ca^{2+} homeostasis and excitation–contraction coupling, such as RyR2 and calsequestrin, are typical. These mutations promote leakage of Ca^{2+} from the SR and resultant arrhythmias triggered by after-depolarizations.

CARDIAC TUMORS

Primary cardiac tumors are rare, but can cause serious problems when they occur.

Myxomas Are the Most Common Primary Cardiac Tumors

These tumors account for 30%–50% of all primary cardiac tumors.

MOLECULAR PATHOGENESIS: Most cardiac myxomas are sporadic, but about 7% are part of a familial autosomal dominant syndrome that also includes pigmented lesions of the skin and adrenocortical hyperplasia. These cases have been linked to mutations in the gene encoding a regulatory subunit of cyclic adenosine monophosphate (cAMP)-dependent protein kinase (protein kinase A), which, among other actions, appears to be a tumor suppressor gene that controls cell proliferation.

PATHOLOGY: Myxomas can occur in any cardiac chamber or on a valve, but most (75%) arise in the left atrium. The tumors appear as glistening, gelatinous, polypoid masses, usually 5–6 cm, with a short stalk (Fig. 17-48), and may be sufficiently mobile to obstruct the mitral valve orifice. They show loose myxoid stroma containing abundant proteoglycans. Polygonal stellate cells are found within the matrix, singly or in small clusters.

CLINICAL FEATURES: More than half of patients with left atrial myxomas have clinical evidence of mitral valve dysfunction. The tumor does not metastasize in the usual sense, but it often embolizes. Some patients with myxomas of the left heart die from tumor emboli to the brain. Surgical tumor removal is usually curative.

Rhabdomyomas Are the Most Common Primary Childhood Cardiac Tumors

They form nodular myocardial masses. These lesions may really be hamartomas (see below) rather than true neoplasms, but the issue is still debated. Almost all are multiple and involve both ventricles and, in 1/3 of cases, the atria as well. In half of cases, the tumors project into a cardiac chamber and obstruct the lumen or valve orifices.

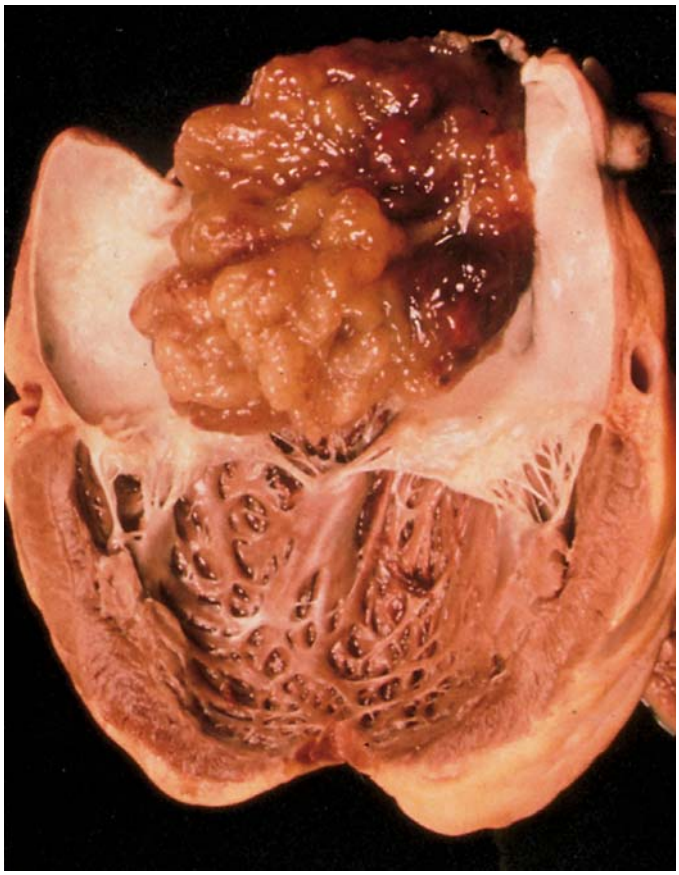

FIGURE 17-48. Cardiac myxoma. The left atrium contains a large, polypoid tumor that protrudes into the mitral valve orifice.

MOLECULAR PATHOGENESIS: Rhabdomyomas occur in 1/3 of patients with tuberous sclerosis, the familial form of which is caused by mutations in *TSC1* and *TSC2,* genes that encode hamartin and tuberin, respectively. Both genes are tumor suppressors (see Chapter 5) and regulate embryonic and neonatal growth and differentiation of cardiac myocytes.

PATHOLOGY: Cardiac rhabdomyomas are pale masses, 1 mm to several centimeters. Tumor cells show small central nuclei and abundant glycogen-rich clear cytoplasm, in which fibrillar processes containing sarcomeres radiate to the margin of the cell ("spider cell"). About 1/3 to 1/2 of these tumors occur in association with tuberous sclerosis. A few cardiac rhabdomyomas have been successfully excised.

Papillary Fibroelastoma Involves the Valves

Papillary fronds resembling a sea anemone and measuring up to 3–4 cm may grow on the heart valves. These are not neoplasms, and are more appropriately termed **hamartomas**. The fronds have central dense cores of collagen and elastic fibers surrounded by looser connective tissue. They are covered by a continuation of valvular endothelium on which the tumor originates. In most instances, papillary fibroelastomas are not clinical problems, but they can fragment and embolize to other organs or occlude a coronary artery orifice and produce myocardial ischemia.

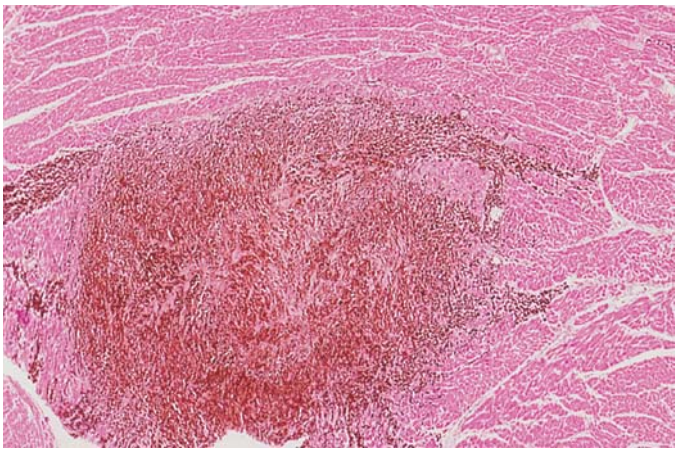

FIGURE 17-49. Malignant melanoma metastatic to the heart. The myocardium contains a heavily pigmented tumor metastasis.

Other Tumors in the Heart Are Rare

Other primary tumors of the heart include angiomas, fibromas, lymphangiomas, neurofibromas and their sarcomatous counterparts. Lipomatous hypertrophy of the interatrial septum and encapsulated lipomas have been reported.

Metastatic tumors to the heart are seen most often in patients with the most common carcinomas—that is, lung, breast and gastrointestinal tract. Still, only a minority of patients with these tumors develop cardiac metastases. Lymphomas and leukemia also may involve the heart. Of all tumors, the one most likely to metastasize to the heart is malignant melanoma (Fig. 17-49). Metastatic cancer involving the myocardium can result in clinical manifestations of restrictive cardiomyopathy, particularly if the cardiac tumors are associated with extensive fibrosis. Occasionally, metastatic tumors may disrupt components of the atrioventricular conduction system, giving rise to heart block or bundle branch block patterns on the surface electrocardiogram.

DISEASES OF THE PERICARDIUM

Pericardial Effusions Can Cause Cardiac Tamponade

Pericardial effusions are accumulations of excess fluid within the pericardial cavity, as either a transudate or an exudate. The pericardial sac normally contains no more than 50 mL of lubricating fluid. If the pericardium is slowly distended, it can accommodate up to 2 L of fluid without notable hemodynamic consequences. However, rapid accumulation of as little as 150–200 mL of pericardial fluid or blood may significantly increase intrapericardial pressure and restrict diastolic filling, especially of the right atrium and ventricle.

- **Serous pericardial effusion** often complicates an increase in extracellular fluid volume, as occurs in congestive heart failure or nephrotic syndrome. The fluid has a low protein content and few cellular elements.
- **Chylous effusion** (fluid containing chylomicrons) results from a communication of the thoracic duct with the pericardial space due to lymphatic obstruction by tumor or infection.

FIGURE 17-50. Hemopericardium. The parietal pericardium has been opened to reveal the pericardial cavity distended with fresh blood. The patient sustained a rupture of a myocardial infarct.

- **Serosanguineous pericardial effusion** may develop after chest trauma, either accidentally or after cardiopulmonary resuscitation.
- **Hemopericardium** is bleeding directly into the pericardial cavity (Fig. 17-50). The most common cause is ventricular free wall rupture at a myocardial infarct. Less frequent causes are penetrating cardiac trauma, rupture of a dissecting aneurysm of the aorta, infiltration of a vessel by tumor or a bleeding diathesis.

Cardiac tamponade ***is the syndrome caused by rapid accumulation of pericardial fluid, restricting the filling of the heart.*** Hemodynamic consequences range from a minimally symptomatic condition to abrupt cardiovascular collapse and death. As pericardial pressure increases, it reaches and then exceeds central venous pressure, thus limiting blood return to the heart. Cardiac output and blood pressure decrease, and **pulsus paradoxus** (an abnormal decrease in systolic pressure with inspiration) occurs in almost all patients. Acute cardiac tamponade is almost always fatal unless the pressure is relieved by removing pericardial fluid, via needle pericardiocentesis or surgery.

Acute Pericarditis May Follow Viral Infections

Pericarditis is inflammation of the visceral or parietal pericardium.

ETIOLOGIC FACTORS: The causes of pericarditis are similar to those for myocarditis (Table 17-7). In most cases, the cause of acute pericarditis is obscure and (as in myocarditis) is attributed to undiagnosed

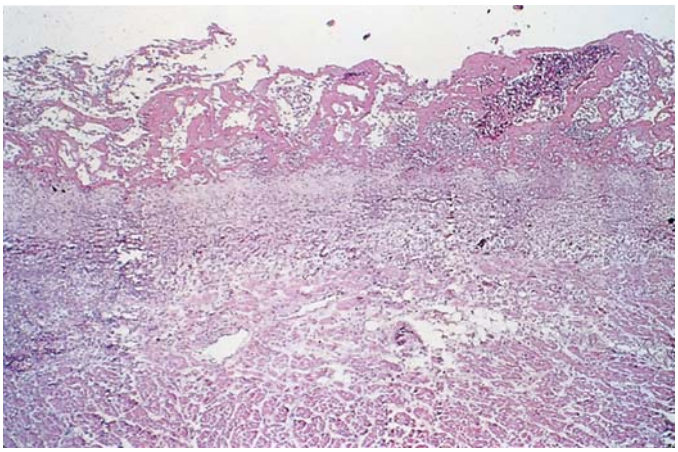

FIGURE 17-51. Fibrinous pericardial exudate. The epicardial surface is edematous, inflamed and covered with tentacles of fibrin.

viral infection. Bacterial pericarditis is unusual in the antibiotic era. Metastatic tumors may induce serofibrinous or hemorrhagic exudative and inflammatory reactions when they involve the pericardium. The most common tumors to involve the pericardium and cause malignant pericardial effusions are breast and lung carcinomas. Pericarditis associated with myocardial infarction and rheumatic fever is discussed above.

PATHOLOGY: Acute pericarditis can be **fibrinous, purulent** or **hemorrhagic,** depending on gross and microscopic characteristics of the pericardial surfaces and fluid. The most common form is fibrinous pericarditis, in which the normal smooth, glistening pericardial surfaces are replaced by a dull, granular fibrin-rich exudate (Fig. 17-51). The rough texture of inflamed pericardial surfaces produces a characteristic friction rub on auscultation. Effusion fluid in fibrinous pericarditis is usually rich in protein, and the pericardium contains mainly mononuclear inflammatory cells. Uremia can cause fibrinous pericarditis (Fig. 17-52), but with the widespread availability of renal dialysis, uremic pericarditis is now unusual in the United States. The most common causes are viral infection and pericarditis after myocardial infarcts.

Bacterial infection leads to a purulent pericarditis, in which the pericardial exudate resembles pus and is full of neutrophils. Bleeding into the pericardial space caused by aggressive infectious or neoplastic processes or coagulation defects leads to hemorrhagic pericarditis.

CLINICAL FEATURES: Initial manifestations of acute pericarditis are sudden, severe, substernal chest pain, sometimes referred to the back, shoulder or neck. These differ from the pain of angina pectoris or myocardial infarction by their failure to radiate down the left arm. A characteristic pericardial friction rub is easily heard. Electrocardiographic changes reflect repolarization abnormalities of the myocardium.

Idiopathic or viral pericarditis is a self-limited disorder, but it may infrequently lead to constrictive pericarditis. Corticosteroids are the treatment of choice. Therapy for other specific forms of acute pericarditis varies with the cause.

FIGURE 17-52. Fibrinous pericarditis. The heart of a patient who died in uremia displays a shaggy, fibrinous exudate covering the visceral pericardium.

Constrictive Pericarditis May Mimic Right Heart Failure

Constrictive pericarditis is a chronic fibrosing disease of the pericardium that compresses the heart and restricts inflow.

ETIOLOGIC FACTORS AND PATHOLOGY: Constrictive pericarditis is not an active inflammatory condition. Rather, it reflects exuberant healing after acute pericardial injury. The pericardial space becomes obliterated, and visceral and parietal layers become fused in a dense, rigid mass of fibrous tissue. The scarred pericardium may be so thick (up to 3 cm) that it narrows the orifices of the venae cavae (Fig. 17-53). The fibrous envelope may contain calcium. The condition is uncommon today and, in developed countries, is predominantly idiopathic. Prior radiation therapy to the mediastinum and cardiac surgery account for more than 1/3 of cases. In others, it follows a purulent or tuberculous infection. Tuberculosis today accounts for fewer than 15% of cases of constrictive pericarditis in industrialized countries, but it is still the major cause in underdeveloped regions.

CLINICAL FEATURES: Patients with constrictive pericarditis have small, quiet hearts in which venous inflow is restricted, as the rigid pericardium limits the diastolic volume of the heart. These patients have high venous pressure, low cardiac output, small pulse pressure and fluid retention with ascites and peripheral edema. Total pericardiectomy is the treatment of choice.

Adhesive pericarditis is a much milder form of healing of an inflamed pericardium. Commonly seen as an incidental

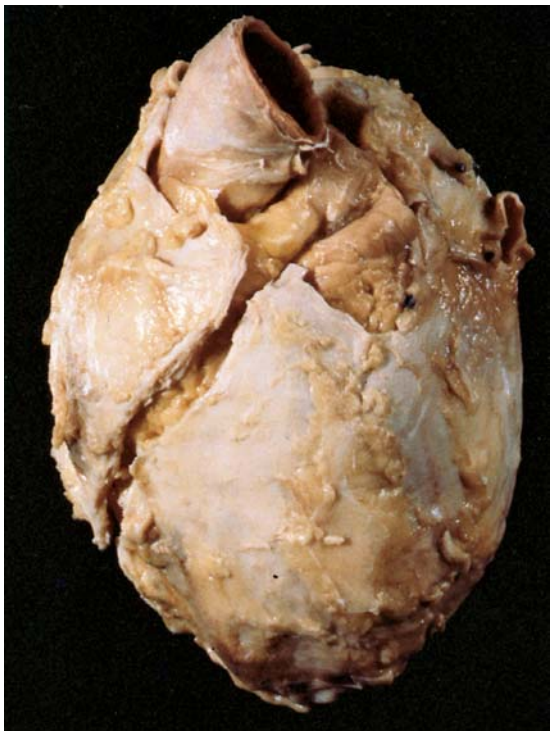

FIGURE 17-53. Constrictive pericarditis. The pericardial space has been obliterated, and the heart is encased in a fibrotic, thickened pericardium.

finding at autopsy, it is the outcome of many different types of pericarditis that have healed and left only minor fibrous adhesions between the visceral and parietal surfaces.

PATHOLOGY OF INTERVENTIONAL THERAPIES

Percutaneous Coronary Interventions Are Used to Treat Atherosclerotic Coronary Arterial Disease

PCI is used to mechanically dilate an artery narrowed by atherosclerosis and keep the lumen open. A catheter with a deflated balloon covered by a collapsed cylindrical metallic mesh **(stent)** is positioned in the stenotic segment. Inflating the balloon fractures the plaque and stretches the vessel wall. As the stent deploys, it holds the fragmented wall open and keeps the vessel lumen patent. Acute complications of PCI such as coronary artery dissection, acute thrombotic occlusion and perforation are uncommon. Most patients receive drug-eluting stents, which slowly release antiproliferative agents such as everolimus or paclitaxel. Their use has dramatically reduced the incidence of restenosis.

Coronary Bypass Grafts Circumvent Obstructed Segments

Coronary bypass grafting, using a saphenous vein or left internal mammary artery to redirect blood around a blockage, is common treatment for proximal coronary stenosis. Although operative mortality is low and early symptomatic relief occurs in most patients, myocardial perfusion is not permanently improved, owing to several complications: (1) early thrombosis, (2) intimal hyperplasia and (3) atherosclerosis of vein grafts. Moreover, progressive atherosclerosis of the native coronary arteries is not affected by the grafting procedure.

Internal mammary artery grafts develop fewer pathologic changes and so last longer than vein grafts. Excised saphenous vein segments used as grafts are subjected to unavoidable surgical manipulation and an interval of ischemia during harvesting, which injures endothelial cells. Grafted veins are also exposed to arterial pressures that are much higher than those in their native location. Finally, the caliber of the vein, which is expanded by arterial blood pressure, is usually much greater than that of the distal coronary artery at the graft anastomosis, and this mismatch promotes blood stasis. In the immediate postoperative period, these factors enhance the chance of thrombosis and probably eventually lead to intimal hyperplasia. Intimal hyperplasia is a concentric increase of smooth muscle cells, fibroblasts and collagen in the intima of the vein. After several years, lipids may deposit and atherosclerotic plaques may form in the thickened intima of vein grafts. Atherosclerosis is the most frequent cause of vein graft failure in patients who have had good graft function for several years after surgery.

Since arteries are better aortocoronary bypass conduits than veins, some surgeons have developed total arterial bypass procedures that use internal mammary, radial and selected abdominal arteries that can be taken without end-organ damage.

Tissue Xenografts and Mechanical Valves Typically Are Used to Replace Damaged Cardiac Valves

In most patients with severe valve dysfunction, valve replacement is the best prospect for long-term symptomatic improvement. Operative mortality is low, especially for patients with good preoperative myocardial function. Half of all patients with prosthetic valves are free of complications after 10 years.

TISSUE VALVES: The most commonly used tissue-valve prostheses use a mechanical frame to which glutaraldehyde-fixed porcine aortic valve cusps or pieces of bovine pericardium are attached. These valves have good hemodynamic characteristics, cause little obstruction and resist thromboembolic complications. Unfortunately, they are not very durable. The most common cause of failure of tissue-valve prostheses is tissue degeneration with calcification and fragmentation of prosthetic valve cusps. This developed within 5 years of implantation in virtually all early-generation porcine aortic valves and led to valve failure in 20%–30% of patients within 10 years. Improved understanding of prosthetic tissue-valve calcification has led to development of anticalcification treatments that improve valve longevity and performance. Tissue-valve calcification occurs mainly within residual cells killed by glutaraldehyde treatment. Strategies to prevent or delay such calcification include removal of residual cells, binding of calcification inhibitors to the glutaraldehyde-fixed tissue and use of other tissue cross-linking and preservation reagents.

MECHANICAL VALVES: The most widely used mechanical prostheses involve single or bileaflet tilting disk designs that do not obstruct blood flow across the valve and have excellent durability. However, the risk of thromboembolism makes long-term anticoagulant therapy imperative.

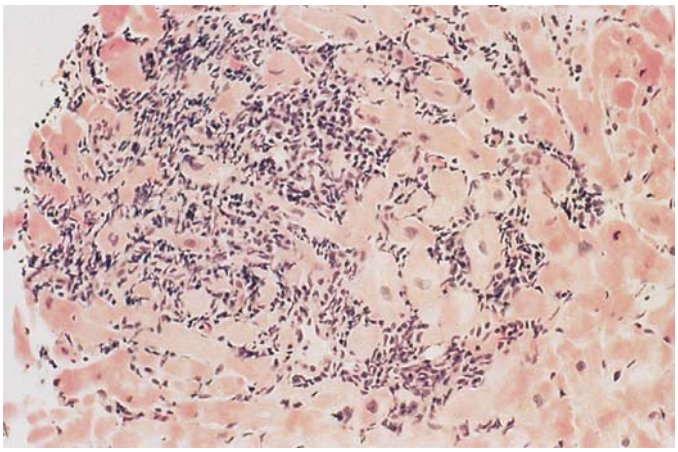

FIGURE 17-54. Cardiac transplant rejection. An endomyocardial biopsy shows lymphocytes surrounding individual myocytes and expanding the interstitium.

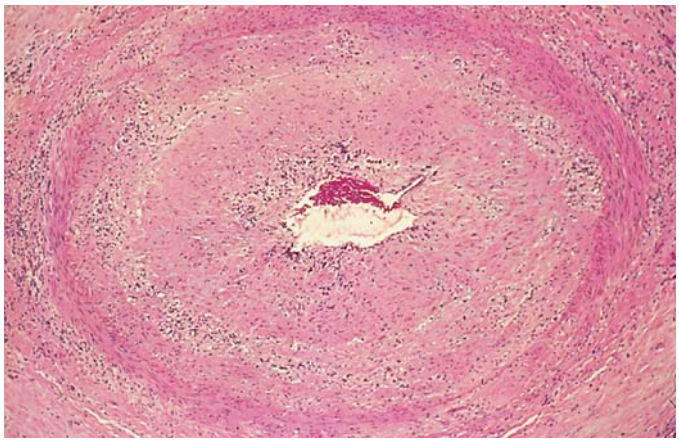

FIGURE 17-55. Chronic cardiac transplant rejection. An intramyocardial branch of a coronary artery shows prominent intimal proliferation and inflammation with concentric narrowing of the lumen.

Cancer Survivors May Experience Long-Term Cardiovascular Complications

As more patients survive cancer chemotherapy and/or radiation therapy, increased rates of cardiovascular disease attributable to their therapy are becoming recognized. Exposing the heart to radiation increases the rate of ischemic heart disease. Each gray of radiation (see Chapter 8) is associated with an estimated 7.4% increase in risk of a major coronary event, which apparently persists for at least two decades after the radiation ends. Radiation also contributes to pericardial disease, cardiomyopathy and valvular dysfunction. Breast cancer patients treated with drugs that target HER2/neu experience greater risk of both coronary events and ventricular dysfunction.

Heart Transplantation May Cure Many End-Stage Heart Diseases but Is Subject to Host Rejection Processes

The development of effective immunosuppressive regimens and surveillance endomyocardial biopsy protocols has made cardiac transplantation an effective treatment for end-stage heart disease. Allograft rejection (see Chapter 4), however, is a major complication of cardiac transplantation.

Hyperacute rejection occurs if there are blood-group incompatibility or major histocompatibility differences. In these situations, preformed antibodies cause immediate vascular injury to the donor heart, with diffuse hemorrhage, edema, intracapillary platelet–fibrin thrombi, vascular necrosis and infiltration of neutrophils. Screening for blood-group incompatibility has rendered this complication rare.

Acute humoral rejection is characterized by vascular deposition of antibody and complement, endothelial cell swelling and edema. This unusual form of rejection has a worse prognosis than acute cellular rejection.

Acute cellular rejection, the most common form of allograft rejection, usually occurs in the first few months after transplantation. It begins as perivascular T-cell infiltration, which is focal and is not associated with acute myocyte necrosis. This reaction often resolves spontaneously and, therefore, does not necessitate a change in the immunosuppressive regimen. Moderate cellular rejection is characterized by T-cell infiltration into adjacent interstitial spaces, where lymphocytes surround individual myocytes and expand the interstitium (Fig. 17-54). In this instance, focal acute myocyte necrosis is also present. Moderate cellular rejection usually does not produce detectable functional impairment and tends to resolve within a few days to a week after treatment. However, additional immunosuppressive therapy is instituted because moderate cellular rejection can progress to severe rejection. The latter is characterized by vascular damage, widespread myocyte necrosis, neutrophil infiltration, interstitial hemorrhage and functional impairment, which is difficult to reverse.

The early stage of cellular allograft rejection is often asymptomatic. Once symptoms develop, rejection is usually advanced and has caused irrecoverable loss of cardiac myocytes. The most reliable screening procedure is endomyocardial biopsy of the right side of the interventricular septum, via cardiac catheterization.

Chronic vascular rejection, also referred to as **accelerated coronary artery disease,** is the most common cause of death in heart transplant patients beyond the first year after transplantation. It affects proximal and distal epicardial coronary arteries, the penetrating coronary artery branches and even arterioles. Accelerated coronary artery disease is characterized by concentric intimal proliferation (Fig. 17-55), which can lead to coronary occlusion and myocardial infarction. This complication is silent because the transplanted heart is denervated. Thus, extensive myocardial damage can develop before a transplant patient is aware that ischemic injury has occurred.

The Normal Respiratory System

EMBRYOLOGY

The respiratory system includes the larynx, trachea, bronchi, bronchioles and alveoli. During the fourth week of gestation, the laryngotracheal groove develops as a ventral outpouching of the foregut.

1. **Embryonic period:** Between 4 and 6 weeks' gestation, the tracheobronchial bud divides to form proximal airways to the level of segmental bronchi.
2. **Pseudoglandular period:** From 6 to 16 weeks' gestation, the distal airways are formed to the level of the terminal bronchioles.

3. **Acinar or canalicular development:** During weeks 17–28, (a) the framework of the gas-exchanging unit of the lung develops, (b) acini are formed, (c) the vascular system develops, (d) capillaries reach the epithelium and (e) gas exchange can occur. At this point extrauterine life becomes possible.
4. **Saccular period:** At 28–34 weeks of gestation, primary saccules become subdivided by secondary crests, resulting in greater complexity of the gas-exchanging surface and thinning of airspace walls.
5. **Alveolar period:** The last step is alveolar development during weeks 34–36. At birth, the number of alveoli is highly variable, ranging from 20 to 150 million. Most alveoli develop in the first 2 years of life.

ANATOMY

TRACHEA AND BRONCHI: The trachea is a hollow tube up to 25 cm in length and 2.5 cm in diameter. The right bronchus diverges at a lesser angle from the trachea than does the left, which is why foreign material is more frequently aspirated on the right side. On entering the lung, the main bronchi divide into lobar bronchi, then into segmental bronchi, which supply the 19 lung segments. Since segments are individual units with their own bronchovascular supply, they can be resected individually.

The tracheobronchial tree contains cartilage and submucosal mucous glands in the wall (Fig. 18-1). The latter are compound tubular glands, which contain **mucous cells** (pale) and **serous cells** (granular, more basophilic). The pseudostratified epithelium appears as layers, but all cells reach the basement membrane. Most cells are ciliated, but there are also mucus-secreting **(goblet)** cells and basal cells. The **basal cells,** which do not reach the surface, are precursors that differentiate into more specialized tracheobronchial epithelial cells. There are also nonciliated columnar cells, or **club cells** (formerly **Clara cells**), which accumulate and detoxify many inhaled toxic agents (e.g., nitrogen dioxide [NO_2]). **Neuroendocrine cells** are scattered in the tracheobronchial mucosa and contain a variety of hormonally active polypeptides and vasoactive amines.

BRONCHIOLES: Distal to the bronchi are the bronchioles, which differ from bronchi in that they lack cartilage and mucus-secreting glands (Fig. 18-1). Bronchiolar epithelium becomes thinner with progressive branching, until only one cell layer is present. The last purely conducting structure free of alveoli is the **terminal bronchiole,** which exhibits pseudostratified ciliated respiratory epithelium and a smooth muscle wall. Mucous cells gradually disappear from the lining of the bronchioles until they are entirely replaced in the small bronchioles by nonciliated, columnar club cells (formerly Clara cells). Terminal bronchioles divide into **respiratory bronchioles,** which merge into **alveolar ducts** and **alveoli**. The gas exchange units of the lung are called **acini** and consist of respiratory bronchioles, alveolar ducts and alveoli.

ALVEOLI: Alveoli are lined by two types of epithelium (Fig. 18-1). **Type I cells** cover 95% of the alveolar surface but constitute only 40% of alveolar epithelial cells. They are thin and have a large surface area, a combination that facilitates gas exchange. **Type II cells** produce surfactant and make up 60% of the alveolar lining cells. As they are more cuboidal than type I cells, they cover only 5% of the alveolar surface. Type I cells are highly vulnerable to injury. When they are lost, type II pneumocytes multiply and differentiate to form new type I cells, restoring the integrity of the alveolar surface.

Alveolar epithelial and endothelial cells are ideally arranged for gas exchange. The cytoplasm of epithelial and endothelial cells is spread very thinly on either side of a fused basement membrane, allowing efficient exchange of oxygen and carbon dioxide. An extensive capillary network supplies 85%–95% of the alveolar surface. Away from the site of gas exchange, interstitial connective tissue is more abundant, consisting of collagen, elastin and proteoglycans. Fibroblasts and myofibroblasts may also be present. This expanded region forms the interstitial space of the alveolar wall, where significant fluid and molecular exchange occurs.

PULMONARY VASCULATURE: The lung has a **dual blood supply** from the pulmonary and the bronchial systems. Pulmonary arteries accompany airways in a sheath of connective tissue, the **bronchovascular bundle**. The more proximal arteries are elastic and are succeeded by muscular arteries, pulmonary arterioles and eventually pulmonary capillaries.

The smallest veins, which resemble the smallest arteries, join other veins and drain into lobular septa, connective tissue partitions that subdivide the lung into small respiratory units. In these septa, the veins form a network separate from the bronchovascular bundles.

Bronchial arteries arise from the thoracic aorta and nourish the bronchial tree as far as the respiratory bronchioles. These arteries are accompanied by their respective veins, which drain into the azygous or hemiazygous veins.

There are no lymphatics in most alveolar walls**.** These vessels begin in alveoli at the periphery of acini, which lie along lobular septa, bronchovascular bundles or the pleura. The lymphatics of the lobular septa and bronchovascular bundle accompany these structures, and the pleural lymphatics drain toward the hilus through the bronchovascular lymphatics.

DEFENSE MECHANISMS

The respiratory system has effective defense mechanisms to cope with the numerous particulates and infectious agents inhaled on inspiration.

The **nose and trachea** warm and humidify air entering the lung. The nose traps almost all particles over 10 µm in diameter and about half of all particles of 3 µm aerodynamic diameter (Fig. 18-2, see also Chapter 8). (Aerodynamic diameter refers to the way particles behave in air rather than to their actual size.)

The **mucociliary blanket** of the airway epithelium disposes of particles 2–10 µm in diameter. The ciliary beat drives the mucous blanket toward the trachea. Particles that land on it are thus removed from the lungs and swallowed or coughed up.

Alveolar macrophages protect the alveolar space. These cells are derived from the bone marrow, probably undergo a maturation division in the interstitium of the lung and then enter the alveolar space. They are particularly effective in dealing with particles with aerodynamic diameters under 2 µm. Very small particles are not phagocytosed and are exhaled.

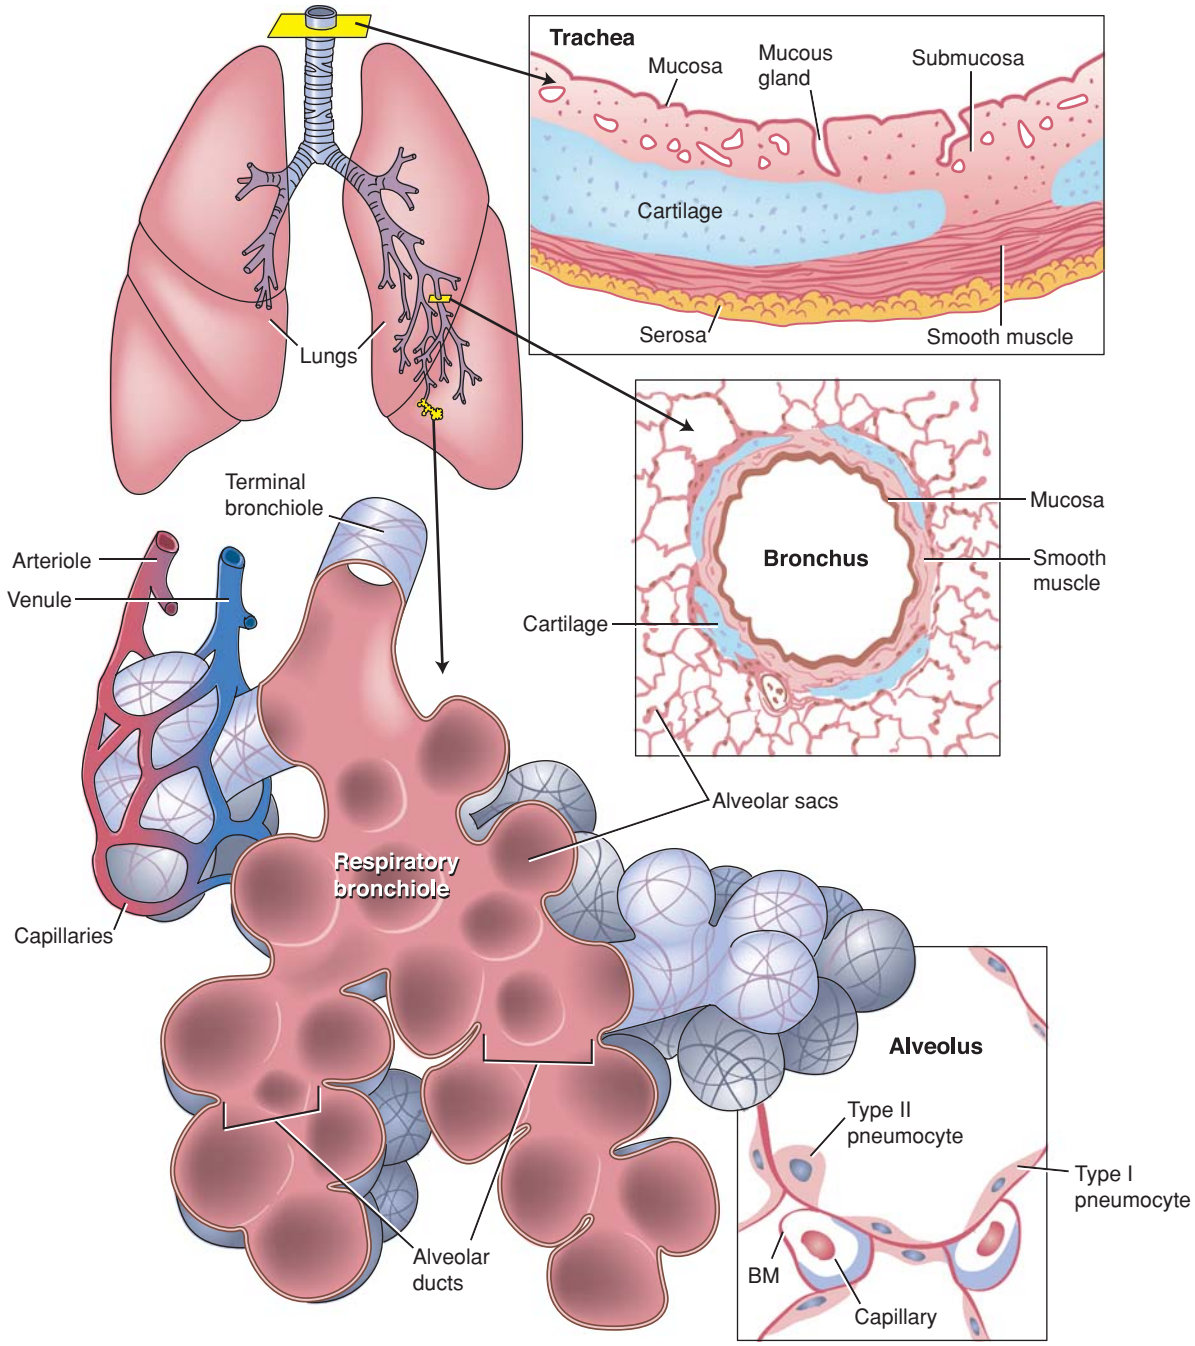

FIGURE 18-1. Anatomy of the lung. The conducting structures of the lung include (1) the trachea, which has horseshoe-shaped cartilages; (2) the bronchi, which have plates of cartilage in their walls (both the trachea and bronchi have mucus-secreting glands in their walls); and (3) the bronchioles, which do not have cartilage in their walls and terminate in the terminal bronchioles. The gas-exchanging components compose the unit distal to the terminal bronchiole, namely, the acinus. Alveoli are lined by type I cells, which are large, flat cells that cover most of the alveolar wall, and by type II cells, which secrete surfactant and are the progenitor cells of the alveolar epithelium. Gas exchange occurs at the level of the alveolar wall.

The Lungs

CONGENITAL ANOMALIES

BRONCHIAL ATRESIA: This abnormality most often involves the bronchus to the apical posterior segment of the left upper lobe. In infants, the lesion may result in an overexpanded part of the lung. In later life, the overexpanded lobe may also be emphysematous. Bronchial mucus accumulating distal to the atretic region may appear on radiologic examination as a mass.

PULMONARY HYPOPLASIA: This condition reflects incomplete or defective lung development. The lung is smaller than normal, with fewer and smaller acini. This is the most common congenital lesion of the lung, found in 10% of

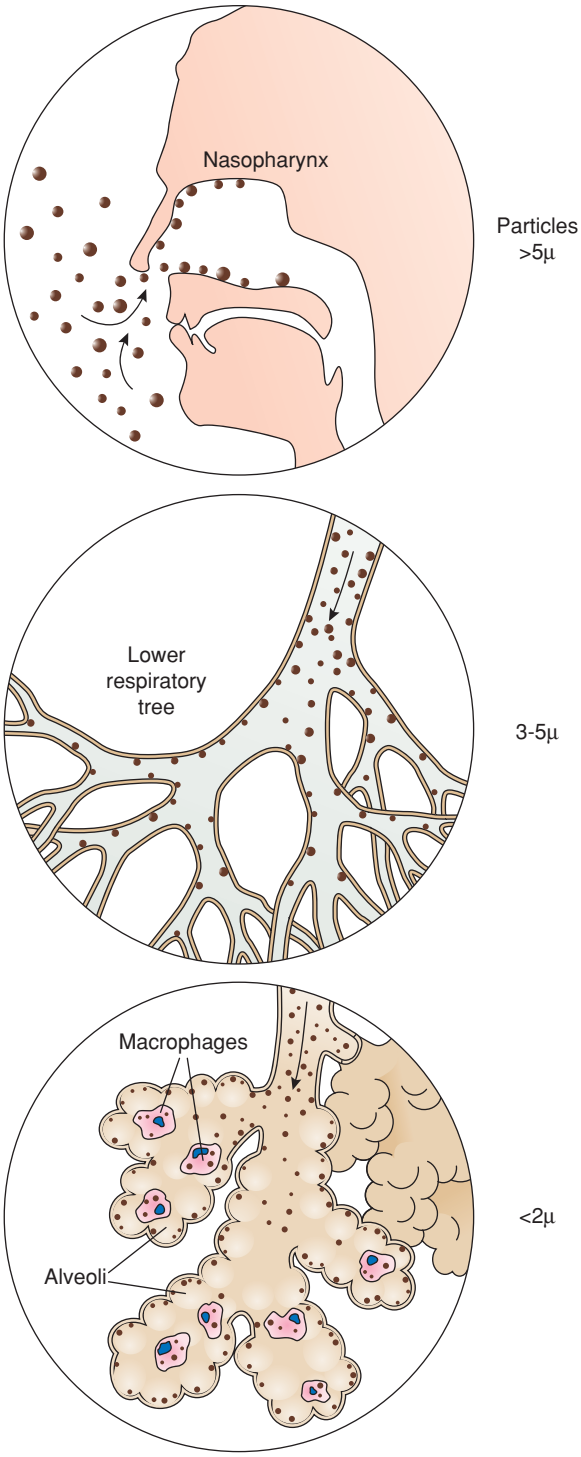

FIGURE 18-2. Deposition of particles in the respiratory tract. Large particles are trapped in the nose. Intermediate-sized particles deposit on the bronchi and bronchioles and are removed by the mucociliary blanket. Smaller particles terminate in the airspaces and are removed by macrophages. Very small particles behave as a gas and are breathed out.

neonatal autopsies. In most cases (90%), it occurs in association with other congenital anomalies, most of which involve the thorax. The lesion may be accompanied by hypoplasia of bronchi and pulmonary vessels if the insult occurs early in gestation, as in congenital diaphragmatic hernia. Pulmonary hypoplasia also is seen in trisomies 13, 18 and 21.

ETIOLOGIC FACTORS: Three major factors may lead to pulmonary hypoplasia:

- **Congenital diaphragmatic hernia** typically occurs on the left side, because the pleuroperitoneal canal fails to close. Abdominal viscera are variably present in the affected hemithorax and result in compression of the lung. The degree of hypoplasia is thus variable. At one extreme, the lung on the affected side is reduced to a small nubbin of tissue and the lung on the opposite side is severely hypoplastic. At the other extreme, hypoplasia is so slight that the infant has no symptoms and the abnormalities are found incidentally on a routine chest radiograph. Other causes of hypoplasia include abnormalities of the chest wall, pleural effusions and ascites, as in hydrops fetalis. Abnormal development of the pulmonary vasculature often leads to persistent pulmonary hypertension.
- **Oligohydramnios** (low amniotic fluid volume) is usually due to genitourinary anomalies and is an important cause of pulmonary hypoplasia (see Chapter 6).
- **Decreased respiration** has been shown experimentally to produce hypoplastic lungs, probably due to lack of repetitive stretching of the lung.

CONGENITAL CYSTIC ADENOMATOID MALFORMATION (CONGENITAL PULMONARY ADENOMATOID MALFORMATION): This common anomaly consists of abnormal bronchiolar structures of varying sizes or distribution. Most cases are seen in the first 2 years of life. The lesion usually affects one lobe of the lung and consists of multiple cyst-like spaces lined by bronchiolar epithelium and separated by loose fibrous tissue (Fig. 18-3). Some patients will have other congenital anomalies. The most common presenting symptoms are respiratory distress and cyanosis. Surgical resection is the treatment of choice.

BRONCHOGENIC CYSTS: These are discrete, extrapulmonary, fluid-filled masses lined by respiratory epithelium and limited by walls that contain muscle and cartilage. They are most commonly found in the middle mediastinum. In newborns, a bronchogenic cyst may compress a major airway and cause respiratory distress. Later in life, secondary infections of cysts may lead to hemorrhage and perforation. Many bronchogenic cysts are asymptomatic and are found on routine chest radiographs.

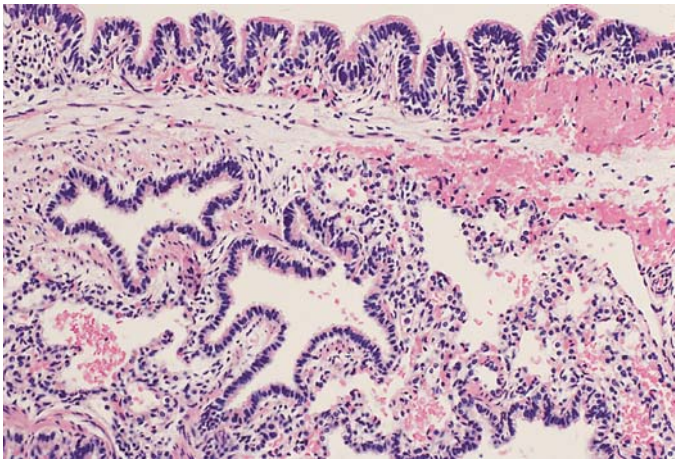

FIGURE 18-3. Congenital cystic adenomatoid malformation. Multiple gland-like spaces are lined by bronchiolar epithelium.

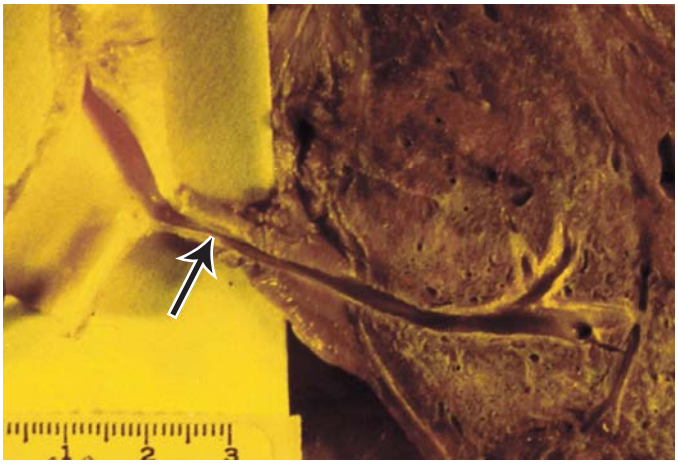

FIGURE 18-4. Extralobar sequestration. The sequestered pulmonary tissue is situated outside the lung parenchyma. It is supplied by an aberrant artery (*arrow*) from the aorta and is not connected to the bronchial tree.

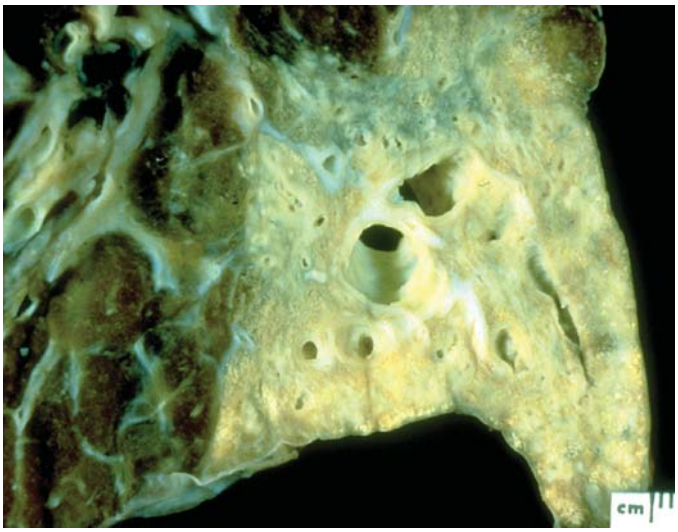

FIGURE 18-5. Intralobar sequestration. The sequestered tissue lies within the visceral pleura and exhibits cystic change and dense fibrosis. An aberrant arterial supply to this lesion was identified (not shown).

EXTRALOBAR SEQUESTRATION: Extralobar sequestration is a mass of lung tissue that is not connected to the bronchial tree and is located outside the visceral pleura. An abnormal artery, usually arising from the aorta, supplies the sequestered tissue (Fig. 18-4).

ETIOLOGIC FACTORS: This lesion is thought to originate from an outpouching of the foregut, distinct from the pulmonary anlage, but later loses its connection to the original foregut. It occurs three to four times more often in males than in females and is associated with other anomalies in two thirds of patients.

PATHOLOGY: Extralobar sequestrations are 1–15-cm pyramidal or round masses, covered by pleura. Microscopically, dilated bronchioles, alveolar ducts and alveoli are noted. Infection or infarction may alter the histologic appearance.

CLINICAL FEATURES: In half of cases, extralobar sequestration is detected before 1 month of age, and is recognized by 2 years of age in 75% of patients. The condition is often associated with congenital cystic adenomatoid malformation. In the neonatal period, extralobar sequestration may cause dyspnea and cyanosis, often in the first day of life. In older children, recurrent bronchopulmonary infections may bring it to medical attention. Surgical excision is curative.

INTRALOBAR SEQUESTRATION: Intralobar sequestrations are masses of lung tissue in the visceral pleura, isolated from the tracheobronchial tree and supplied by a systemic artery (Fig. 18-5). These are felt to be acquired abnormalities.

PATHOLOGY: Intralobar sequestrations are almost always found in a lower lobe. Bilateral involvement is distinctly unusual. On gross examination, the sequestered tissue shows the result of chronic recurrent pneumonia, with end-stage fibrosis and honeycomb cystic changes. These cysts range up to 5 cm in diameter and lie in a dense fibrous stroma. Microscopically, the cystic spaces are mostly lined by cuboidal or columnar epithelium and the lumen contains foamy macrophages and eosinophilic material. Interstitial chronic inflammation and follicular lymphoid hyperplasia are often prominent. Acute and organizing pneumonia may be seen.

CLINICAL FEATURES: Cough, sputum production and recurrent pneumonia are seen in almost all patients. Most cases are discovered in adolescents or young adults. Only one fourth of patients are in the first decade of life, and the lesion is rarely identified in infants. Surgical resection is often indicated.

DISEASES OF THE BRONCHI AND BRONCHIOLES

Most bronchial and bronchiolar diseases are acute conditions and their sequelae. Chronic bronchitis is discussed later.

Airway Infections Are Caused by Diverse Organisms

Here, we distinguish between airway and parenchyma infections for convenience and for reasons of classification, but this division should not be thought of as rigid. Causative agents are discussed in Chapter 9.

Many infectious agents that involve the intrapulmonary airways tend to affect the more peripheral airways **(bronchiolitis),** for example, adenovirus, respiratory syncytial virus (RSV) and measles. All are more serious in malnourished children and in populations not ordinarily exposed to these agents. Severe symptomatic infections occur more often in infants and children, and recovery is the rule. Symptoms include cough, a feeling of tightness in the chest and, in extreme cases, shortness of breath and even cyanosis.

INFLUENZA: This is a characteristic example of tracheobronchitis, and in the occasional patient who dies with this infection, the appearance of the bronchi is dramatic. The surface of the airway is fiery red, reflecting acute inflammation and congestion of the mucosa.

ADENOVIRUS: Infection with adenovirus causes the most serious sequelae, with extensive bronchiolitis (Fig. 18-6) and then healing by fibrosis. Bronchioles may become

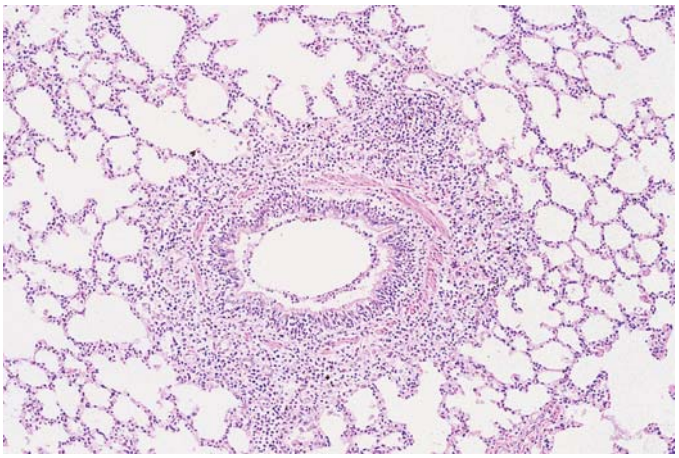

FIGURE 18-6. Bronchiolitis due to adenovirus. The wall of this bronchiole shows an intense chronic inflammatory infiltrate with local extension into the surrounding peribronchial tissue.

obliterated or occluded by loose fibrous tissue **(obliterative bronchiolitis)**.

RESPIRATORY SYNCYTIAL VIRUS (RSV): RSV infection often occurs in epidemics in nurseries. It is usually self-limited, but rare fatal cases do occur. It can cause nosocomial infection in children and (rarely) in adults. Histologically, peribronchiolar inflammation and disorganization of the epithelium are evident. Severe overdistention may be found without obvious bronchiolar obstruction, possibly due to displacement of surfactant from the bronchiolar surface.

MEASLES: At one time a major cause of bronchiolitis, measles is rarely a problem in developed countries since the advent of the measles vaccine. However, measles-induced bronchiolitis remains a serious problem particularly in populations seldom exposed to the virus. Similar to adenovirus, it may cause bronchiolar obliteration and bronchiectasis.

BORDETELLA PERTUSSIS: This bacterium commonly infects the airways and is the cause of whooping cough. With widespread use of a pertussis vaccine, the disease became rare in the United States. Unfortunately, vaccination is no longer compulsory in England, and the incidence of pertussis is rising. Clinically, whooping cough is typified by fever and severe prolonged bouts of coughing, followed by a characteristic deep whooping inspiration. Severe bronchial and bronchiolar inflammation are found in fatal cases. Before immunization was available, whooping cough commonly led to the development of bronchiectasis.

HAEMOPHILUS INFLUENZAE AND STREPTOCOCCUS PNEUMONIAE: In addition to causing pneumonia, these organisms have been implicated in exacerbations of chronic bronchitis. Such episodes contribute to the morbidity of chronic bronchitis and are treated with antibiotics.

CANDIDA ALBICANS: This fungus is a normal commensal organism in the oral cavity, gut and vagina and is best known for infections in those regions. It may also affect the lungs, usually as a noninvasive growth on airway surface epithelium, where it may produce mucosal ulceration. Predisposing factors for invasive growth include trauma, burns, gastrointestinal surgery, indwelling catheters and neutropenia, such as may be associated with cytotoxic chemotherapy for acute leukemia.

Irritants Derive from Air Pollution and Industrial Accidents

The most important irritant gases in the atmosphere are oxidants (ozone, nitrogen oxides) and sulfur dioxide (SO_2). Oxidants derive from the action of sunlight on automobile exhaust and are important in major urban areas (see Chapter 8). SO_2 is produced mainly by burning fossil fuels. These gases, plus particulate carbon carrying toxins from diesel exhaust, may also compound adverse effects of tobacco smoke. Indeed, inhabitants of urban and more polluted areas have worse pulmonary function (e.g., reduced expiratory flow rates) than do those who reside in cleaner environments. Respiratory infections are also more common in young children who live in regions of high pollution. However, these effects are small in the healthy population.

In people with chronic pulmonary disease, the situation is different: experimentally, ozone makes airways more reactive, an effect related to airway inflammation. ***Thus, air pollution may exacerbate symptoms in asthmatic people and in those with established respiratory disease. In high concentrations, irritant gases produce serious morphologic and functional effects.***

NO_2: NO_2 is often encountered in industrial settings, including welding, electroplating, metal cleaning and blasting. It is also produced by decaying grain stored in silos. As NO_2 is heavier than air, it accumulates immediately above the surface of the grain. A worker entering the silo inhales it in high concentrations, resulting in lung injury known as **silo-filler disease**. Respiratory symptoms in such cases may be delayed for up to 30 hours, after which cough and dyspnea develop. Most patients recover, but some develop progressive bronchiolitis obliterans and may die of respiratory failure.

SO_2: This highly soluble gas, when inhaled chronically by experimental animals, produces lesions in the more central airways that resemble chronic bronchitis and that may progress to squamous metaplasia. In humans, exposure to very high concentrations of SO_2 has been associated with severe inflammation and bronchiolitis.

CHLORINE AND AMMONIA: These gases may be released in high concentrations in industrial accidents. If inhaled, they produce extensive bronchial and bronchiolar mucosal injury. Secondary inflammation may cause bronchiectasis, owing partly to bronchiolar obliteration and partly to direct bronchial damage.

Bronchocentric Granulomatosis Is Usually a Response to Infection

Bronchocentric granulomatosis is a nonspecific granulomatous inflammation centered on bronchi or bronchioles (Fig. 18-7). ***This histologic pattern can be seen in a number of clinical settings and is not a distinct clinical entity.***

Asthmatic patients, for the most part, have allergic bronchopulmonary aspergillosis (see below). In addition to having bronchocentric granulomatosis, they have bronchial mucous plugs, bronchiectasis and bronchiolectasis and eosinophilic pneumonia. Irregular, fragmented *Aspergillus* hyphae may be seen in the mucous plugs. A nonspecific secondary vasculitis is centered on airways rather than vessels.

Nonasthmatic patients with bronchocentric granulomatosis are likely to have an infection, especially tuberculosis or fungi such as *Histoplasma capsulatum.* The disorder can also

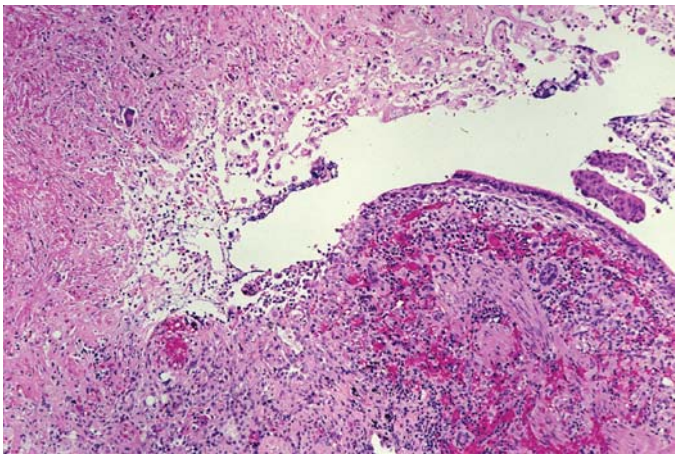

FIGURE 18-7. Bronchocentric granulomatosis. This bronchiole shows ulceration and necrosis of the mucosa and submucosa with granulomatous inflammation. The patient had granulomatosis polyangiitis (formerly Wegener granulomatosis) with lung involvement in the pattern of bronchocentric granulomatosis.

be a manifestation of immune problems, such as rheumatoid arthritis, ankylosing spondylitis and granulomatosis with polyangiitis (formerly Wegener granulomatosis). Patients with bronchocentric granulomatosis of either allergic or nonallergic type generally respond well to corticosteroid therapy.

Constrictive Bronchiolitis May Obliterate an Airway

In constrictive bronchiolitis, an initial inflammatory bronchiolitis is followed by bronchiolar scarring and fibrosis, with progressive narrowing and, eventually, complete destruction of the airway lumen (Fig. 18-8). **Obliterative bronchiolitis** is a synonym.

PATHOLOGY: Bronchioles show chronic mural inflammation and varying amounts of fibrosis between the epithelium and smooth muscle, with resultant narrowing of the lumen. These lesions are often focal and may be difficult to identify. Elastic stains may help in recognizing the scarred bronchioles. Bronchiolectasis and mucous plugs may be seen in adjacent airways. The surrounding lung is usually normal.

CLINICAL FEATURES: Patients may have dyspnea and wheezing due to severe obstructive pulmonary function. Chest radiographs and computed tomography (CT) scans may be normal or show overinflation caused by air trapping distal to the obliterated bronchioles. This pattern of fibrosis is seen in several situations, including (1) bone marrow transplantation (graft-versus-host disease), (2) lung transplantation (chronic rejection), (3) collagen vascular diseases (especially rheumatoid arthritis), (4) postinfectious disorders (especially viral infections), (5) after inhalation of toxins (SO_2, ammonia, phosgene) and (6) ingestion of certain drugs (penicillamine). It may also be idiopathic. Most patients have a relentless progressive clinical course. Although many patients are treated with steroids, no therapy is effective for this disease.

Bronchial Obstruction Leads to Atelectasis

Bronchial obstruction in adults occurs mostly because of endobronchial extension of primary lung tumors, although mucous plugs, aspirated gastric contents or foreign bodies may also be responsible, especially in children. If obstruction is partial, trapped air may cause overdistention of the distal affected segment; complete obstruction results in atelectasis. Areas distal to the obstruction may also develop pneumonia, abscesses and bronchiectasis (see below).

Atelectasis is the collapse of expanded lung tissue (Fig. 18-9). If the air supply is obstructed, gas transfers from the alveoli to the blood, causing the affected region to collapse. Atelectasis occurs as an important postoperative complication of abdominal surgery, because of mucous

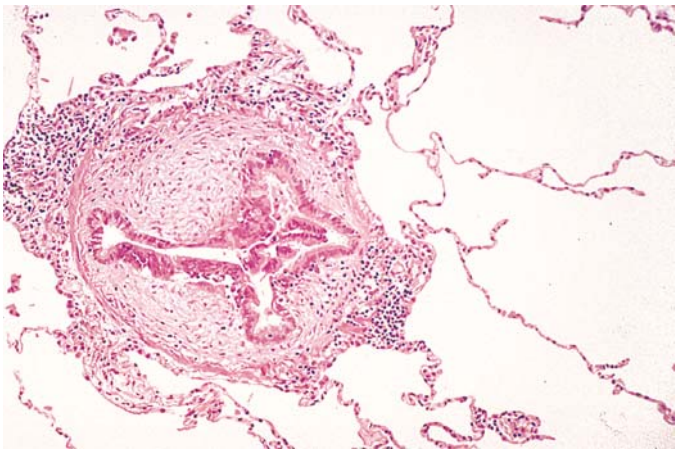

FIGURE 18-8. Constrictive bronchiolitis. The lumen of a bronchiole is markedly narrowed, owing to marked submucosal fibrosis.

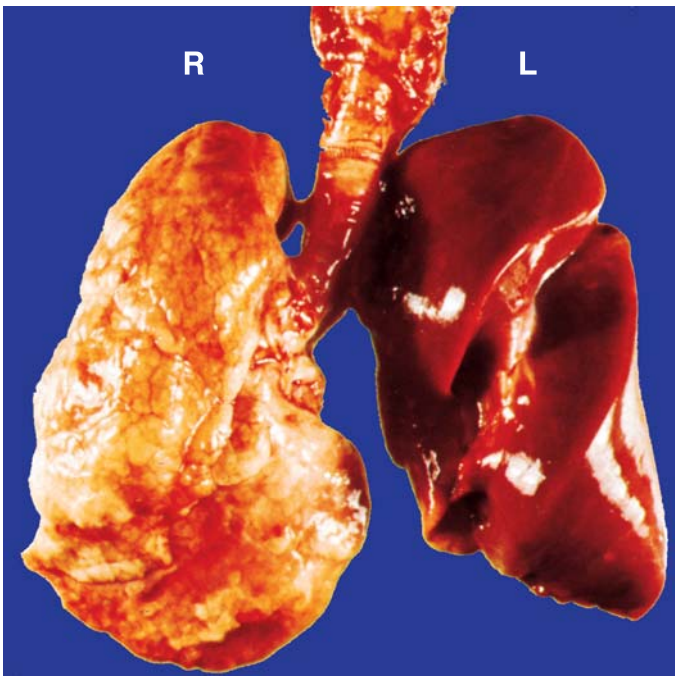

FIGURE 18-9. Atelectasis. The right lung (R) of an infant is pale and expanded by air; the left lung (L) is collapsed.

obstruction of a bronchus and/or diminished respiratory movement resulting from postoperative pain. It is often asymptomatic, but when severe, it results in hypoxemia and a shift of the mediastinum *toward* the affected side.

Atelectasis is usually caused by bronchial obstruction but may also result from direct compression of the lung (e.g., hydrothorax or pneumothorax). If the compression is severe enough, the function of the affected lung may be jeopardized and the mediastinum may shift *away* from the affected side.

In long-standing atelectasis, the area of collapsed lung becomes fibrotic and bronchi dilate, in part owing to infection distal to the obstruction. Permanent bronchial dilation (bronchiectasis) results.

Right middle lobe syndrome refers to atelectasis due to obstruction of the bronchus to the right middle lobe, usually from external compression by hilar lymph nodes. This bronchus is particularly susceptible to external compression because it is long and slender and surrounded by lymph nodes. Histologically, the lung shows bronchiectasis, chronic bronchitis and bronchiolitis, lymphoid hyperplasia, abscess formation and dense fibrosis. Acute and organizing pneumonia may both be present. Tuberculous lymphadenitis or metastatic lung cancer may cause the lymph node enlargement, but the cause of the obstruction is often undetermined.

Bronchiectasis Is Irreversible Bronchial Dilation Caused by Destruction of Bronchial Wall Muscle and Elastic Elements

ETIOLOGIC FACTORS: Bronchiectasis may be obstructive or nonobstructive.

Obstructive bronchiectasis is localized and occurs distal to a mechanical obstruction of a central bronchus by, for example, tumors, inhaled foreign bodies, mucous plugs in asthma or lymph node enlargement. **Nonobstructive bronchiectasis** usually follows respiratory infections or defects in airway defenses from infection. It may be localized or generalized.

Localized nonobstructive bronchiectasis was once common, usually after childhood bronchopulmonary infections with measles, pertussis or other bacteria. Vaccines and antibiotics have reduced the incidence of bronchiectasis, but most cases still follow bronchopulmonary infection, usually with adenovirus or RSV. Childhood respiratory infections still cause bronchiectasis in less developed parts of the world.

Generalized bronchiectasis is, for the most part, secondary to inherited impairment in host defense mechanisms or acquired conditions that permit introduction of infectious organisms into the airways. Acquired disorders that predispose to bronchiectasis include (1) neurologic diseases that impair consciousness, swallowing, respiratory excursions and the cough reflex; (2) incompetence of the lower esophageal sphincter; (3) nasogastric intubation; and (4) chronic bronchitis. The main **inherited conditions** associated with generalized bronchiectasis are cystic fibrosis, dyskinetic ciliary syndromes, hypogammaglobulinemias and deficiencies of specific immunoglobulin (Ig) G subclasses.

Kartagener syndrome is one of the immotile cilia syndromes (ciliary dyskinesia) and consists of the triad of dextrocardia (with or without situs inversus), bronchiectasis and sinusitis. It is caused by defects in the outer or inner dynein arms of cilia, which generate or regulate cilia beats, respectively. Other dyskinetic ciliary syndromes include **radial spoke deficiency** ("Sturgess syndrome") and absence of the central doublet of cilia. In these diseases, cilia are deficient throughout the body. Both men and women are sterile, because of impaired ciliary mobility in the vas deferens and the fallopian tube. In the respiratory tract, ciliary defects lead to repeated upper and lower respiratory tract infections and, thus, to bronchiectasis.

Immunodeficiencies may also predispose to repeated pulmonary infection and bronchiectasis. In hypogammaglobulinemias, lack of IgAs or IgGs that protect against viruses or bacteria can lead to recurrent lung infections. Acquired and inherited defects of neutrophils also increase the risk of respiratory infections and bronchiectasis.

PATHOLOGY: Bronchial dilation is saccular, varicose or cylindrical.

- **Saccular bronchiectasis** affects the proximal third to fourth bronchial branches (Fig. 18-10). These bronchi are severely dilated and end blindly in dilated sacs, associated with collapse and fibrosis of the distal lung parenchyma.
- **Cylindrical bronchiectasis** involves the sixth to eighth bronchial branchings, which show uniform, moderate dilation. It is a milder disease than saccular bronchiectasis and leads to fewer clinical symptoms.
- **Varicose bronchiectasis** results in bronchi that resemble varicose veins on bronchographic examination, with irregular dilations and constrictions. Two to eight branchings of bronchi are recognized grossly. Bronchiolar obliteration is not as severe, and parenchymal abnormalities are variable.

FIGURE 18-10. Bronchiectasis. The resected upper lobe shows widely dilated bronchi, with thickening of the bronchial walls and collapse and fibrosis of the pulmonary parenchyma.

Generalized bronchiectasis is usually bilateral and is most common in the lower lobes, the left more than the right. Localized bronchiectasis may occur wherever there was obstruction or infection. Bronchi are dilated, with thick, white or yellow walls. Bronchial lumens often contain dense, mucopurulent secretions. Severe inflammation of bronchi and bronchioles results in destruction of all components of the bronchial wall. Collapse of distal lung parenchyma causes damaged bronchi to dilate. Inflammation of central airways leads to mucus hypersecretion and abnormalities of the surface epithelium, including squamous metaplasia and increased goblet cells. Lymphoid follicles are often seen in bronchial walls, and distal bronchi and bronchioles are scarred and often obliterated. Bronchial arteries enlarge to supply the inflamed bronchial wall and fibrous tissue. A vicious circle may be established in which pools of mucus become infected, which further promotes destruction of the bronchial walls.

CLINICAL FEATURES: Patients with bronchiectasis have chronic cough, often producing several hundred milliliters of mucopurulent sputum a day. Hemoptysis is common, as bronchial inflammation erodes the walls of adjacent bronchial arteries. Dyspnea and wheezing are variable, depending on the extent of the disease. Pneumonia is common, and patients with long-standing cases are at risk of chronic hypoxia and pulmonary hypertension. Radiologically, the bronchi appear dilated and have thickened walls. Definitive diagnosis is made by CT scan of the lung. Surgical resection of localized bronchiectasis may be necessary, especially if complications such as severe hemoptysis or pneumonia arise. However, in the generalized disease, surgical resection is more palliative than curative.

Acute, reversible bronchial dilation may follow bacterial or viral respiratory infections; it may take months before the bronchi return to normal size.

INFECTIONS

Pulmonary infections are discussed in detail in Chapter 9. The major pulmonary entities are described below, with particular emphasis on pathologic features.

Bacterial Pneumonia Is Inflammation and Consolidation of Lung Parenchyma

Bacterial pneumonia was once divided into lobar pneumonia or bronchopneumonia, but these terms have little clinical relevance today. In **lobar pneumonia,** an entire lobe is consolidated (Fig. 18-11), whereas **bronchopneumonia** refers to scattered solid foci in the same or several lobes (Fig. 18-12).

ETIOLOGIC FACTORS: *Streptococcus pneumoniae* (pneumococcus) was the classic cause of lobar pneumonia, but with antibiotic therapy, involvement of a lobe tends to be incomplete, and more than one lobe is usually affected. By contrast, bronchopneumonia is still a common cause of death. It typically develops in terminally ill patients, usually in dependent and posterior portions of the lung. Scattered irregular foci of pneumonia are centered on terminal bronchioles and respiratory bronchioles. Bronchiolitis is seen, with polymorphonuclear exudates

FIGURE 18-11. Lobar pneumonia. The entire left lower lobe is consolidated and in the stage of red hepatization. The upper lobe is normally expanded.

in adjacent alveoli. Large contiguous areas of alveolar involvement do not occur in bronchopneumonia.

Bacterial pneumonias occur in three settings:

- **Community-acquired pneumonia** arises outside the hospital in people with no primary disorder of the immune system. The term is also used loosely to denote lobar pneumonia.

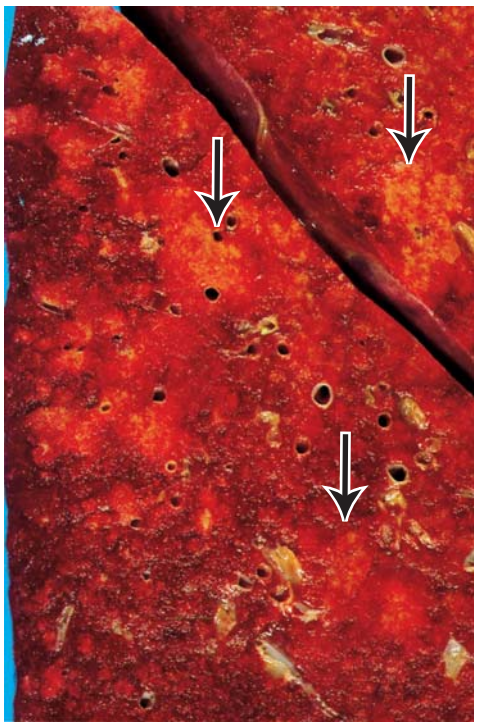

FIGURE 18-12. Bronchopneumonia. Scattered foci of consolidation (*arrows*) are centered on bronchi and bronchioles.

- **Nosocomial pneumonia** is infection that develops in hospital environments and tends to affect compromised patients.
- **Opportunistic pneumonia** afflicts people whose immune status is defective.

Bacterial pneumonias are best classified by etiologic agent, as clinical and morphologic features, and thus therapies, often vary with the causative organism.

Most bacteria that cause pneumonia are normal inhabitants of the oropharynx and nasopharynx that reach alveoli by aspiration of secretions. Other routes of infection include inhalation from the environment, hematogenous dissemination from an infectious focus elsewhere and (rarely) spread of bacteria from an adjacent site. Emergence of a virulent organism in the oropharyngeal flora often precedes the development of pneumonia. Predisposing conditions usually entail depressed host defenses related to cigarette smoking, chronic bronchitis, alcoholism, severe malnutrition, wasting diseases and poorly controlled diabetes. Debilitated or immunosuppressed patients in the hospital often have altered oropharyngeal flora, and as many as 25% may develop nosocomial pneumonia.

Pneumococcal Pneumonia

Antibiotic therapy notwithstanding, *S. pneumoniae* (pneumococcus) pneumonia remains a significant problem. It is mainly a disease of young to middle-aged adults. It is rare in infants, less common in the elderly and much more frequent in men than women.

ETIOLOGIC FACTORS: Pneumococcal pneumonia is mostly a result of altered respiratory tract defenses. For example, a viral upper respiratory infection (e.g., influenza) stimulates bronchial secretions. These provide a hospitable environment for *S. pneumoniae,* which are normal flora of the nasopharynx, to proliferate. The thin, watery secretions carry the organisms into the alveoli, thus initiating an inflammatory response**.** The remarkably severe acute inflammation with spreading edema suggests that immunologic mechanisms may be involved. Aspiration of pneumococci may also follow impaired epiglottic reflexes, as occurs with exposure to cold, anesthesia and alcohol intoxication. Lung injury caused, for example, by congestive heart failure or irritant gases also increases susceptibility to pneumococcal pneumonia.

The pneumococcal capsule protects the bacteria against phagocytosis by alveolar macrophages. The organisms must therefore be opsonized before they can be ingested and killed. In an immune-competent person, antipneumococcal antibodies act as opsonins, but a host not previously exposed to the specific infecting strain of *S. pneumoniae* must use the alternative complement pathway to opsonize the bacteria.

PATHOLOGY: In the earliest stage of pneumococcal pneumonia, protein-rich edema fluid with abundant organisms fills the alveoli (Fig. 18-13). Marked capillary congestion leads to massive outpouring of polymorphonuclear leukocytes and intra-alveolar hemorrhage (Fig. 18-14). Because the color and firm consistency of the affected lung are reminiscent of the liver, this stage has been aptly named **"red hepatization"** (Fig. 18-13).

The next phase, 2 or more days later (depending on the success of treatment), involves lysis of neutrophils and appearance of macrophages, which phagocytose the fragmented leukocytes and other inflammatory debris. At this stage, the congestion has diminished, but the lung is still firm **("gray hepatization")** (Fig. 18-13). The alveolar exudate is then removed and the lung gradually returns to normal.

A number of complications may follow pneumococcal pneumonia:

- **Pleuritis (inflammation of the pleura),** often painful, is common, because the pneumonia readily extends to the pleura.
- **Pleural effusion** (fluid in the pleural space) is common but usually resolves.
- Empyema/**pyothorax (pus in the pleural space)** results from infection of a pleural effusion and may heal with extensive fibrosis.
- **Bacteremia** occurs during the early stages of pneumococcal pneumonia in more than 25% of patients and may lead to endocarditis or meningitis. Patients whose spleens have been removed often die of this bacteremia.
- **Pulmonary fibrosis** is a rare complication of pneumococcal pneumonia. The intra-alveolar exudate organizes to form intra-alveolar plugs of granulation tissue, known as **organizing pneumonia**. Gradually, increasing alveolar fibrosis leads to a shrunken and firm lobe, a rare complication known as **carnification**.
- **Lung abscess (localized collection of pus)** is an unusual complication of pneumococcal pneumonia.

CLINICAL FEATURES: Pneumococcal pneumonia begins abruptly, with fever and chills. Chest pain due to pleural involvement is common. Sputum is characteristically "rusty," because it is derived from altered blood in alveolar spaces. Radiologic studies show alveolar filling in large areas of lung, producing a solid appearance that extends to entire lobes or segments. Before antibiotic therapy, severe fever, dyspnea, debility and even loss of consciousness were common. Such symptoms were followed by **"crisis"** after 5–10 days, when a moribund patient would suddenly become afebrile and return from death's door. Satisfactory resolution of a crisis reflected effective immune responses to the infection. Nevertheless, about 1/3 of patients died. Current treatment for pneumococcal pneumonia is effective, and although symptoms resolve rapidly, radiographic lesions still take several days to clear.

Klebsiella Pneumonia

Other than *S. pneumoniae, Klebsiella pneumoniae* is the only organism that causes lobar pneumonia with any frequency. However, *K. pneumoniae* accounts for only about 1% of community-acquired pneumonias. *Klebsiella* pneumonia occurs mostly in middle-aged, often alcoholic, men. Diabetes and chronic lung disease also increase the risk.

PATHOLOGY: The pathologic stages of *Klebsiella* pneumonia are not as distinctly defined as those in pneumococcal pneumonia, but acute phase congestion and hemorrhage are less pronounced. *K. pneumoniae* has a thick, gelatinous capsule, giving the cut lung surface a characteristic mucoid appearance. Another distinctive feature of *Klebsiella* pneumonia is increased size of the affected

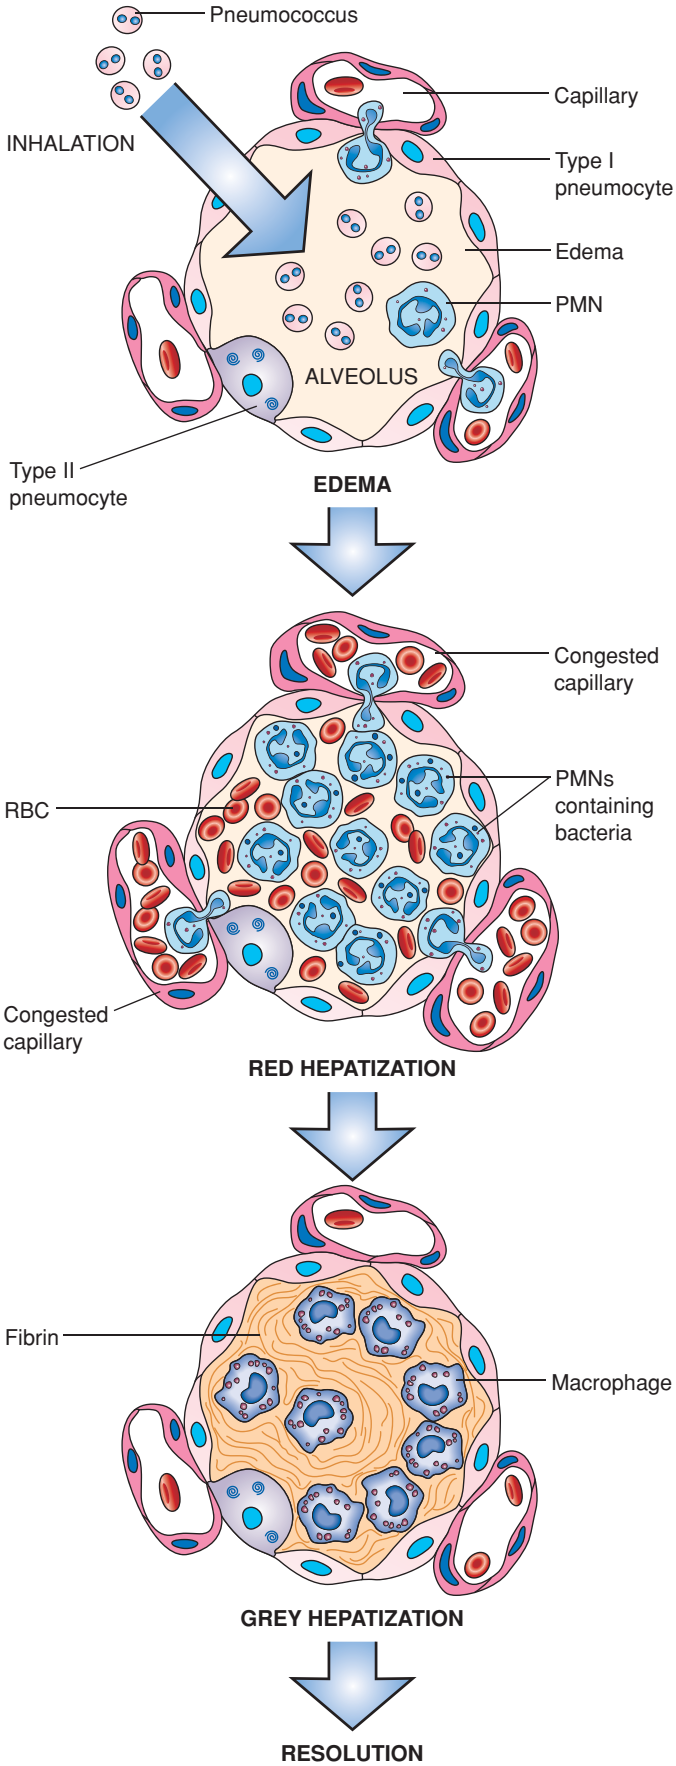

FIGURE 18-13. Pathogenesis of pneumococcal lobar pneumonia. Pneumococci, characteristically in pairs (diplococci), multiply rapidly in alveolar spaces and produce extensive edema. They incite an acute inflammatory response in which polymorphonuclear leukocytes and congestion are prominent (red hepatization). As the inflammatory process progresses, macrophages replace the polymorphonuclear leukocytes and ingest debris (gray hepatization). The process usually resolves, but complications may ensue. *PMN* = polymorphonuclear neutrophil; *RBC* = red blood cell.

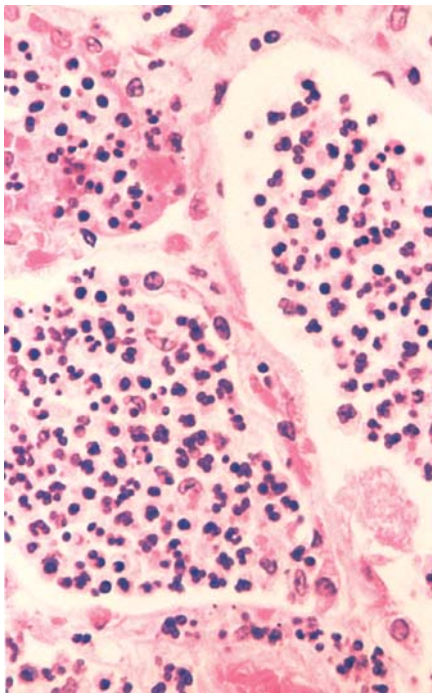

FIGURE 18-14. Pneumococcal pneumonia. Alveoli are packed with an exudate composed of polymorphonuclear leukocytes and occasional macrophages.

lobe, causing the fissure to "bulge" toward the unaffected region. There is a tendency toward tissue necrosis and abscess formation. A serious complication is **bronchopleural fistula** (i.e., a communication between the bronchial airway and the pleural space).

The onset of *Klebsiella* pneumonia is less dramatic than that of pneumococcal pneumonia, but the disease may be more dangerous. Before antibiotics, mortality from *Klebsiella* pneumonia was 50%–80%. Even with prompt antibiotic treatment, mortality remains considerable.

Staphylococcal Pneumonia

Staphylococci account for only 1% of community-acquired bacterial pneumonias. However, *S. aureus* is a common pulmonary superinfection after influenza and other viral respiratory tract infections. Repeated episodes of staphylococcal pneumonia are seen in patients with cystic fibrosis, owing to colonization of bronchiectatic airways. Nosocomial staphylococcal pneumonia typically occurs in chronically ill people who are prone to aspiration and in intubated patients.

PATHOLOGY: Like staphylococcal infections elsewhere, staphylococcal pneumonia is characterized by abscess development. The multiple foci of staphylococcal pneumonia produce many small abscesses. In infants and, less often, in adults, these may lead to **pneumatoceles,** thin-walled cystic spaces lined primarily by respiratory tissue. Pneumatoceles may enlarge rapidly and compress surrounding lung or rupture into the pleural cavity and cause a tension pneumothorax. A pneumatocele develops when an abscess breaks into an airway, allowing drainage of purulent material and expansion of the former abscess by the pressure of inspired air. Cavitation and pleural effusions are common complications of staphylococcal pneumonia, but empyema is infrequent. Staphylococcal pneumonia requires aggressive therapy, particularly because *S. aureus* is often antibiotic resistant.

Other Streptococcal Pneumonias

Pulmonary infections with group A *Streptococcus pyogenes* were identified among soldiers during the 19th century. Its features were described during World War I. Streptococcal pneumonia typically follows viral respiratory tract infections. It is distinctly unusual in a community setting but is occasionally encountered in debilitated patients.

PATHOLOGY: On gross examination, the lungs of patients who die of streptococcal pneumonia are heavy, with bloody edema. Dry consolidation (hepatization) is not a feature of this disease. Microscopically, alveoli are filled with fibrin-containing fluid, but neutrophils are few. Alveolar necrosis may follow prolonged pneumonia. Empyema is a common complication.

CLINICAL FEATURES: Patients with streptococcal pneumonia have abrupt fever, dyspnea, cough, chest pain, hemoptysis and often cyanosis. Radiographically, a bronchopneumonia pattern is observed; lobar consolidation is not seen. Intensive antibiotic therapy is indicated.

Streptococcal pneumonia in the newborn is usually caused by group B streptococci (*Streptococcus agalactiae*), a normal resident of the female genital tract. Symptoms are similar to those of the infantile respiratory distress syndrome. The infants, however, are often full term, have severe toxemia and may die within a few hours.

Legionella Pneumonia

In 1976, a mysterious respiratory disease with high mortality broke out at an American Legion convention in Philadelphia. The responsible organism, *Legionella pneumophila,* is a fastidious bacterium that is difficult to grow in culture. Serologic and histologic studies showed that several previously unrecognized epidemics of the same disease had occurred. *Legionella* organisms thrive in aquatic environments, and outbreaks of pneumonia have been traced to contaminated water in air-conditioning cooling towers, evaporative condensers and construction sites. Person-to-person spread does not occur, and there is no animal or human reservoir.

PATHOLOGY: In fatal *Legionella* pneumonia, multiple lobes show bronchopneumonia, with large confluent areas. Alveoli contain fibrin and inflammatory cells, with either neutrophils or macrophages predominating. Necrosis of inflammatory cells (leukocytoclasis) may be extensive. If the patient survives for several weeks, the exudate may show fibrous organization. Empyema occurs in 1/3 of cases. *Legionella* organisms are usually abundant within and outside the phagocytic cells. They are gram-negative but are difficult to visualize without silver impregnation or immunofluorescent stains.

CLINICAL FEATURES: *Legionella* pneumonia tends to begin abruptly, with malaise, fever, muscle aches and pains and, curiously, abdominal pain. A productive cough is usual, and chest pain due to pleuritis occasionally occurs. The chest radiograph is variable, but the most common pattern shows focal alveolar infiltrates, which may be bilateral. Symptoms are usually less severe than radiographs suggest. Mortality is 10%–20%, especially in immunocompromised patients.

Pontiac fever, also caused by *Legionella* species, is mainly a febrile illness with slight respiratory symptoms, radiologic abnormalities and a good prognosis. It has occurred in epidemics in office buildings and affects apparently healthy individuals.

Pneumonia Caused by Gram-Negative Bacteria

Pneumonias caused by gram-negative organisms, most commonly *Escherichia coli* and *Pseudomonas aeruginosa,* have become more common with the advent of immunosuppressive and cytotoxic therapies, treatment with broad-spectrum antibiotics and AIDS.

ESCHERICHIA COLI: *E. coli* pneumonia may follow bacteremia after abdominal and urogenital surgery, even in patients who are not immunosuppressed. It also is seen in cancer patients given chemotherapy and in people with chronic lung or heart disease. It occurs as a bronchopneumonia and responds poorly to treatment.

PSEUDOMONAS AERUGINOSA: *Pseudomonas* pneumonia is most common in patients who are immunocompromised or who have burns or cystic fibrosis. A history of antibiotic treatment for another infection is common. Often an infectious vasculitis, with large numbers of organisms in blood vessel walls, results in pulmonary infarction. Antibiotic treatment of *Pseudomonas* pneumonia is often unsatisfactory.

Pneumonias Caused by Anaerobic Organisms

Many anaerobic organisms are normal commensals of the oral cavity, especially in people with poor dental hygiene. These include certain streptococci, fusobacteria and *Bacteroides* sp. Swallowing disorders, as in stuporous alcoholics, anesthetized patients and people subject to seizures, predispose to aspirating anaerobic bacteria. Resulting pulmonary infections cause necrotizing pneumonias, which often lead to lung abscesses. The most dramatic complication is gangrene of the lung, a result of thrombosis of a branch of the pulmonary artery and consequent infarction. This is a medical emergency and requires resection of the affected lung.

Psittacosis

Psittacosis is a lung infection due to inhalation of *Chlamydia psittaci* in dust contaminated with excreta from birds, usually pets and often parrots. It is characterized by severe systemic symptoms, with fever, malaise and muscle aches, but

surprisingly few respiratory symptoms other than cough. Chest radiographs may be negative, and when abnormal, they show irregular consolidation and an interstitial pattern. The morphologic patterns in most cases are unknown, but the disease is likely to be an interstitial pneumonia. In fatal cases, varying degrees of diffuse alveolar damage are present, together with edema, intra-alveolar pneumonia and necrosis.

Anthrax Pneumonia and Pneumonic Plague

Recent world events have focused attention on infectious agents that could be used as weapons of bioterrorism. Chief among these are ***Bacillus anthracis*** and ***Yersinia pestis***.

B. anthracis, a gram-positive, spore-forming bacillus, is the causative agent of anthrax. Anthrax occurs in many species of domestic animals, but human infection occurs rarely, or in sporadic outbreaks. Transmission is via direct contact with the spores; person-to-person transmission is uncommon. Cutaneous anthrax is rarely fatal, but inhalational anthrax has a high mortality. Anthrax spores are extremely resistant to drying. When inhaled, they are transported to mediastinal lymph nodes where bacilli emerge and disseminate rapidly through the bloodstream to other organs, including the lungs. Hemorrhagic necrosis of infected organs ensues along with severe hemorrhagic mediastinitis related to local lymphadenopathy. In the lungs, the disease is manifested by hemorrhagic bronchitis and confluent areas of hemorrhagic pneumonia.

Y. pestis, the causative agent of **plague,** produces two main forms of infection, a bubonic form and a pneumonic form. In pneumonic plague, the organisms are inhaled directly without an intermediary arthropod vector, and disease may be spread from person to person. The lungs typically show extensive hemorrhagic bronchopneumonia, pleuritis and mediastinal lymph node enlargement. Untreated disease progresses rapidly and is highly fatal.

Mycoplasma Pneumoniae Causes "Atypical Pneumonia"

Unlike lobar pneumonia, atypical pneumonia begins insidiously. Leukocytosis is absent or slight and the course is prolonged. Respiratory symptoms may be minimal or severe, and chest radiography shows patchy intra-alveolar pneumonia or interstitial infiltrates. Infection characteristically causes a bronchiolitis with a neutrophilic intraluminal exudate and intense lymphoplasmacytic infiltration in bronchiolar walls (Fig. 18-15). *Mycoplasma* lack rigid cell walls that most bacteria possess. They grow slowly and are difficult to culture by traditional methods. Diagnosis is usually established by serologic detection of *Mycoplasma pneumoniae* antibodies or cold agglutinins. Erythromycin is effective, and the infection is only rarely fatal.

Tuberculosis Is the Classic Granulomatous Infection

Known since ancient Egypt, tuberculosis was the scourge of the industrialized world in the 19th and early 20th centuries. It declined quickly as living and working conditions improved during the 20th century, and the introduction of antituberculosis drugs further decreased its impact. However, tuberculosis has recently reemerged, particularly drug-resistant strains and among patients with AIDS (see Chapter 9).

Tuberculosis mostly represents infection with *tuberculosis,* although atypical mycobacterial infections may cause similar manifestations. The disease is divided into primary and secondary (or reactivation) tuberculosis.

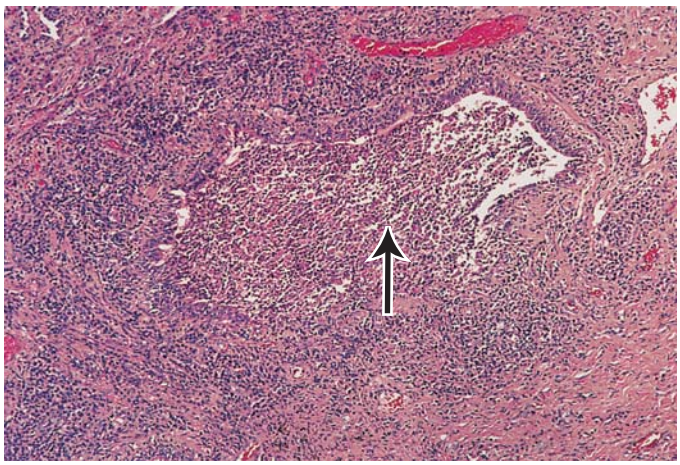

FIGURE 18-15. Mycoplasma pneumonia. Chronic bronchiolitis with a neutrophilic luminal exudate (*arrow*).

PRIMARY TUBERCULOSIS: The disease is acquired after initial exposure to *Mycobacterium tuberculosis,* most commonly from inhaling infected aerosols generated when a person with cavitary tuberculosis coughs. Inhaled organisms multiply in the alveoli because alveolar macrophages cannot readily kill them.

PATHOLOGY: The **Ghon lesion** is the first lesion of primary tuberculosis and consists of a peripheral parenchymal granuloma, often in the upper lobes. When this lesion is associated with an enlarged mediastinal lymph node, a **Ghon complex** is formed (Fig. 18-16). On gross examination, the healed, subpleural Ghon nodule is

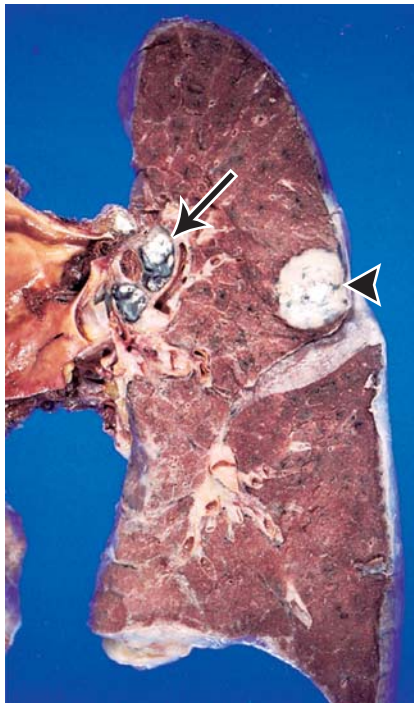

FIGURE 18-16. Primary tuberculosis. A healed Ghon complex is represented by a subpleural nodule (*arrowhead*) and involved hilar lymph nodes (*arrow*).

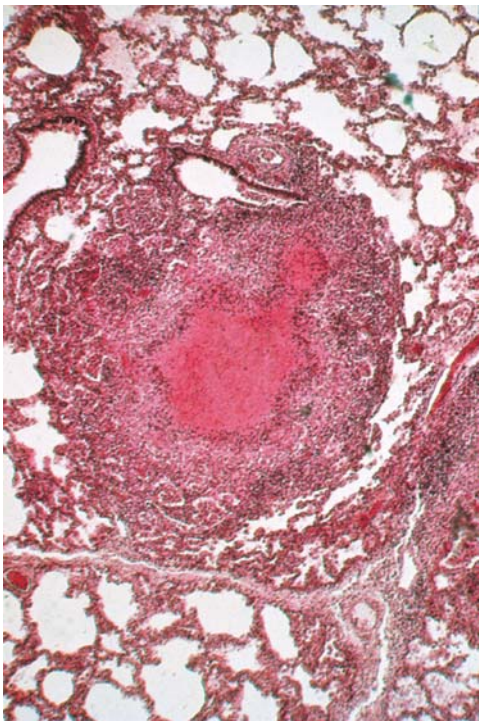

FIGURE 18-17. Necrotizing granuloma due to *Mycobacterium tuberculosis*. A small tuberculous granuloma with conspicuous central caseation is present in the pulmonary parenchyma. The necrotic center is surrounded by histiocytes, giant cells and fibrous tissue.

1–2 cm in diameter, well circumscribed and centrally necrotic. In later stages, it is fibrotic and calcified. Microscopically, a granuloma with central caseous necrosis (Fig. 18-17) shows varying degrees of fibrosis. The microscopic features of draining hilar lymph nodes are similar to those of the peripheral parenchymal lesion.

Most (>90%) primary tuberculous infections are asymptomatic; lesions remain localized and heal. Sometimes there is self-limited extension to the pleura, with secondary pleural effusion. Less often, primary tuberculosis is not limited but spreads to other parts of the lung **(progressive primary tuberculosis)**. This usually occurs in young children or immunosuppressed adults. In this situation, the initial lesion enlarges, producing necrotic areas up to 6 cm. Central liquefaction results in cavities, which may expand to occupy most of the lower lobe. At the same time, draining lymph nodes display similar histologic changes. Erosion of a bronchus by the necrotizing process leads to further pulmonary dissemination of the disease.

SECONDARY TUBERCULOSIS: This stage represents reactivation of primary pulmonary tuberculosis or new infection in someone previously sensitized by primary tuberculosis.

PATHOLOGY: The initial reaction to *M. tuberculosis* is different in secondary tuberculosis. A cellular immune response occurs after a latent interval and leads to formation of many granulomas and extensive tissue necrosis. Apical and posterior segments of the upper lobes are most commonly involved, but the superior segment of the lower lobe is also often affected, and no part of the lung can be excluded. A diffuse, fibrotic, poorly defined lesion develops, with focal areas of caseous necrosis. Often these foci heal and calcify, but some may erode into bronchi, after which drainage of infectious material creates a tuberculous cavity.

Tuberculous cavities range from under 1 cm to large, cystic areas occupying almost the entire lung. Most measure 3–10 cm. They prefer the apices of the upper lobes (Fig. 18-18) but may occur anywhere in the lung. The cavity wall is composed of an inner, thin, gray membrane encompassing soft necrotic nodules; a middle zone of granulation tissue; and an outer collagenous border. The lumen is filled with caseous material containing acid-fast bacilli. Cavities often communicate with a bronchus, and the release of infectious material into airways spreads infection within the lung. The walls of healed tuberculous cavities eventually become fibrotic and calcified.

Secondary tuberculosis is associated with a number of complications:

- **Miliary tuberculosis** is the presence of multiple, small (size of millet seeds), tuberculous granulomas (Fig. 18-19) in many organs. The organisms disseminate from the lung or other sites via the blood, usually during secondary tuberculosis, but occasionally in primary disease.
- **Hemoptysis** is caused by erosion into small pulmonary arteries adjacent to the cavity wall. It may be severe enough to drown patients in their own blood.
- **Bronchopleural fistula** occurs when a subpleural cavity ruptures into the pleural space. In turn, tuberculous empyema and pneumothorax result.
- **Tuberculous laryngitis** is a consequence of coughing up infectious material.
- **Intestinal tuberculosis** may follow swallowing of the same tuberculous material.
- **Aspergilloma** is a fungal mass arising by superinfection of a persistent open cavity with *Aspergillus;* the fungi may fill the entire cavity.

MYCOBACTERIUM AVIUM-INTRACELLULARE (MAI): In immunodeficient patients, whose ability to mount a granulomatous reaction may be impaired, MAI pneumonia is characterized by an extensive infiltrate of macrophages and innumerable acid-fast organisms (Fig. 18-20). MAI may colonize airways of older, immunocompetent individuals with underlying pulmonary disorders such as bronchiectasis, or it may produce granulomatous inflammation with or without

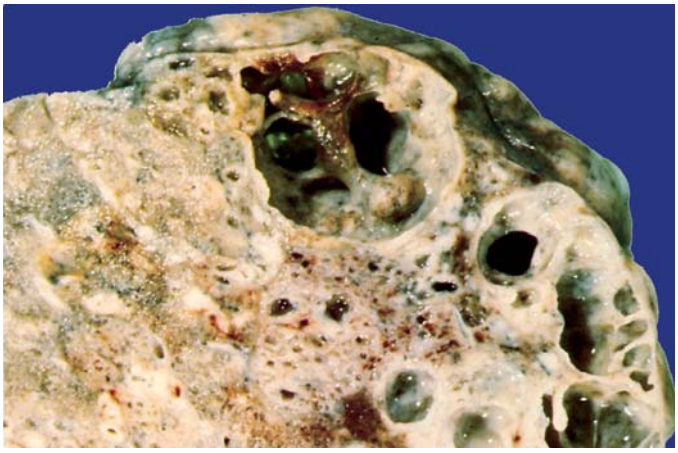

FIGURE 18-18. Cavitary tuberculosis. The apex of the left upper lobe shows tuberculous cavities surrounded by consolidated and fibrotic pulmonary parenchyma that contains small tubercles.

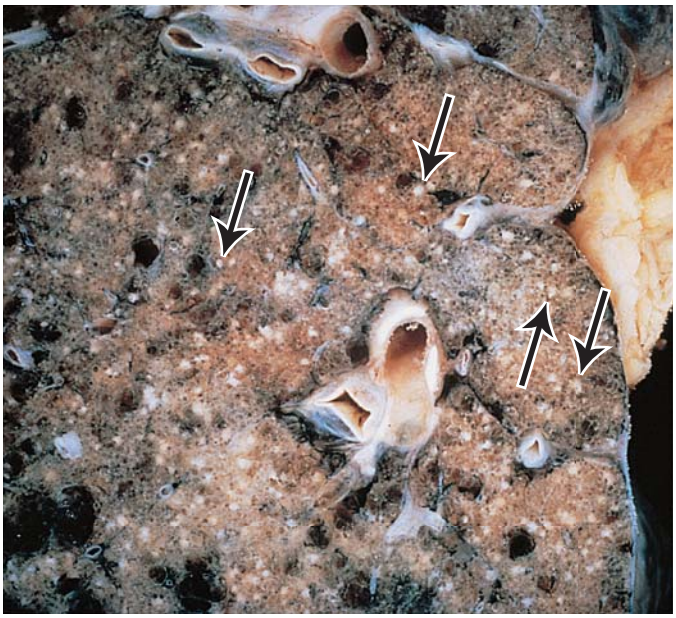

FIGURE 18-19. Miliary tuberculosis. Multiple millimeter-sized nodules (*arrows*) are scattered throughout the lung parenchyma.

cavitation. *Mycobacterium kansasii* produces a spectrum of disease similar to that of MAI but is not as frequently encountered, owing to a more restricted geographic distribution.

Actinomycosis Features Multiple Lung Abscesses

Actinomycosis is caused by infection with actinomycetes, and the usual pulmonary organism is *Actinomyces israelii*. Although actinomycetes resemble fungi in appearance, they are anaerobic, gram-positive, filamentous bacteria. They normally inhabit the mouth and nose and infect the lung by aspiration of oropharyngeal contents or by extension from an actinomycotic subdiaphragmatic abscess or liver abscess.

PATHOLOGY: Lung lesions of actinomycosis consist of multiple, interconnecting, small lung abscesses. The abscess margins are granulomatous, but central necrotic areas are purulent and contain colonies of thin, branching, filamentous, gram-positive bacteria. Clubbed basophilic filaments, noted at the colony margins, are visible to the naked eye as small yellow particles **("sulfur granules")**. The abscesses may extend to the pleura and produce bronchopulmonary fistulas and empyema. They may also invade the chest wall.

Nocardia Is Usually an Opportunistic Organism

Nocardia is a gram-positive filamentous bacterium that causes an acute progressive or chronic bacterial pneumonia. Infection is mostly seen in immunocompromised patients, particularly those with lymphomas, neutropenia, chronic granulomatous disease of childhood and pulmonary alveolar proteinosis. *Nocardia asteroides* is the most common *Nocardia* sp. to cause pneumonia.

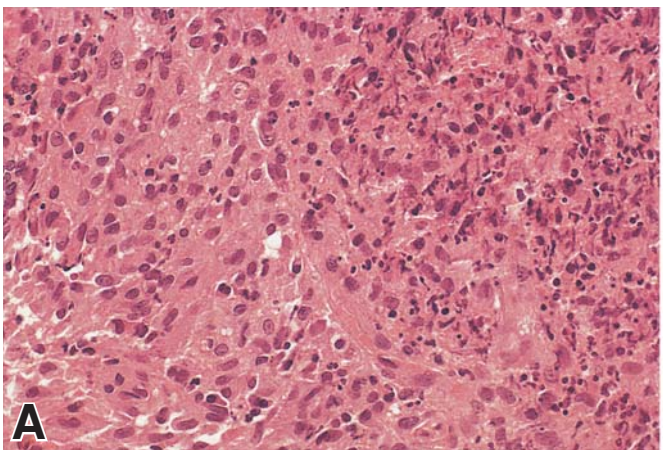
PATHOLOGY: Histologically, lungs show abscesses (Fig. 18-21A), which may have granulomatous features in chronic infections. The organisms are delicate, beaded, thin filaments, which branch mostly at right angles (Fig. 18-21B). They are best seen with Gram or Gomori methenamine silver stains (Fig. 18-21B) and are also weakly acid fast.

Fungal Infections May Be Geographic or Opportunistic

Histoplasmosis

Histoplasmosis is a disease of the midwestern and southeastern United States, particularly the Mississippi and Ohio river valleys. It is caused by inhalation of *Histoplasma capsulatum* in infected dust, commonly from bird droppings.

PATHOLOGY: Histoplasmosis resembles tuberculosis clinically and pathologically. Most infections are asymptomatic and result in lesions like Ghon complexes, including a parenchymal granuloma and similar lesions in the draining lymph nodes. The granulomas are particularly prone to calcify, often with a concentric laminar pattern. In the acute phase, numerous organisms



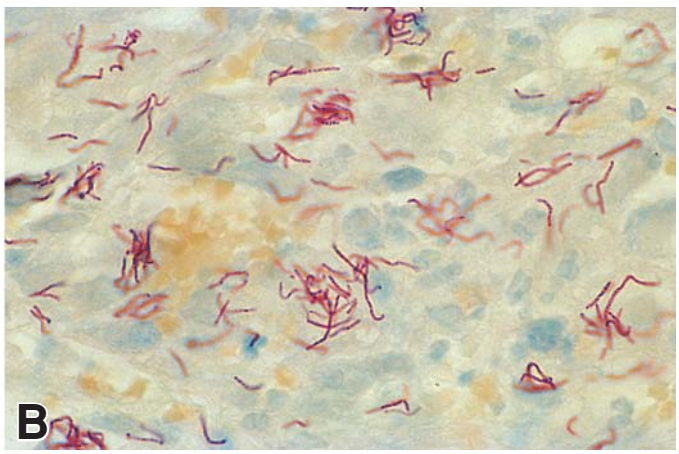


FIGURE 18-20. *Mycobacterium avium-intracellulare* pneumonia in AIDS. **A.** The pneumonia is characterized by an extensive infiltrate of macrophages. **B.** The Ziehl-Neelsen stain shows numerous acid-fast organisms.

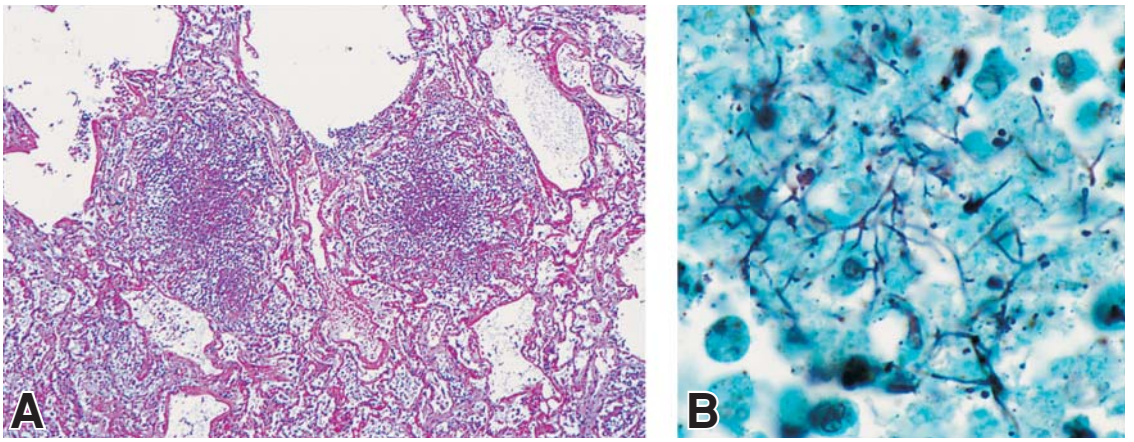

FIGURE 18-21. Nocardiosis. A. This lung shows abscesses consisting of focal collections of acute inflammation. **B.** The organisms are thin, filamentous, branching bacteria (Gomori methenamine silver stain).

are seen within macrophages. Granulomatous inflammation follows, often with central areas of necrosis. The granulomas heal by fibrosis and calcification, but central necrotic areas may persist. The spherical organisms are best seen with a silver stain as 2–4 μm in diameter with narrow-based budding.

In a few cases, pulmonary lesions progress or reactivate, leading to a progressive fibrotic and necrotic lesion that closely resembles that of reactivation tuberculosis. However, histoplasmosis lesions are more fibrotic than those of tuberculosis, and cavitation is less common. The reason for progression is not known, although large infective doses and poor host responses are usually considered to be responsible. Immunocompromised patients are at particular risk for the dissemination of *Histoplasma* within the lungs and spread to other organs.

Coccidioidomycosis

Coccidioidomycosis, caused by inhalation of spores of *Coccidioides immitis,* was originally known as San Joaquin Valley fever, after the location where the disease has been endemic for many years. However, the infection is widespread throughout the southwestern part of the United States and shares many of the clinical and pathologic features of histoplasmosis and tuberculosis. In histologic sections, the organism is a spherule, 30–100 μm, with a thick refractile wall. Spherules contain innumerable 2–5-μm endospores. Empty spherules or endospores that have been released into the tissue may also be visible.

PATHOLOGY: In most instances, lesions are limited to a peripheral parenchymal granuloma, with or without lymph node granulomas. Sometimes, the lesion may be slowly progressive. In immunocompromised hosts, the disease may progress rapidly, with release of endospores into the lung, in which case the tissue reaction may be purulent as well as granulomatous.

Cryptococcosis

Cryptococcosis results from the inhalation of spores of *Cryptococcus neoformans,* which are often found in pigeon droppings. Lung lesions range from small parenchymal granulomas to several large granulomatous nodules, pneumonic consolidation and even cavitation. Most serious cases of pulmonary cryptococcosis occur in immunocompromised patients, in whom the organisms proliferate extensively within alveolar spaces, with little tissue reaction. The organisms are 4–6 μm, but may be larger, with narrow-based budding and a thick mucoid capsule.

North American Blastomycosis

Blastomycosis is an uncommon condition caused by *Blastomyces dermatitidis.* It is concentrated in the Missouri, Mississippi and Ohio river basins in the United States, and in southern Manitoba and northwestern Ontario in Canada. Clinical and pathologic features resemble those of the fungi mentioned above. Initial infection produces a lesion resembling a Ghon complex or progressive pneumonitis. Unlike tuberculous Ghon complexes, the focal lesions of blastomycosis show central necrosis with a purulent reaction, surrounded by granulomatous inflammation. The organisms are 8–15 μm, have a thick refractile wall and exhibit broad-based budding.

Aspergillosis

Lung infections by *Aspergillus* spp., usually *Aspergillus niger* or *Aspergillus fumigatus,* may occur as:

- **Invasive aspergillosis:** This is the most serious form of *Aspergillus* infection, occurring almost exclusively as an opportunistic infection in people with compromised immunity, usually due to cytotoxic therapy or AIDS. The lungs show patchy, multifocal consolidation and, occasionally, cavities. Extensive blood vessel invasion (usually arterial [Fig. 18-22]) results in occlusion, thrombosis and infarction of lung tissue. Invasive aspergillosis is a fulminant pulmonary infection that is not amenable to therapy.
- **Aspergilloma ("fungus ball" or mycetoma):** *Aspergillus* spp. may grow in preexisting cavities, such as those caused by tuberculosis or bronchiectasis, where they proliferate to form fungus balls (Fig. 18-23). Radiographs show a large mass within an air-filled cavity. Fungus balls are usually clinically silent and merely represent interesting radiologic findings. However, if they become

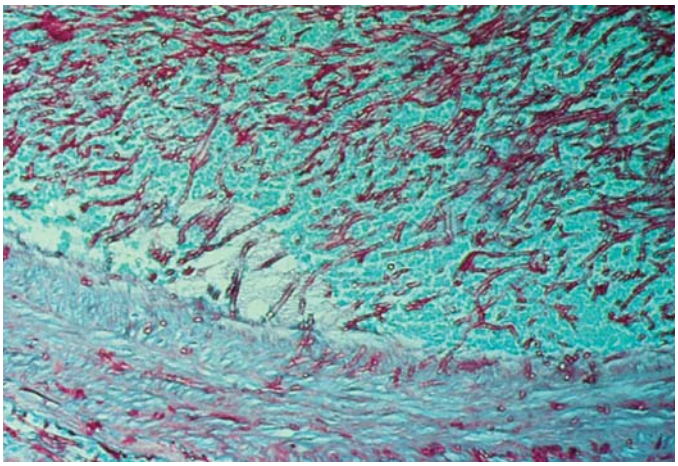

FIGURE 18-22. Invasive pulmonary aspergillosis. A branch of the pulmonary artery shows fungal hyphae in the wall and within the lumen (Gomori methenamine silver stain).

clinically evident, they most often present with hemoptysis, arising either from the underlying condition or, less commonly, fungal infection of the cavity wall.

- **Allergic bronchopulmonary aspergillosis (ABPA):** Certain asthmatics have an unusual immunologic reaction to *Aspergillus* that is characterized by (1) transient pulmonary infiltrates on chest radiographs, (2) eosinophilia of blood and sputum, (3) skin sensitivity and serum precipitins to *A. fumigatus* antigens and (4) increased serum IgE. Computed tomography shows thickened bronchial walls and mucous plugs in the bronchi.

PATHOLOGY: ABPA is invariably associated with proximal (central) bronchiectasis, involving segmental bronchi and the next 2–4 orders of subsegmental bronchi. There are bronchial and bronchiolar mucous plugs, eosinophilic infiltrates and Charcot-Leyden crystals (Fig. 18-24A,B). Bronchocentric granulomatosis and eosinophilic pneumonia may be present. The bronchial mucus may contain septate, fungal hyphae, with 45-degree branching. Interestingly, the peripheral bronchial tree is spared.

FIGURE 18-23. *Aspergillus* fungus ball. The lung contains a cavity filled with a fungus ball.

CLINICAL FEATURES: Patients with ABPA wheeze, with chest pain and cough, and often have thick mucous plugs. Systemic corticosteroids usually control acute episodes.

Pneumocystis jiroveci

First described as "plasma cell pneumonia" in malnourished infants at the end of World War II, pulmonary infections with *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) most often cause pneumonia in immunosuppressed patients or those with immunodeficiencies such as HIV/AIDS. Patients receiving immunosuppressive drugs after organ transplantation or chemotherapy for malignant disease are particularly at risk. Once considered a protozoan, *Pneumocystis* is now recognized as a fungus.

PATHOLOGY: The classic lesions of *Pneumocystis* pneumonia are interstitial infiltrates of plasma cells and lymphocytes and hyperplasia of type II

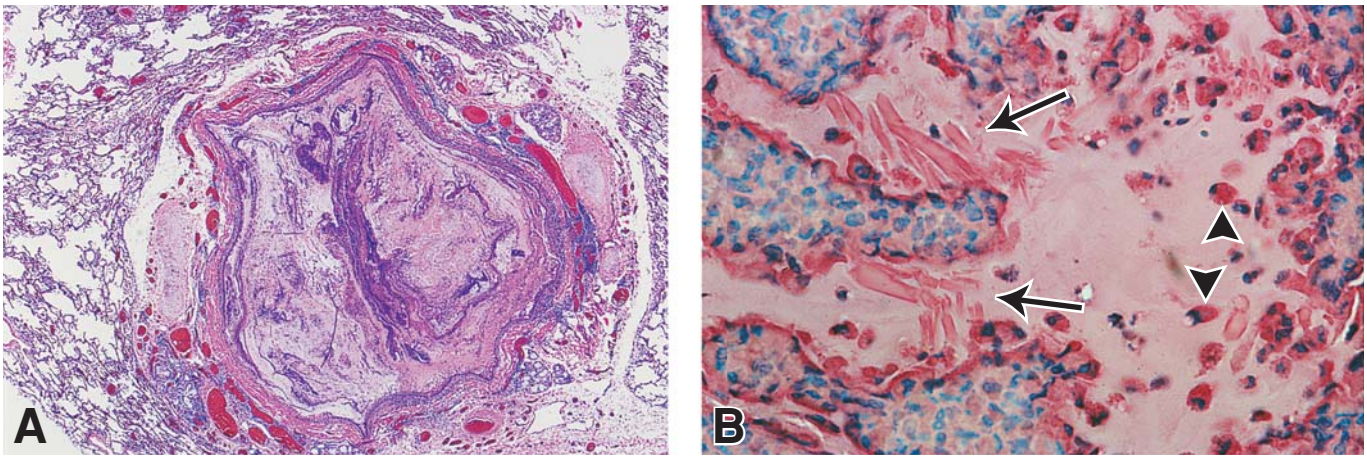

FIGURE 18-24. Allergic bronchopulmonary aspergillosis. A. A dilated bronchus is filled with a mucous plug that has dense layers of eosinophilic infiltrates. **B.** Higher magnification shows numerous eosinophils (*arrowheads*) and Charcot-Leyden crystals (*arrows*).

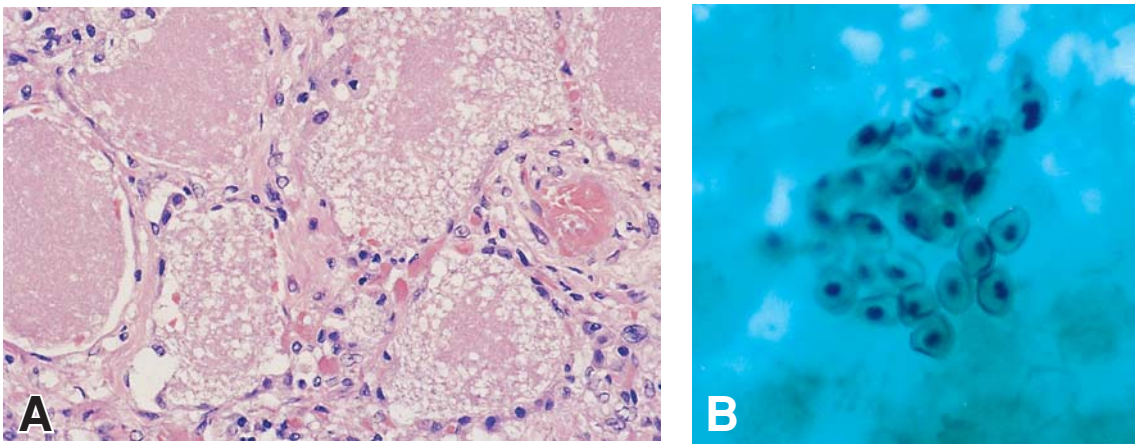

FIGURE 18-25. *Pneumocystis jiroveci* pneumonia. A. The alveoli are filled with a foamy exudate, and the interstitium is thickened and contains a chronic inflammatory infiltrate. **B.** A centrifuged bronchoalveolar lavage specimen impregnated with silver shows a cluster of *Pneumocystis* cysts.

pneumocytes. Alveoli are filled with a characteristic foamy exudate, in which the organisms appear as small bubbles in a background of proteinaceous exudate (Fig. 18-25A). With silver impregnation, cysts appear as round or indented ("crescent moon") bodies, 5 µm in diameter (Fig. 18-25B). After sporozoites develop within the cyst, it ruptures and assumes an indented shape. Sporozoites develop into trophozoites, which may be seen with stains such as Giemsa in cytology specimens but are very difficult to see in routine histologic sections. Granulomatous inflammation in *Pneumocystis* pneumonia is rare but occurs in up to 5% of lung biopsies from HIV-infected patients. In some cases, *Pneumocystis* also produces diffuse alveolar damage (see below).

CLINICAL FEATURES: Clinically and radiologically, *Pneumocystis* pneumonia presents a variable picture. At one extreme, symptoms may be minimal, while at the other, there is rapidly progressive respiratory failure. In AIDS patients, thin-walled parenchymal cysts may develop and predispose to pneumothorax. The diagnosis is made by identifying the organism by sputum examination, bronchoalveolar lavage, transbronchial biopsy, needle aspiration of the lung or open lung biopsy. Treatment is with trimethoprim–sulfamethoxazole or pentamidine.

Viral Pneumonitides Cause Diffuse Alveolar Damage or Interstitial Pneumonia

PATHOLOGY: Viral infections initially affect the alveolar epithelium and elicit interstitial mononuclear infiltrates (Fig. 18-26). Hyaline membranes and necrosis of type I epithelial cells lead to an appearance indistinguishable from diffuse alveolar damage from other causes. Sometimes, alveolar damage is indolent, and disease is characterized by type II pneumocyte hyperplasia and chronic interstitial inflammation. This is unlike most bacterial infections, in which intra-alveolar neutrophilic exudates predominate and the interstitium is only incidentally involved (Fig. 18-27).

Cytomegalovirus (CMV) pneumonia entails intense interstitial lymphocytic infiltration. Alveoli are lined by type II cells that have regenerated to cover the epithelial defect left by necrosis of type I cells. The infected alveolar cells are very large (cytomegaly) with a single, dark, basophilic nuclear inclusion with a peripheral halo and multiple, indistinct cytoplasmic, basophilic inclusions (Fig. 18-28).

Measles infection involves both the airways and the parenchyma. It is characterized by very large (100 µm across) multinucleated giant cells with nuclear inclusions and large eosinophilic cytoplasmic inclusions (Fig. 18-29). Interstitial pneumonia, a well-characterized complication of measles, is rarely fatal, except in immunocompromised, previously unexposed individuals.

Varicella infection (chickenpox and herpes zoster) produces disseminated, focally necrotic lung lesions and interstitial pneumonia. Pulmonary involvement is usually asymptomatic, except in immunocompromised hosts, in whom it may be fatal. The viral inclusions are nuclear, eosinophilic and refractile and are surrounded by a clear halo. Multinucleation can occur.

Herpes simplex can cause a necrotizing tracheobronchitis as well as diffuse alveolar damage. Viral inclusions are identical to those seen in varicella infection.

Adenovirus causes necrotizing bronchiolitis and bronchopneumonia. Two types of nuclear inclusions are seen: eosinophilic nuclear inclusions surrounded by a clear halo and "smudge cells," with indistinct, basophilic, nuclear inclusions that fill the entire nucleus and are surrounded by only a thin rim of chromatin (Fig. 18-30).

Influenza virus typically produces interstitial pneumonitis and bronchiolitis similar to those seen in other viral pneumonias. It does not produce characteristic viral cytopathic changes in histologic sections. A recent pandemic of H1N1 influenza drew attention to the pathology of influenza pneumonia. Most cases of H1N1 infection are fortunately mild and self-limited. But in some patients, mainly those with underlying health problems, fatal disease may occur. Pathologies vary from interstitial pneumonia and bronchiolitis to diffuse alveolar damage. In some cases, extensive hemorrhage is present. With most strains of influenza, bacterial superinfection is not uncommon.

The Most Common Cause of Lung Abscess Is Aspiration

Lung abscesses are localized accumulations of pus, with destruction of pulmonary parenchyma, including alveoli, airways and blood vessels.

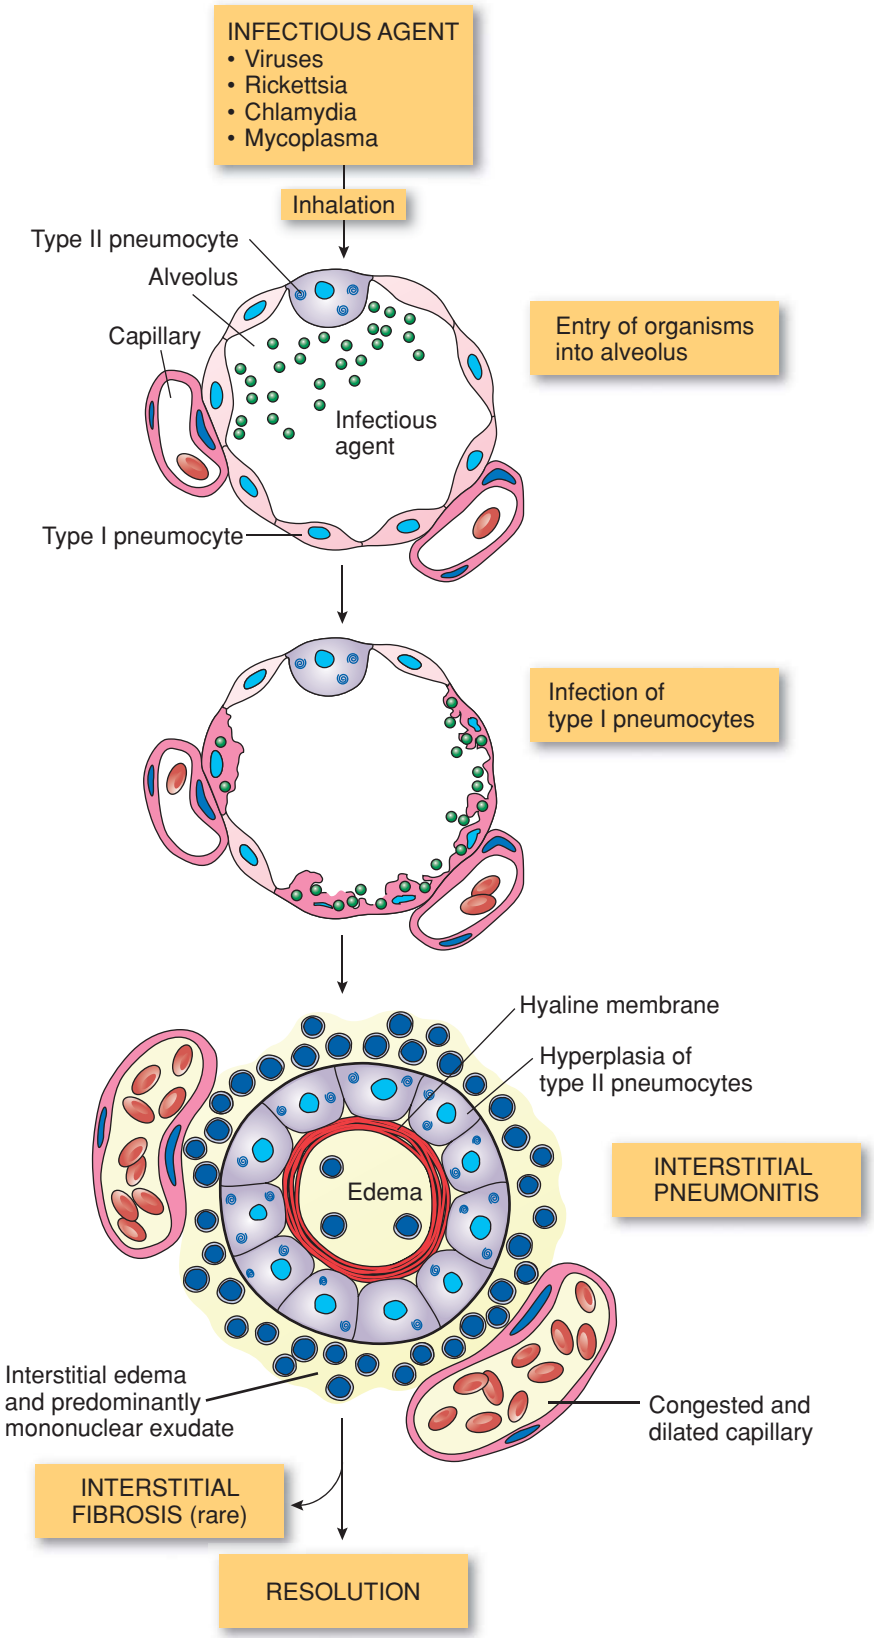

FIGURE 18-26. Pathogenesis of interstitial pneumonia. Although interstitial pneumonia is most commonly caused by viruses, other organisms also may cause significant interstitial inflammation. Type I cells are the most sensitive to damage, and loss of their integrity leads to intra-alveolar edema. The proteinaceous exudate and cell debris form hyaline membranes, and type II cells multiply to line the alveoli. Interstitial inflammation is characterized mainly by mononuclear cells. The disease usually resolves completely but occasionally progresses to interstitial fibrosis.

States of depressed consciousness often predispose to the aspiration that causes lung abscesses, and aspirated oropharyngeal anaerobic bacteria are responsible in over 90% of cases. Infections are typically polymicrobial, often with fusiform bacteria and *Bacteroides* spp. Other organisms encountered in lung abscesses caused by aspiration include *S. aureus, K. pneumoniae, S. pneumoniae* and *Nocardia.*

Development of lung abscess after aspiration requires a large number of anaerobic bacteria in the oral flora, as in people with poor oral hygiene or periodontal disease. The cough

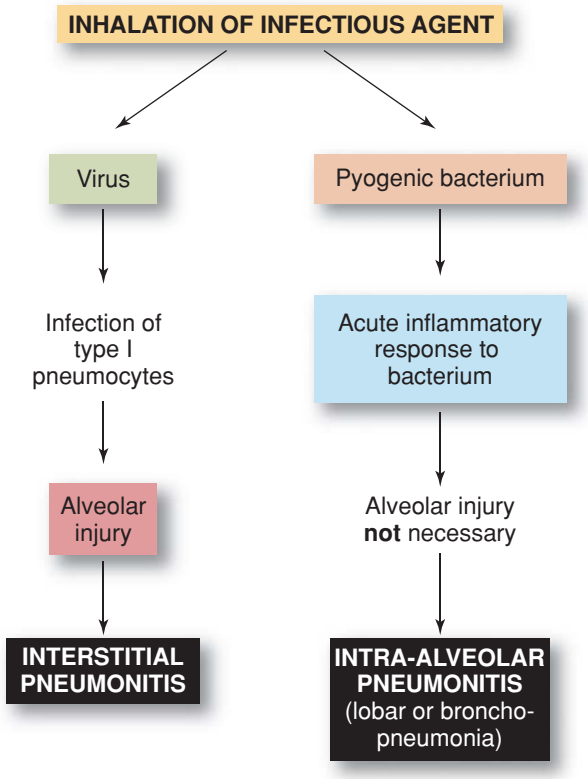

FIGURE 18-27. Pathogenesis of interstitial and intra-alveolar pneumonitis.

reflex or tracheobronchial clearance must also be impaired. Not surprisingly, alcoholism is the most common condition predisposing to lung abscess. Drug overdoses, epilepsy and neurologic impairment also increase the risk. Other causes of lung abscess include necrotizing pneumonias, bronchial obstruction, infected pulmonary emboli, penetrating trauma and extension of infection from adjacent tissues.

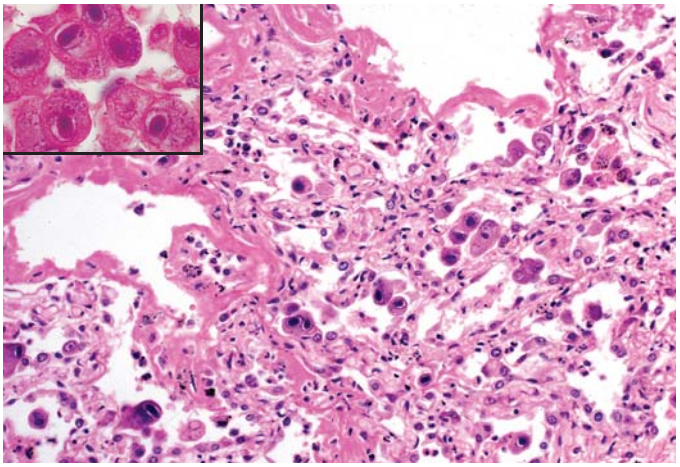

FIGURE 18-28. Cytomegalovirus pneumonitis. Infected alveolar cells are enlarged and display the typical dark blue nuclear inclusions. *Inset.* A higher-power view shows infected alveolar cells that display a single basophilic nuclear inclusion with a perinuclear halo and multiple, indistinct, basophilic, cytoplasmic inclusions.

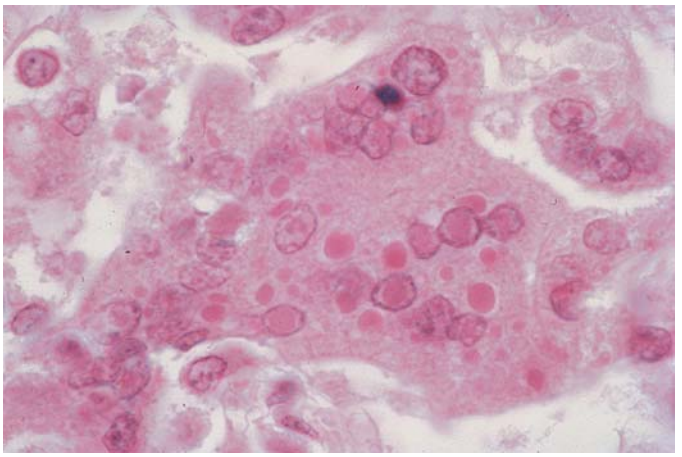

FIGURE 18-29. Measles pneumonitis. This multinucleated giant cell shows single, eosinophilic, refractile inclusions within each of the nuclei, as well as multiple, irregular, eosinophilic, cytoplasmic inclusions.

PATHOLOGY: Lung abscesses typically range from 2 to 6 cm; 10%–20% have multiple cavities, usually arising after a necrotizing pneumonia or a shower of septic pulmonary emboli. The right side of the lung is more often involved than the left, because the right main bronchus follows the direction of the trachea more closely at its bifurcation. Acute lung abscesses are not distinctly separated from the surrounding lung parenchyma. They contain abundant polymorphonuclear leukocytes and, depending on the age of the lesion, variable numbers of macrophages and necrotic tissue debris. Initially, they are surrounded by hemorrhage, fibrin and inflammation, but as they age, a fibrous wall forms around the margin. Lung abscesses differ from abscesses elsewhere in that they may drain spontaneously into an airway. The cavity thus formed contains air, necrotic debris and inflammatory exudate (Fig. 18-31), creating an air-fluid level that is easily seen radiographically. The cavity lining eventually becomes covered with regenerating squamous epithelium. Walls of old

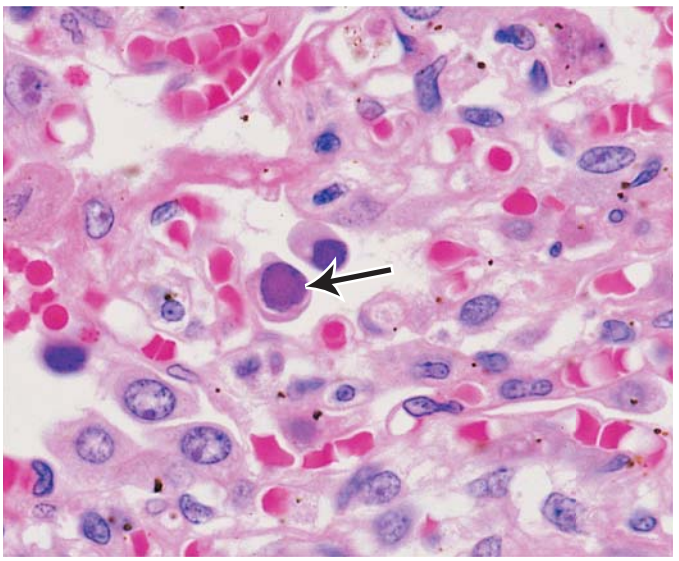

FIGURE 18-30. Adenovirus pneumonia. The "smudge" cell in the center (*arrow*) contains a smudgy basophilic nuclear inclusion.

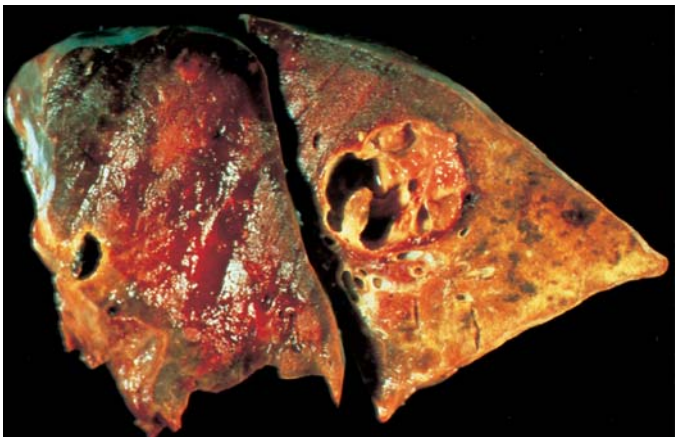

FIGURE 18-31. Pulmonary abscess. A large cystic abscess contains a purulent exudate and is lined by a fibrous wall. Pneumonia is present in the surrounding pulmonary parenchyma.

abscesses may be lined by ciliated respiratory epithelium, making them difficult to distinguish from bronchiectasis.

CLINICAL FEATURES: Almost all patients with lung abscess present with fever and cough, characteristically producing large amounts of foul-smelling sputum. Many patients complain of pleuritic chest pain, and 20% develop hemoptysis.

The differential diagnosis of lung abscess includes lung cancer and cavitary tuberculosis. Indeed, cancer is a more common cause of cavitation than lung abscess. Cavitation due to cancer arises from tumor necrosis half the time, with the other half following bronchial obstruction with subsequent infection. Tuberculous cavities only rarely show the air-fluid levels characteristic of lung abscesses.

Complications of lung abscess include rupture into the pleural space, which causes empyema, and severe hemoptysis. Abscess drainage into a bronchus may spread infection to other parts of the lung. Despite vigorous antimicrobial therapy, principally directed against anaerobic bacteria, the mortality of lung abscess remains 5%–10%.

DIFFUSE ALVEOLAR DAMAGE

Diffuse alveolar damage (DAD) is a pattern of reaction of alveolar epithelial and endothelial cells to a variety of acute insults (Table 18-1). The clinical expression of severe DAD is **acute respiratory distress syndrome** (ARDS). In ARDS, apparently normal lungs sustain damage that progresses rapidly to respiratory failure. Lung compliance is impaired (usually requiring mechanical ventilation), with hypoxemia and extensive bilateral radiologic opacities ("white-out"). ARDS mortality exceeds 50%, and in patients over 60, it is as high as 90%.

ETIOLOGIC FACTORS: DAD is a final common pathologic pathway triggered by a large variety of insults (Table 18-1), including infections, sepsis, shock, aspiration of gastric contents, inhalation of toxic gases, near-drowning, radiation pneumonitis and many drugs and other chemicals. The common pathogenic link is acute alveolar epithelial and endothelial cell injury, thus producing DAD. ***Unless a specific infectious agent is identified, the trigger for DAD is not evident from the lung histology alone.*** In some patients, no cause is found. Such idiopathic DAD, referred to clinically as **acute interstitial pneumonia** (AIP), also includes cases historically called **Hamman-Rich disease (see below)**.

MOLECULAR PATHOGENESIS: Endothelial cell injury allows protein-rich fluid to leak from alveolar capillaries into the interstitial space (Fig. 18-32). Loss of type I pneumocytes permits fluid to enter alveolar spaces, where plasma proteins form fibrin-containing precipitates (hyaline membranes) on the injured alveolar walls (Fig. 18-33). In response to cell injury in DAD, inflammatory cells accumulate in the interstitium. Although lacking type I pneumocytes, alveolar basement membranes remain intact and act as scaffolds for type II pneumocytes, which proliferate to replace the normal alveolar epithelial lining.

If the patient survives the acute phase of ARDS, fibroblasts proliferate in the interstitial space and deposit collagen in the alveolar walls (Fig. 18-34). With complete recovery, the alveolar exudate and hyaline membranes are resorbed and normal alveolar epithelium is restored. Fibroblast proliferation ceases, the extra collagen is metabolized and patients regain normal lung function. In patients who do not recover, DAD can progress to end-stage fibrosis: remodeling of lung architecture produces many cyst-like spaces throughout the lung **(honeycomb lung)**. These spaces are separated by thick fibrous walls lined by type II pneumocytes, bronchiolar epithelium or squamous cells.

Mechanisms of acute injury in DAD are not entirely clear. It is thought that activation of complement (e.g., by endotoxin in the case of gram-negative septicemia) leads to

TABLE 18-1
IMPORTANT CAUSES OF ACUTE RESPIRATORY DISTRESS SYNDROME

Nonthoracic Trauma	Infection	Aspiration	Drugs and Therapeutic Agents
Shock due to any cause	Gram-negative septicemia	Near-drowning	Heroin
Fat embolism	Other bacterial infections Viral infections	Aspiration of gastric contents	Oxygen Radiation Paraquat Cytotoxic drugs

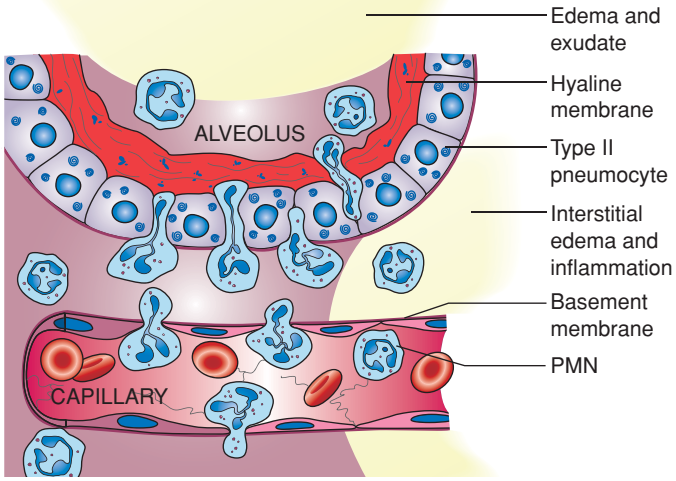

FIGURE 18-32. Diffuse alveolar damage (acute respiratory distress syndrome [ARDS]). In ARDS, type I cells die as a result of diffuse alveolar damage. Intra-alveolar edema follows, after which there is formation of hyaline membranes composed of proteinaceous exudate and cell debris. In the acute phase, the lungs are markedly congested and heavy. Type II cells multiply to line the alveolar surface. Interstitial inflammation is characteristic. The lesion may heal completely or progress to interstitial fibrosis. *PMN* = polymorphonuclear neutrophil.

sequestration of neutrophils in the marginating pool. Only a small proportion, perhaps 1/3, of neutrophils actively circulate in the blood; most of the rest are in the lung. Normally, they cause no damage there, but after activation by complement, they release oxygen radicals and hydrolytic enzymes, which damage pulmonary capillary endothelium. However, neutrophils cannot be obligatory for DAD, because ARDS can develop in severely neutropenic patients.

In DAD following toxic gas inhalation or near-drowning, the damage is mostly at the alveolar epithelial surface. Normal alveolar epithelial junctions are very tight, but epithelial injury disrupts these junctions, permitting exudation of fluid and proteins from the interstitium into alveolar spaces.

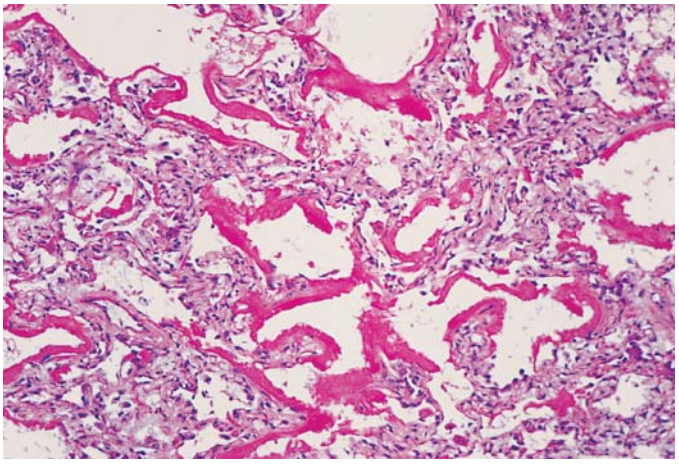

FIGURE 18-33. Diffuse alveolar damage, acute (exudative) phase. Alveolar septa are thickened by edema and a sparse inflammatory infiltrate. Alveoli are lined by eosinophilic hyaline membranes.

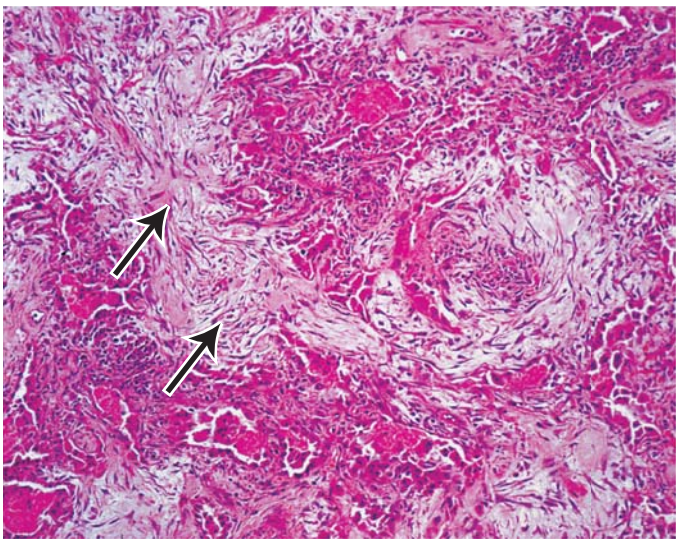

FIGURE 18-34. Diffuse alveolar damage, acute and organizing phase. The alveolar walls are thickened by fibroblasts and loose connective tissue (*arrows*).

PATHOLOGY: The first step is the **exudative phase of DAD,** which develops within a week after pulmonary insult. Edema, hyaline membranes and leakage of plasma proteins are evident, as is accumulation of inflammatory cells (Fig. 18-33). The earliest evidence of alveolar injury is seen by electron microscopy as degenerative changes in endothelial cells and type I pneumocytes. This is followed by sloughing of type I cells, thus denuding basement membranes. Interstitial and alveolar edema is prominent by the first day but soon recedes. **"Hyaline membranes"** appear by the second day and are the most conspicuous morphologic feature of the exudative phase after 4–5 days. They are eosinophilic and glassy, consisting of precipitated plasma proteins and cytoplasmic and nuclear debris from sloughed epithelial cells. Interstitial inflammation, with lymphocytes, plasma cells and macrophages, develops early and peaks in about a week. Toward the end of the first week and persisting during the subsequent **organizing stage,** regularly spaced, cuboidal type II pneumocytes become arrayed along the denuded alveolar septa. Alveolar capillaries and pulmonary arterioles may contain fibrin thrombi. If DAD is fatal, the lungs are heavy, edematous and virtually airless.

The organizing phase of DAD starts about a week after the initial injury and is marked by fibroblast proliferation within alveolar walls (Fig. 18-34). Interstitial inflammation and proliferated type II pneumocytes persist, but hyaline membranes are no longer formed. Alveolar macrophages digest the remnants of hyaline membranes and other debris. Loose fibrosis expands alveolar septa but resolves in mild cases. In severe DAD, fibrosis progresses to restructuring of the pulmonary parenchyma.

CLINICAL FEATURES: Patients destined to develop ARDS have a symptom-free interval for a few hours after the initial insult. Tachypnea and dyspnea mark the onset of ARDS. Blood gas analyses show arterial hypoxemia and decreased pCO_2. As ARDS progresses, dyspnea worsens and the patient becomes cyanotic.

Diffuse, bilateral, interstitial and alveolar infiltrates are noted radiologically. Increasing inspired oxygen concentrations does not restore adequate blood oxygenation, necessitating mechanical ventilation. In fatal cases, the combination of increasing tachypnea and decreasing tidal volume causes alveolar hypoventilation, progressive hypoxemia and increasing pCO_2.

Patients who survive ARDS may recover normal pulmonary function, but in severe cases, they are left with scarred lungs, respiratory dysfunction and, in some instances, pulmonary hypertension.

Diffuse Alveolar Damage Has Diverse Causes

Oxygen Toxicity

Patients who receive high oxygen levels for respiratory problems can develop DAD. Lung lesions may rarely follow long-term exposure to as little as 28% oxygen, but it is usually safe to breathe 40%–60% oxygen for long periods. Oxygen toxicity is thought to be caused by increased production of reactive oxygen species in the lung (see Chapter 1).

Shock

ARDS often follows shock from any cause, including sepsis (see Chapter 12), trauma or blood loss, the pulmonary consequences of which are often called "shock lung." The pathogenesis of DAD associated with shock is poorly understood but is likely multifactorial. Tissue necrosis in organs damaged by trauma or ischemia may lead to release of vasoactive peptides into the circulation. These enhance vascular permeability in the lung. Disseminated intravascular coagulation may damage alveolar capillaries, and fat emboli from bone fractures may obstruct the distal capillary bed of the lung. The pathogenesis of endothelial cell injury in endotoxic shock is discussed in Chapter 7.

Aspiration

Aspiration of gastric contents introduces acid with a pH less than 3.0 into the alveoli. The severe chemical injury to the alveolar lining cells leads to DAD. In near-drowning, aspiration of water produces pulmonary injury and ARDS.

Drug-Induced DAD

Many drugs cause DAD, especially cytotoxic chemotherapeutic agents. The best known is bleomycin, but others include 1,3-bis-(2-chloroethyl)-1-nitrosourea (BCNU), methotrexate, 5-fluorouracil, busulfan and cyclophosphamide. With bleomycin, an imprecise dose-dependent relation has been demonstrated, but such an effect is not apparent with most other drugs.

Bizarre, atypical, hyperchromatic nuclei in type II cells are particularly common when alveolar damage is due to chemotherapy (Fig. 18-35). Damage progresses even when the offending agent is discontinued, but corticosteroid treatment may be helpful. Progressive interstitial fibrosis occurs, usually with retention of lung structure. Methotrexate differs from other chemotherapeutic agents in that it may sometimes cause a hypersensitivity reaction in the lung, in which case the DAD is reversible after the drug is discontinued. Hypersensitivity lesions are characterized by granulomatous inflammation and occasionally vasculitis. Drugs other than chemotherapeutic agents that may cause DAD include nitrofurantoin, amiodarone and penicillamine.

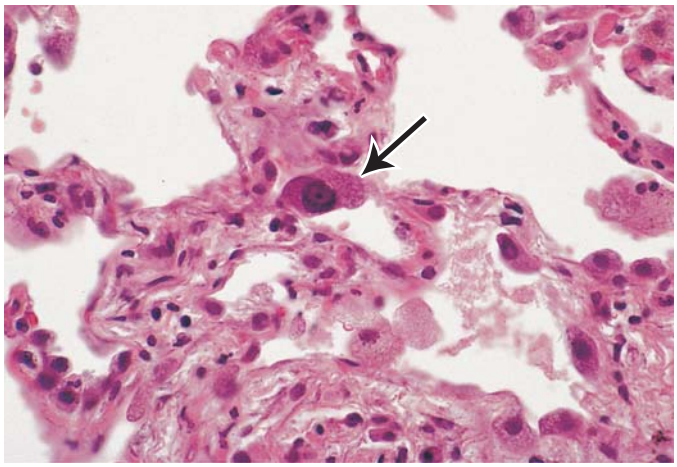

FIGURE 18-35. Diffuse alveolar damage (DAD) associated with busulfan treatment. An atypical pneumocyte (*arrow*) is seen in a case of organizing DAD associated with busulfan therapy.

Radiation Pneumonitis

There are two forms of radiation pneumonitis: acute DAD and chronic pulmonary fibrosis. Alveolar injury is believed to be caused by oxygen radicals generated by the radiolysis of water (see Chapter 1).

Acute radiation pneumonitis occurs in as many as 10% of patients irradiated for lung or breast cancer or for mediastinal lymphoma. DAD caused by radiation is mostly dose related and appears 1–6 months after radiation therapy, when patients develop fever, cough and dyspnea. Pathologically, the lungs show atypical alveolar lining cells, with enlarged hyperchromatic nuclei and multinucleated cells. Most patients recover from acute radiation pneumonitis.

In **chronic radiation pneumonitis,** interstitial fibrosis may follow acute DAD or develop insidiously. Lung biopsy demonstrates interstitial fibrosis, radiation-induced vascular changes and atypical type II pneumocytes. The disease is asymptomatic unless it affects a substantial volume of the lung.

Paraquat

Exposure to paraquat, a common herbicide, may cause DAD. Pulmonary disease becomes apparent 4–7 days after ingestion, as ARDS develops. Patients rarely recover once pulmonary complications have evolved. A curious intra-alveolar exudate and organization occur, as well as the more usual interstitial fibrosis. The intra-alveolar exudate organizes in such a way that the alveolar framework persists and the airspaces are filled with loose granulation tissue.

Neonatal Respiratory Distress Syndrome Resembles ARDS

Neonatal respiratory distress syndrome (NRDS) (see Chapter 6) results from immaturity of the surfactant system at birth, usually because of severe prematurity. The

advent of surfactant replacement therapy and better ventilatory techniques have increased survival and decreased the frequency of complications of NRDS in older premature infants, but very premature infants may still develop **bronchopulmonary dysplasia (BPD)**. Previously, BPD reflected damage to lung acini and subsequent repair, which led to atelectasis, fibrosis and destruction of clusters of acini. With the advent of surfactant replacement therapy, the necrotizing bronchiolitis and alveolar septal fibrosis of BPD have largely disappeared, and decreased alveolarization is the main finding now. NRDS and BPD are discussed in further detail in Chapter 6.

RARE ALVEOLAR DISEASES

Alveolar Proteinosis Features Excess Intra-Alveolar Lipid-Rich Material

Alveolar proteinosis, also called **lipoproteinosis,** is a rare condition in which alveoli are filled with a granular eosinophilic material rich in surfactant. Initially considered idiopathic, alveolar proteinosis is now known to be associated with compromised immunity; various cancers, particularly leukemia and lymphoma; respiratory infections; and exposure to environmental inorganic dusts. There is also a rare congenital form caused by a point mutation in the gene for the granulocyte-macrophage colony-stimulating factor (GM-CSF) receptor.

PATHOPHYSIOLOGY: Alveolar proteinosis is thought to be related to defective surfactant clearance by macrophages. It has recently been attributed to defective activity, or deficiency, of GM-CSF. Anti–GM-CSF autoantibodies are detected in most patients with the idiopathic form of the disease, suggesting an autoimmune etiology. The pathogenesis of secondary alveolar proteinosis is less clear, but appears related to defective macrophage function via altered GM-CSF activity.

PATHOLOGY: The lungs are very heavy and viscid, and yellow fluid leaks from cut surfaces. They contain scattered, firm, yellow-white nodules that vary in diameter from a few millimeters to 2 cm. Granular material composed of surfactant, cell debris, foamy macrophages and detached type II pneumocytes is seen in alveoli, respiratory bronchioles and alveolar ducts (Fig. 18-36). Electron microscopy shows characteristic surfactant tubular myelin structures. Importantly, the interstitial architecture of the lung is intact, and little inflammation is present.

CLINICAL FEATURES: A few cases have been reported in infants and children, but alveolar proteinosis is a disease of adults. Patients have fever, productive cough and dyspnea. Chest radiographs show diffuse, bilateral, symmetric, alveolar infiltrates, which may radiate from the hilar regions. Repeated respiratory tract infections, often with fungi or *Nocardia,* are common, perhaps due to altered neutrophil and macrophage activity. Infections occur at both pulmonary and extrapulmonary sites, suggesting a systemic predisposition to infections. Before treatment became available, alveolar proteinosis often progressed gradually to respiratory failure. Today, bronchoalveolar lavage can remove the alveolar material, and repeated lavage (sometimes for years) cures or arrests the disease. GM-CSF reconstitution is being investigated.

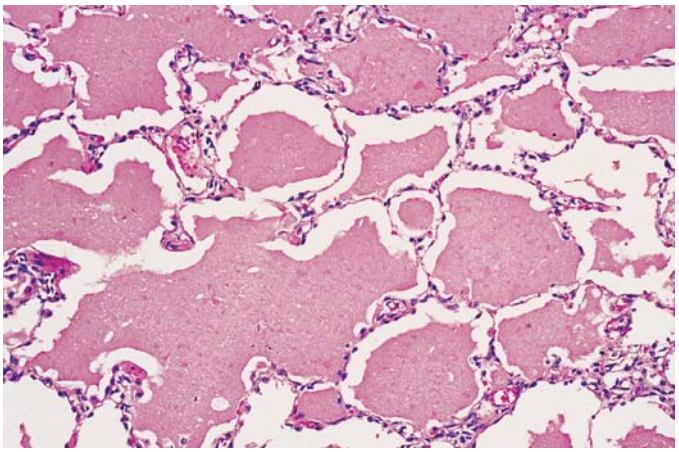

FIGURE 18-36. Alveolar proteinosis. Alveoli and alveolar ducts contain abundant granular, eosinophilic material.

Diffuse Pulmonary Hemorrhage Syndromes Are Immunologic Disorders

Diffuse alveolar hemorrhage can occur in diverse clinical settings (Table 18-2). These diseases are characterized by acute hemorrhage (numerous intra-alveolar red blood cells) or chronic hemorrhage (hemosiderosis). In virtually all of these disorders, neutrophils infiltrate the alveolar capillary walls **(neutrophilic capillaritis),** reminiscent of leukocytoclastic vasculitis seen in other organs such as the skin. This finding tends to be most prominent in hemorrhagic syndromes associated with polyangiitis with granulomatosis (formerly Wegener granulomatosis) or systemic lupus erythematosus.

Some diffuse pulmonary hemorrhage syndromes are associated with characteristic immunofluorescence patterns. Linear fluorescence along alveolar walls is seen in antibasement membrane antibody disease, or Goodpasture syndrome. A granular pattern occurs in immune complex–associated diseases, such as systemic lupus erythematosus. Pauci-immune disorders consist of antineutrophil cytoplasm antibody (ANCA)-associated diseases (e.g., polyangiitis with granulomatosis, microscopic polyangiitis or idiopathic pulmonary hemorrhage syndromes), in which no etiology or immunologic mechanism can be determined (Table 18-2).

Goodpasture Syndrome

Goodpasture syndrome entails a triad: diffuse alveolar hemorrhage, glomerulonephritis and circulating cytotoxic autoantibody to a component of basement membranes. Cross-reactivity between alveolar and glomerular basement membranes accounts for the simultaneous attack on the lung and kidney (see Chapter 22 for pathogenetic details).

PATHOLOGY: Patients with Goodpasture syndrome have extensive intra-alveolar hemorrhage (Fig. 18-37A). Their lungs are dark red and heavy

TABLE 18-2
CONDITIONS OF PULMONARY HEMORRHAGE

Disease	Immunologic Mechanism	Immunofluorescence Pattern
Goodpasture syndrome	Antibasement membrane antibody	Linear
Microscopic polyangiitis	Antineutrophilic cytoplasmic antibody (ANCA)	Negative/pauci-immune
Systemic lupus erythematosus	Immune complexes	Granular
Mixed cryoglobulinemia		
Henoch-Schönlein purpura		
Immunoglobulin A (IgA) disease		
Granulomatosis with polyangiitis (formerly Wegener granulomatosis)	ANCA	Negative or pauci-immune
Idiopathic glomerulonephritis		
Idiopathic pulmonary hemorrhage	No immunologic marker	

in the acute phase and rusty brown later, when the erythrocytes have been phagocytosed. Red blood cells and hemosiderin-laden macrophages fill airspaces. The presence of neutrophils in and around alveolar capillaries may suggest an "alveolitis," but this reaction may be transient. Alveolar septa are mildly thickened by interstitial fibrosis and type II pneumocyte hyperplasia is seen. By immunofluorescence, IgG and complement are deposited in the basement membranes of alveoli and glomeruli (Fig. 18-37B).

CLINICAL FEATURES: Goodpasture syndrome may affect adults of either sex and any age, but it occurs mostly in young men. Most (95%) patients present with hemoptysis, often accompanied by dyspnea, weakness and mild anemia. Evidence of glomerulonephritis follows pulmonary manifestations within about 3 months (1 week to 1 year), although some patients do not develop renal disease. Radiography reveals diffuse, bilateral alveolar infiltrates, which may resolve rapidly in a matter of days as erythrocytes lyse and are phagocytosed. Hypoxemia and respiratory alkalosis are common, but respiratory function returns to normal as the hemorrhage resolves. The diagnosis is made on the basis of a renal or pulmonary biopsy.

Goodpasture syndrome is treated with corticosteroids, cytotoxic drugs and plasmapheresis. Before such aggressive treatment was used, the mortality of Goodpasture syndrome was 80%. Even with current therapy, 2-year survival is now only 50%, and the outlook is worse if renal failure develops.

Idiopathic Pulmonary Hemorrhage

This rare disease (also called **idiopathic pulmonary hemosiderosis**) is characterized by diffuse alveolar bleeding similar to that of Goodpasture syndrome but without renal involvement or antibasement membrane antibodies. It is microscopically indistinguishable from the lung of Goodpasture syndrome.

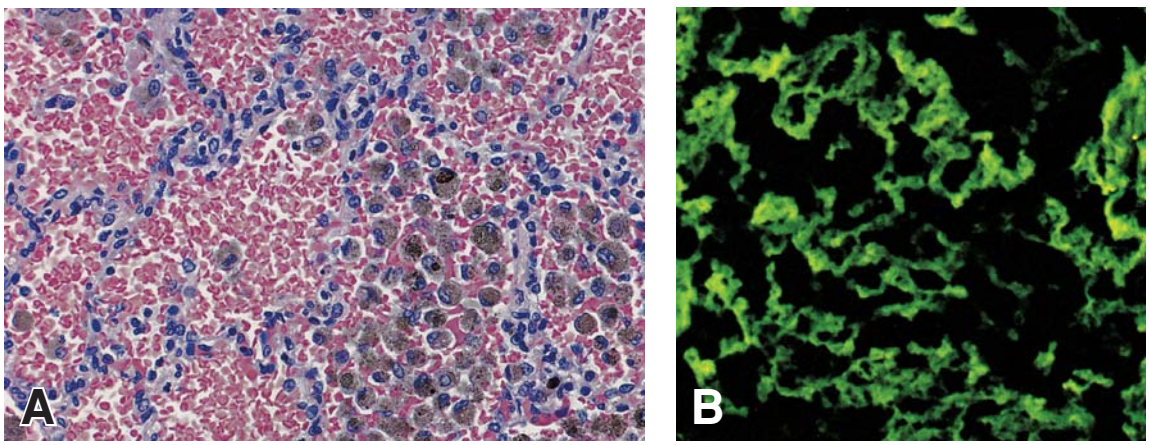

FIGURE 18-37. Goodpasture syndrome. A. A section of lung shows extensive intra-alveolar hemorrhage (*left*) and collections of hemosiderin-laden macrophages (*right*). Alveolar septa are thickened, and alveoli are lined by hyperplastic type II pneumocytes. **B.** Linear deposition of immunoglobulin G (IgG) within the alveolar septa is demonstrated by immunofluorescence.

CLINICAL FEATURES: Idiopathic pulmonary hemosiderosis affects mainly children, but 20% of patients are adults, usually younger than 30. Males predominate, 2:1, among adults, but sex distribution is equal in children. Patients complain of cough (with or without hemoptysis), dyspnea, substernal chest pain, fatigue and iron-deficiency anemia. Pulmonary hemorrhages are recurrent and intermittent. The course is more protracted than that of Goodpasture syndrome.

The response to corticosteroids is variable, and mean survival is 3–5 years. One fourth of patients die rapidly of massive hemorrhage. Another 25% have persistent, active disease; repeated episodes of hemoptysis result in interstitial fibrosis and cor pulmonale. In another 1/4 of patients, the disease remains inactive, but dyspnea and anemia may persist. The remaining patients recover completely without recurrence.

Hypersensitivity to cow's milk in infants and children generally younger than 2 years can result in diffuse pulmonary hemorrhage similar to that seen in idiopathic pulmonary hemorrhage. Removal of milk from the diet ameliorates the condition.

Eosinophilic Pneumonia Is Largely a Hypersensitivity Reaction

Eosinophilic pneumonia entails accumulation of eosinophils in alveolar spaces. The disease is classified as **idiopathic** or **secondary** to an underlying illness (Table 18-3).

TABLE 18-3
TYPES OF EOSINOPHILIC PNEUMONIA

Idiopathic
Chronic eosinophilic pneumonia
Acute eosinophilic pneumonia
Simple eosinophilic pneumonia (Löffler syndrome)
Secondary Eosinophilic Pneumonia
Infection
Parasitic
Tropical eosinophilic pneumonia
Ascaris lumbricoides, Toxocara canis, filaria
Dirofilaria
Fungal
Aspergillus
Drug induced
Antibiotics
Cytotoxic drugs
Anti-inflammatory agents
Antihypertensive drugs
L-Tryptophan (eosinophilic fasciitis)
Immunologic or systemic diseases
Allergic bronchopulmonary aspergillosis
Eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome)
Hypereosinophilic syndrome

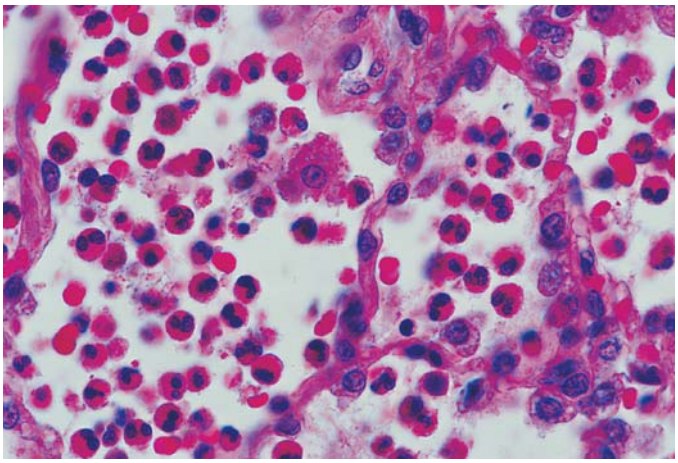

FIGURE 18-38. Eosinophilic pneumonia. Alveolar spaces are filled with an inflammatory exudate composed of eosinophils and macrophages. Alveolar septa are thickened by the presence of numerous eosinophils.

Idiopathic Eosinophilic Pneumonia

SIMPLE EOSINOPHILIC PNEUMONIA: Simple eosinophilic pneumonia (Löffler syndrome) is a mild condition characterized by fleeting pulmonary infiltrates, which usually resolve within a month. Patients typically have peripheral blood eosinophilia but are often asymptomatic. Histologically, the lung shows eosinophilic pneumonia, but the diagnosis is usually established clinically, and lung biopsy is rarely performed.

ACUTE EOSINOPHILIC PNEUMONIA: Patients present with acute (<7 days) symptoms, including fever, hypoxemia and diffuse interstitial and alveolar infiltrates on chest radiograph. The etiology is not known but is thought to be a hypersensitivity reaction. Peripheral blood eosinophilia is often absent, but bronchoalveolar lavage consistently contains increased eosinophils. Histologically, the lung shows eosinophilic pneumonia accompanied by features of diffuse alveolar damage (i.e., hyaline membranes). Patients respond dramatically to corticosteroids, and unlike chronic eosinophilic pneumonia, acute eosinophilic pneumonia does not recur.

CHRONIC EOSINOPHILIC PNEUMONIA: The etiology of chronic eosinophilic pneumonia is unknown, but an allergic diathesis is noted in some patients.

PATHOLOGY: Alveolar spaces are flooded with eosinophils, alveolar macrophages and a proteinaceous exudate (Fig. 18-38). Some cases may also show an eosinophilic interstitial pneumonia. Hyperplasia of type II pneumocytes may be prominent. Eosinophilic abscesses, with central masses of necrotic eosinophils surrounded by palisaded macrophages, are sometimes found. A mild eosinophilic vasculitis may be seen. An organizing pneumonia pattern is also occasionally described (see below).

CLINICAL FEATURES: Patients have fever, night sweats, weight loss, cough productive of eosinophils and dyspnea. Asthma is present in many patients, and circulating eosinophilia may be conspicuous. The chest radiograph is diagnostic and has been described as "the photographic negative of pulmonary edema," characterized by peripheral alveolar infiltrates with

sparing of the hilum. The response to corticosteroids is dramatic and helps confirm the diagnosis.

Secondary Eosinophilic Pneumonia

Eosinophilic pneumonia can occur in a variety of clinical settings, including parasitic or fungal infection, drug toxicity and systemic disorders such as Churg-Strauss syndrome (Table 18-3). In industrialized countries, the most frequent cause of eosinophilic pneumonia is drug hypersensitivity, including reactions to antibiotics, anti-inflammatory agents, cytotoxic drugs and antihypertensive agents. The pulmonary disease resolves without long-term sequelae. The clinical presentations and histologic findings are the same as described above.

The classic form of **infectious eosinophilic pneumonia** associated with parasitic infection is **tropical eosinophilic pneumonia**. Migration of parasites through the lung elicits an acute, self-limited, respiratory illness, characterized clinically by fever, a cough productive of sputum containing eosinophils and transient pulmonary infiltrates.

In temperate zones, *Ascaris lumbricoides* is the usual culprit, but *Toxocara canis* also occasionally is involved. However, the most distinctive infection associated with eosinophilic pneumonia is allergic bronchopulmonary aspergillosis (see above).

In tropical regions, eosinophilic pneumonia is most commonly a response to infestation with the filarial nematodes *Wuchereria bancrofti* and *Brugia malayi,* although other parasites may also be responsible.

Endogenous Lipid Pneumonia Reflects Bronchial Obstruction

This disease, also called "golden pneumonia," is a localized condition distal to an obstructed airway, which is characterized by lipid-laden macrophages in alveolar spaces. The size of the affected area corresponds to the caliber of the involved bronchus. Bronchial obstruction leads to retention of secretions and breakdown products of inflammatory and epithelial cells. Although the protein component is readily digested, lipids are phagocytosed by macrophages, which fill alveoli distal to the obstruction.

PATHOLOGY: Endogenous lipid pneumonia has a characteristic golden-yellow color, from lipid accumulation within alveolar macrophages. Alveoli are flooded by foamy macrophages with needle-shaped clefts characteristic of cholesterol crystals, with mild chronic inflammation and fibrosis. Alveolar walls are intact. If the obstruction is relieved, the affected lung can return to its normal state unless bronchiectasis and chronic recurrent bronchopneumonia have caused irreversible damage.

Exogenous Lipid Pneumonia Is a Response to Aspirated Oils

Causes of exogenous pneumonia include mineral oil (a laxative and a carrier for medications in nose drops), vegetable oils used in cooking and animal oils ingested in the form of cod-liver oil and other vitamin preparations. Oil-based contrast media used for radiologic bronchography have also been associated with the disorder. Exogenous lipid pneumonia is most common in older individuals, who take nose drops or laxatives at bedtime and aspirate during sleep. Computed tomography may reveal a spiculated mass that appears worrisome for malignancy. Children may aspirate oily medications while vigorously resisting the dosing.

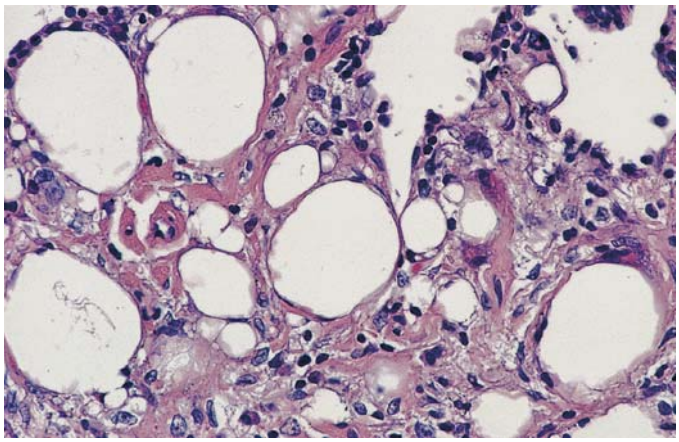

FIGURE 18-39. Exogenous lipoid pneumonia (mineral oil aspiration). The cystic spaces are empty because the lipid was washed out during tissue processing. A giant cell reaction is also present.

PATHOLOGY: Exogenous lipid pneumonia is gray, greasy and poorly demarcated. Foamy macrophages are seen in alveolar and interstitial spaces (Fig. 18-39). Large oil droplets in both locations are surrounded by foreign body granulomas. As processing for paraffin embedding removes most of the oil, there are empty vacuolar spaces in histologic sections. In chronic cases, affected areas may become densely fibrotic.

Patients with exogenous lipid pneumonia are usually asymptomatic; the condition comes to medical attention when a mass simulating an infection or a tumor is seen on a chest radiograph.

OBSTRUCTIVE PULMONARY DISEASES

Several diseases, including chronic bronchitis, emphysema, asthma and in some classifications bronchiectasis and cystic fibrosis, are grouped because they all entail obstruction to airflow in the lungs.

Chronic obstructive pulmonary disease (COPD) includes chronic bronchitis and emphysema, in which forced expiratory volume, measured by spirometry, is decreased.

Airflow can be reduced by increasing resistance to airflow or by reducing outflow pressure. In the lung, narrowed airways produce increased resistance, whereas loss of elastic recoil results in diminished pressure. Airway narrowing occurs in chronic bronchitis or asthma, and emphysema causes loss of recoil.

In Chronic Bronchitis Patients Have a Chronic Productive Cough without a Discernible Cause for 50% or More Days during 2 or More Years

The pathologic definition of the disease is less satisfactory, as its morphologic alterations are a continuum; mild chronic bronchitis may show normal histology.

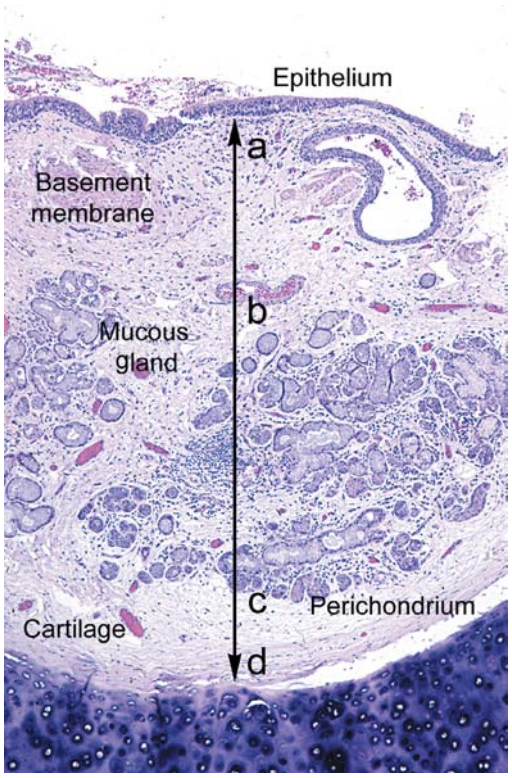

FIGURE 18-40. Chronic bronchitis. The bronchial submucosa is greatly expanded by hyperplastic submucosal glands that compose well over 50% of the thickness of the bronchial wall. The Reid index equals the maximum thickness of the bronchial mucous glands internal to the cartilage (*b to c*) divided by the bronchial wall thickness (*a to d*).

ETIOLOGIC FACTORS: ***Since 90% of chronic bronchitis cases are smokers, the disease mainly reflects the consequences of cigarette smoke (see Chapter 8).*** Chronic bronchitis occurs in less than 5% of nonsmokers, 10%–15% of moderate smokers and over 25% of heavy smokers. The frequency and severity of acute respiratory tract infections are increased in patients with chronic bronchitis; conversely, infections have been incriminated in its etiology and progression. Chronic bronchitis occurs more often in people in areas of substantial air pollution and in workers exposed to toxic industrial inhalants, but the effects of cigarette smoking far outweigh other contributing factors.

How cigarette smoke and other pollutants injure bronchi is not well understood. Experimentally, rodents that inhale cigarette smoke or SO_2, or are given dilute acids by instillation, exhibit squamous metaplasia of the bronchial epithelium. A similar change occurs when certain proteases are introduced into the bronchi, and this effect can be prevented by pretreating with antiproteases. Bronchial epithelial metaplasia also occurs in rodents given adrenergic and cholinergic agonists, suggesting that autonomic stimulation may play a role in the pathogenesis of chronic bronchitis.

PATHOLOGY: The main pathology in chronic bronchitis is increased bronchial mucus-secreting tissue (Fig. 18-40). Two types of cells line bronchial mucous glands: the more abundant pale mucous cells, and basophilic, granular serous cells. In ***chronic bronchitis, mucous cells undergo hyperplasia and hypertrophy and are increased relative to serous cells.*** Thus, both individual acini and glands enlarge (Fig. 18-41).

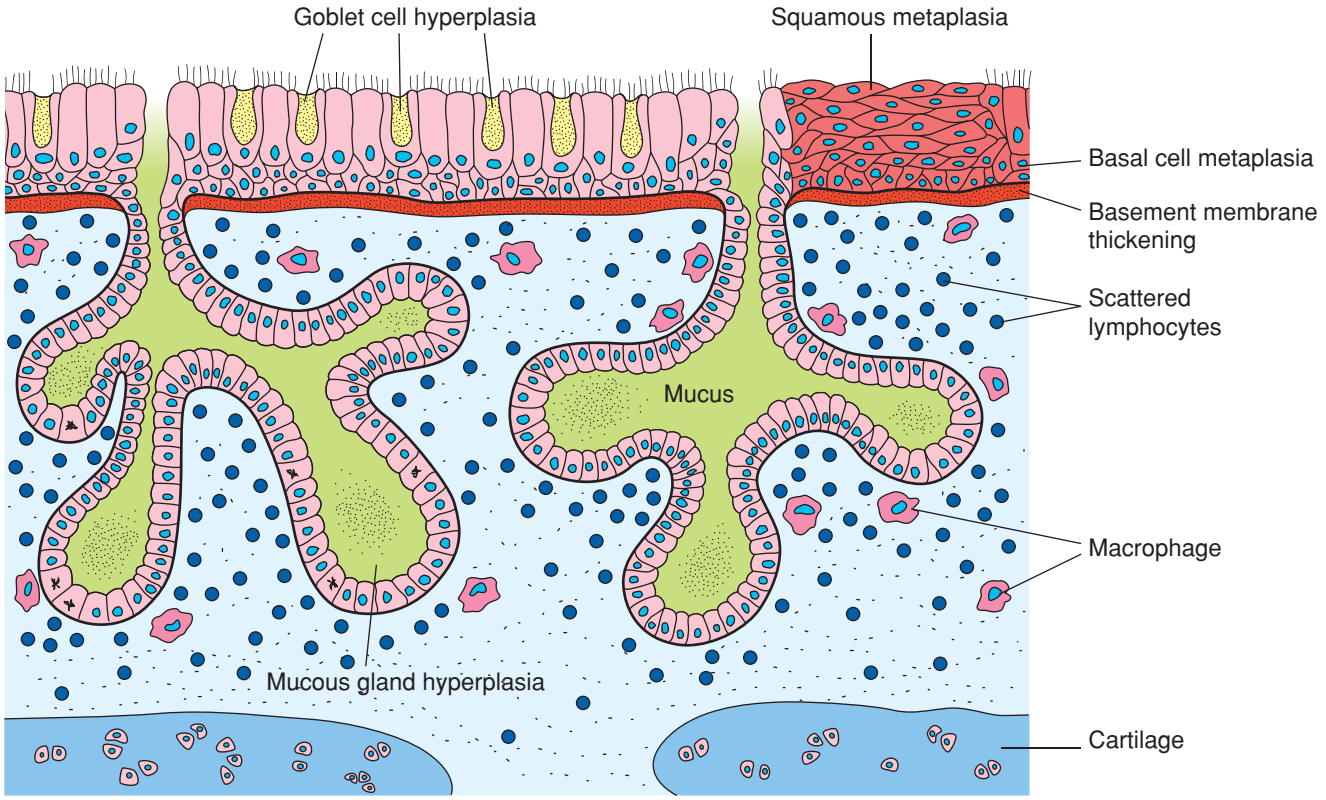

FIGURE 18-41. Chronic bronchitis. Morphologic changes in chronic bronchitis.

The Reid index measures the size of the mucous glands (Fig. 18-40): the area occupied by the glands in the plane vertical to the epithelium as a proportion of the thickness of the entire bronchial wall (basement membrane to inner perichondrium). A normal Reid index is 0.4 or less; in chronic bronchitis, it is more than 0.5.

Other morphologic changes in chronic bronchitis are variable and include:

- Excess mucus in central and peripheral airways
- "Pits" on the surface of the bronchial epithelium, which represent dilated ducts into which several bronchial glands open
- Thickening of the bronchial wall by mucous gland enlargement and edema, encroaching on the bronchial lumen
- Increased numbers of goblet cells (hyperplasia) in the bronchial epithelium
- Increased smooth muscle, which may indicate bronchial hyperreactivity
- Squamous metaplasia of the bronchial epithelium, reflecting epithelial damage from tobacco smoke, an effect that is probably independent of the other changes seen in chronic bronchitis

CLINICAL FEATURES: Chronic bronchitis is often accompanied by emphysema (see below), and separating the contributions of each in an individual patient may be difficult. In general, patients with mainly chronic bronchitis have had a productive cough for many years. Cough and sputum production are initially more severe in the winter but progress over time from hibernal to perennial. Exertional dyspnea and cyanosis supervene, and cor pulmonale may ensue. The combination of cyanosis and edema due to cor pulmonale has led to the label "blue bloater" for such patients.

In patients with advanced chronic bronchitis, multiple factors such as pulmonary infections, thromboembolism, left ventricular failure and major episodes of air pollution may precipitate acute respiratory failure, with progressive hypoxemia and hypercapnia. Because of retained mucous secretions, people with chronic bronchitis are prone to bacterial lung infections, particularly with *Haemophilus influenzae* and *S. pneumoniae.*

People with chronic bronchitis must be warned to stop smoking. Prompt antibiotic treatment of pulmonary infections, use of bronchodilator drugs and occasionally bronchopulmonary drainage are mainstays of treatment.

Emphysema Causes Overinflation of the Lungs in Smokers

Emphysema is a chronic lung disease in which airspaces distal to terminal bronchioles are enlarged owing to destruction of their walls, without fibrosis. Although it is classified in anatomic terms, the severity of emphysema is more important than the anatomic type. In practical terms, as emphysema becomes more severe, it becomes more difficult to classify. Moreover, several anatomic patterns may be present in the same lung.

ETIOLOGIC FACTORS AND PATHOPHYSIOLOGY: The major cause of emphysema is cigarette smoking. Moderate to severe emphysema is rare in nonsmokers (see Chapter 8). In considering the pathogenesis of emphysema, it is thought that a balance exists between elastin synthesis and catabolism in the normal lung. Emphysema results when elastolytic activity increases or antielastolytic activity is reduced (Fig. 18-42).

Increased numbers of neutrophils, which contain serine elastase and other proteases, are found in the bronchoalveolar lavage fluid of smokers. Smoking also interferes with α_1-antitrypsin (α_1-AT) activity, by oxidizing methionine residues in α_1-antitrypsin. In this way, unopposed and increased elastolytic activity leads to destruction of elastic tissue in the walls of distal airspaces, impairing elastic recoil. At the same time, other cellular proteases may be involved in injury to the airspace walls. This theory, although attractive, awaits further confirmation.

α_1-ANTITRYPSIN (α_1-AT) DEFICIENCY: Hereditary lack of α_1-AT accounts for about 1% of patients with COPD and is much more common in young people with severe emphysema. α_1-AT is a circulating inhibitor of serine proteases, including elastase, trypsin, chymotrypsin, thrombin and bacterial proteases. Made in the liver, it accounts for 90% of blood antiproteinase activity. In the lung, it inhibits neutrophil elastase, an enzyme that digests elastin and other alveolar wall components.

MOLECULAR PATHOGENESIS: The amount and type of α_1-AT is determined by a pair of codominant *Pi* (protease inhibitor) alleles. The most common allele is *PiM and the most common genotype is PiMM,* but more than 100 variants are known. The amount of α_1-AT in the blood depends on the genotype. Some mutant forms fail to fold properly and are thus targeted for proteasomal degradation in liver cells. Other mutant forms may polymerize and accumulate within hepatocytes. The most serious abnormality involves the *PiZ* allele, which occurs in 5% of the population. It is more common in people of Scandinavian origin and is rare in Jews, blacks and Japanese. Because the abnormal protein is poorly secreted by the liver, plasma α_1-AT in *PiZZ* homozygotes is only 15%–20% of normal. These people are at risk for cirrhosis of the liver (see Chapter 20) and emphysema. **Most patients with clinically diagnosed emphysema under age 40 have α_1-AT deficiency (PiZ).** In *PiZZ* homozygotes who do not smoke, emphysema begins between ages 45 and 50; those who smoke develop it 5–10 years earlier. Most nonsmoking *PiZZ* homozygotes show no evidence of emphysema. The association of α_1-AT deficiency with emphysema supports the concept that cigarette smoking by itself causes emphysema by altering the balance of proteases and antiproteases in the lung.

PATHOLOGY: Emphysema is morphologically classified according to the location of the lesions within the pulmonary acinus (Fig. 18-43). Only the proximal acinus (the respiratory bronchiole) is affected in centrilobular emphysema, whereas the entire acinus is destroyed in panacinar emphysema.

CENTRILOBULAR EMPHYSEMA: This form of emphysema is most common. It usually accompanies cigarette smoking and is symptomatic. The clusters of terminal bronchioles near the end of the bronchiolar tree in the central part of the pulmonary lobule are destroyed (Fig. 18-44A). These are the smallest portion of the lung bounded by septa and

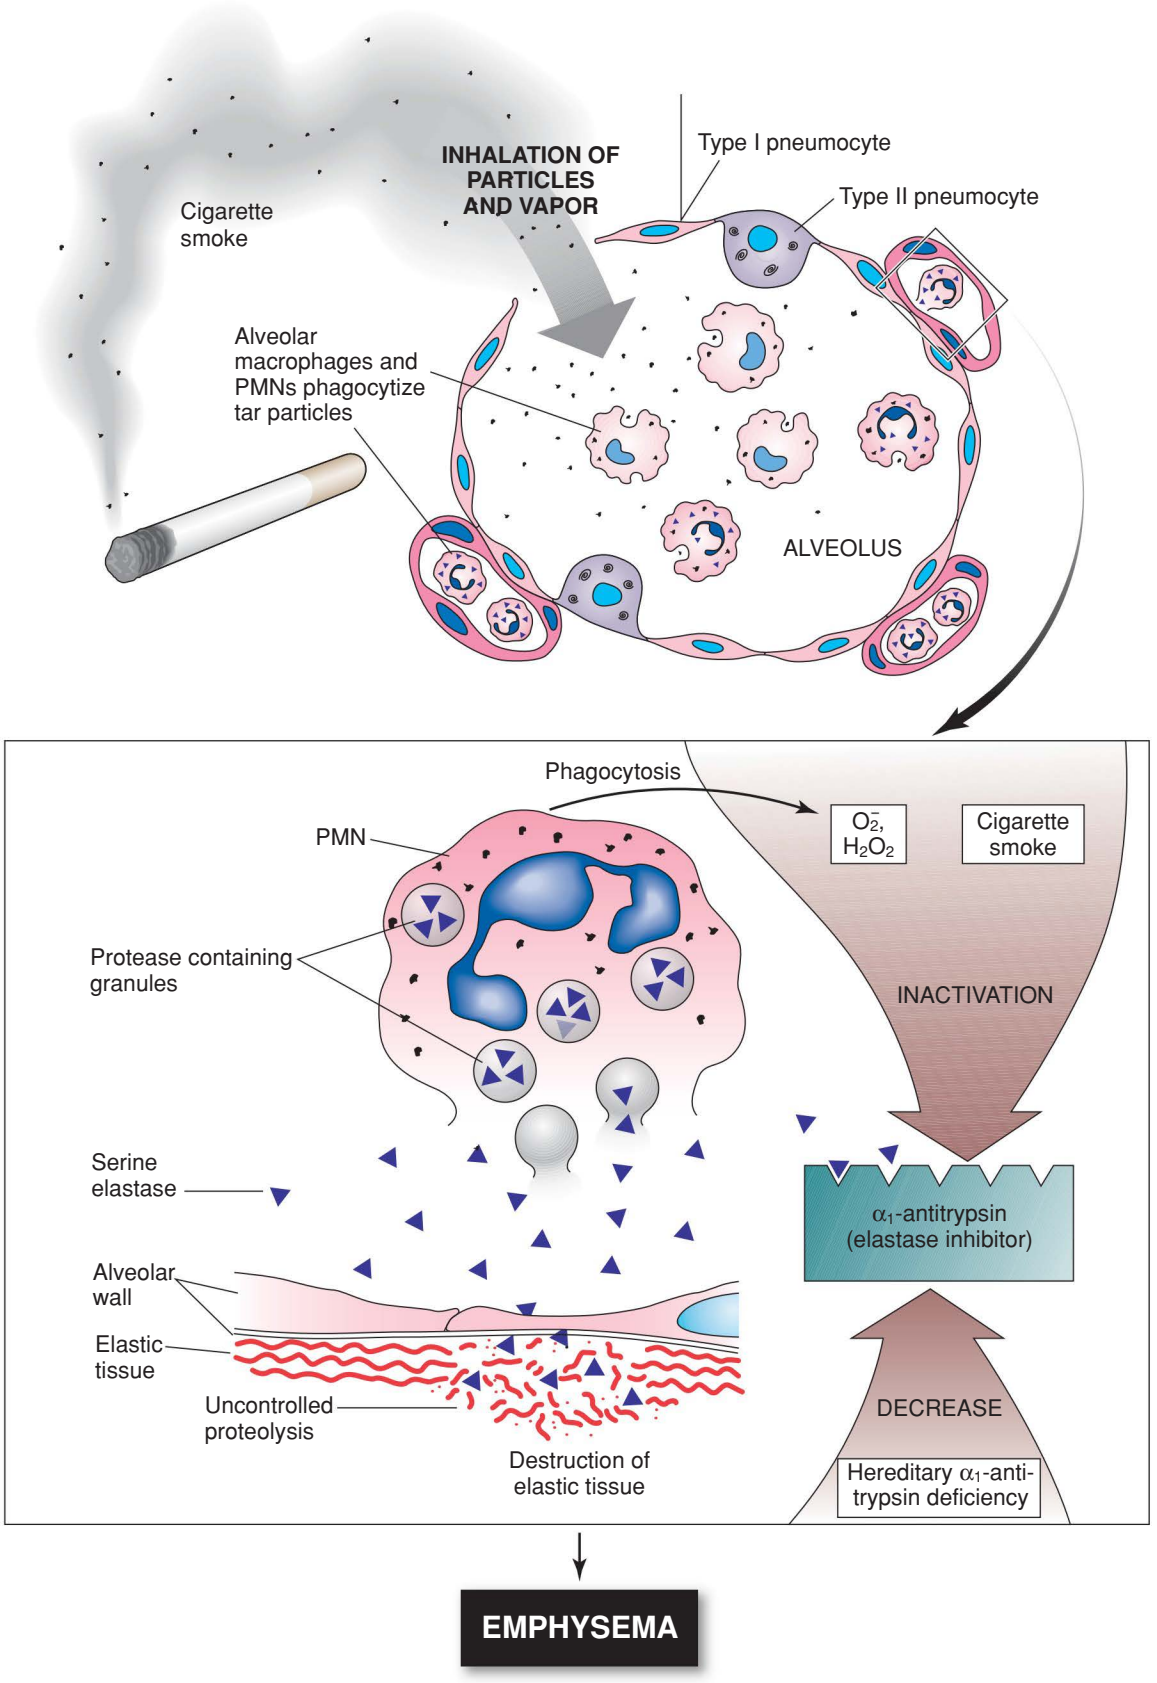

FIGURE 18-42. The proteolysis–antiproteolysis theory of the pathogenesis of emphysema. Cigarette (tobacco) smoking is closely related to the development of emphysema. Some products in tobacco smoke induce an inflammatory reaction. The serine elastase in polymorphonuclear leukocytes, a particularly potent elastolytic agent, injures the elastic tissue of the lung. Normally, this enzyme activity is inhibited by α_1-antitrypsin, but tobacco smoke, directly or through the generation of free radicals, inactivates α_1-antitrypsin (protease inhibitor). H_2O_2 = hydrogen peroxide; O_2^- = superoxide ion; *PMN* = polymorphonuclear neutrophil.

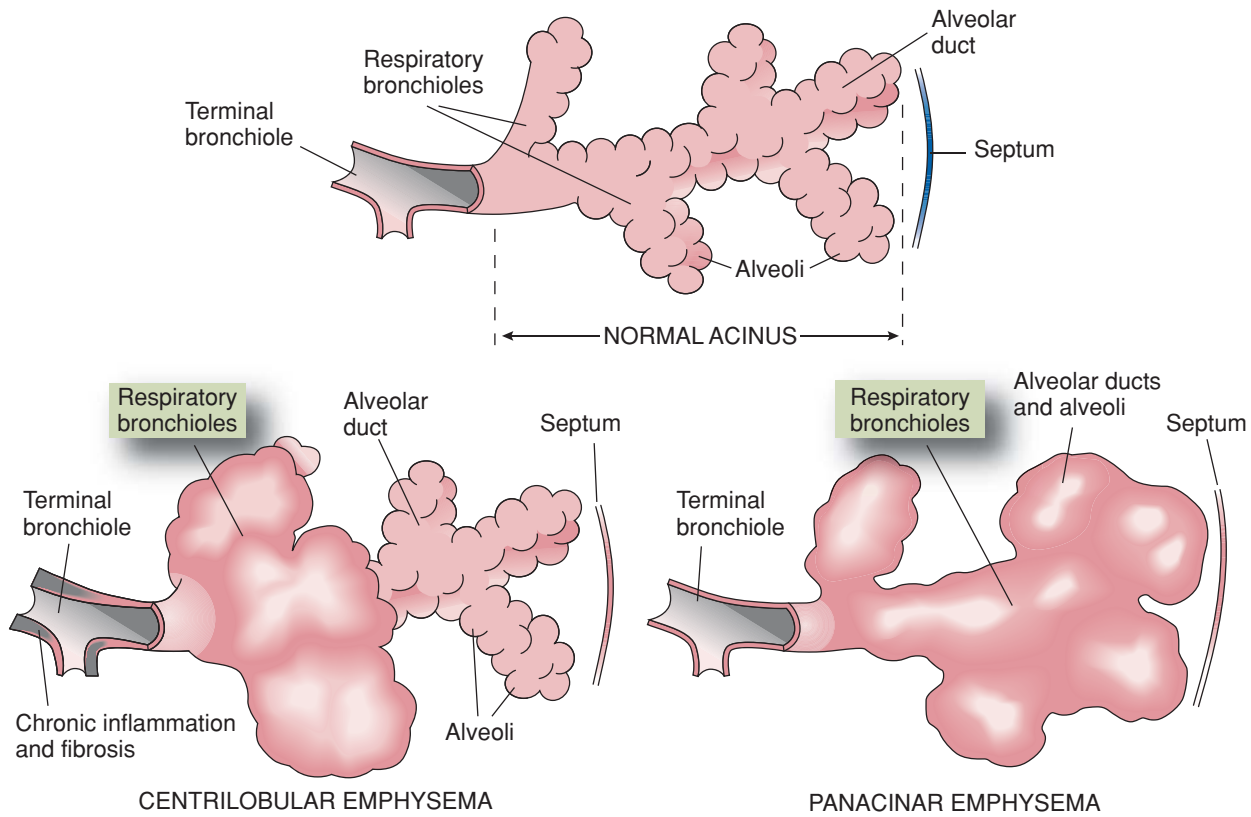

FIGURE 18-43. Types of emphysema. The acinus is the gas-exchanging structural unit of the lung distal to the terminal bronchiole. It consists of (from proximal to distal) respiratory bronchioles, alveolar ducts, alveolar sacs and alveoli. In centrilobular (proximal acinar) emphysema, the respiratory bronchioles are predominantly involved. In paraseptal (distal acinar) emphysema, the alveolar ducts are particularly affected. In panacinar (panlobular) emphysema, the acinus is uniformly damaged.

include several acini. Dilated respiratory bronchioles form enlarged airspaces separated from each other and from lobular septa by normal alveolar ducts and alveoli. As centrilobular emphysema progresses, these distal structures may also be involved (Fig. 18-44B). Bronchioles proximal to emphysematous spaces are inflamed and narrowed. Centrilobular emphysema is most severe in the upper lobes and in superior segments of the lower lobes.

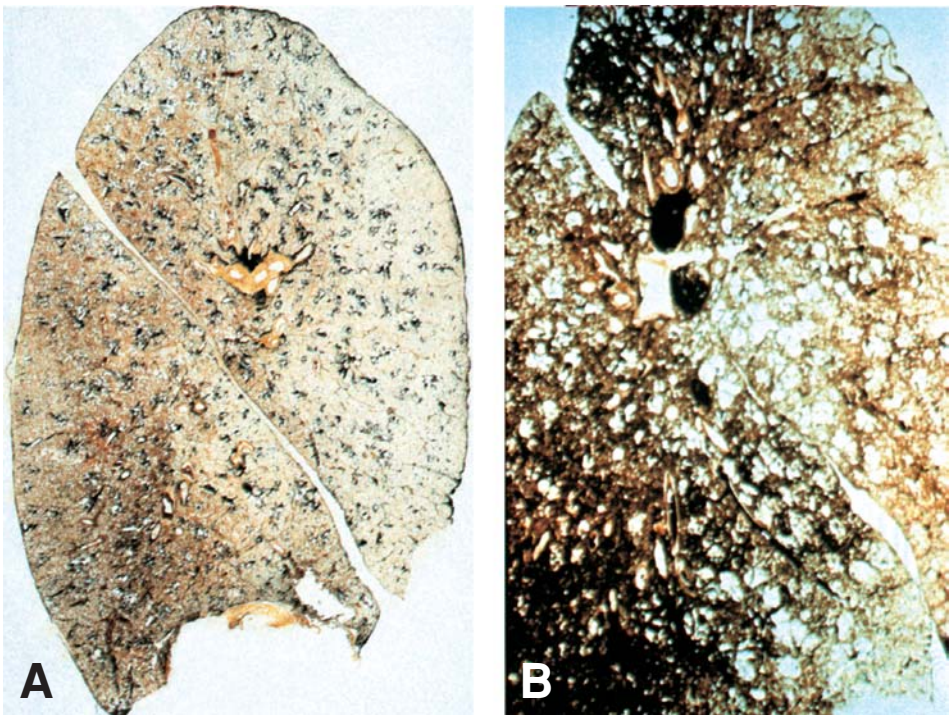

FIGURE 18-44. Centrilobular emphysema. A. A whole mount of the left lung of a smoker with mild emphysema shows enlarged airspaces scattered throughout both lobes, which represent destruction of the terminal bronchioles in the central part of the pulmonary lobule. These abnormal spaces are surrounded by intact pulmonary parenchyma. **B.** In a more advanced case of centrilobular emphysema, destruction of the lung has progressed to produce large, irregular airspaces.

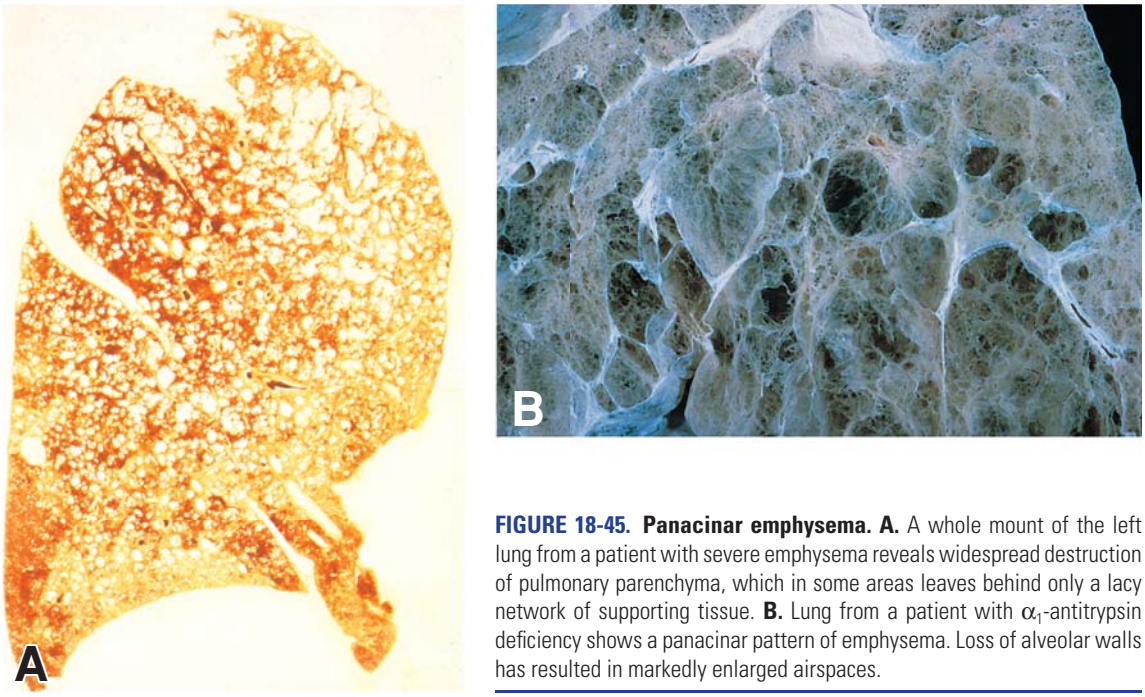

FIGURE 18-45. Panacinar emphysema. A. A whole mount of the left lung from a patient with severe emphysema reveals widespread destruction of pulmonary parenchyma, which in some areas leaves behind only a lacy network of supporting tissue. **B.** Lung from a patient with α_1-antitrypsin deficiency shows a panacinar pattern of emphysema. Loss of alveolar walls has resulted in markedly enlarged airspaces.

Focal dust emphysema, a disease of coal miners, resembles centrilobular emphysema but differs in that affected spaces are smaller and more regular and lack inflammation of the bronchioles. The lesions mainly distend, rather than destroy, alveolar walls. This disease is discussed below with coal workers' pneumoconiosis.

PANACINAR EMPHYSEMA: In panacinar emphysema, acini are uniformly involved, with destruction of alveolar septa from the center to the periphery of acini (Fig. 18-45). Loss of alveolar septa is illustrated by histologic comparison of normal lungs with those affected by α_1-AT deficiency (Fig. 18-46). In its final stage, panacinar emphysema leaves behind a lacy network of supporting tissue ("cotton-candy lung"). This type of emphysema is typically associated with α_1-AT deficiency. But it may also occur in cigarette smokers in association with centrilobular emphysema, in which cases the panacinar pattern tends to occur in more basal lung zones, while centrilobular emphysema prefers upper regions (see above).

LOCALIZED EMPHYSEMA: This disease, once called "paraseptal emphysema," entails alveolar destruction and leads to emphysema at only one or at most a few locations. The remainder of the lungs is normal. The lesion is usually found at the apex of an upper lobe in a subpleural location but may occur anywhere (Fig. 18-47). It is not clinically significant itself, but a focus of localized emphysema may rupture and cause spontaneous pneumothorax (see below). Localized emphysema can also progress to large areas of destruction, or **bullae,** which can be as small as 2 cm or can occupy an entire hemithorax.

CLINICAL FEATURES: Most patients with emphysema present at age 60 or older, with long histories of exertional dyspnea but minimal,

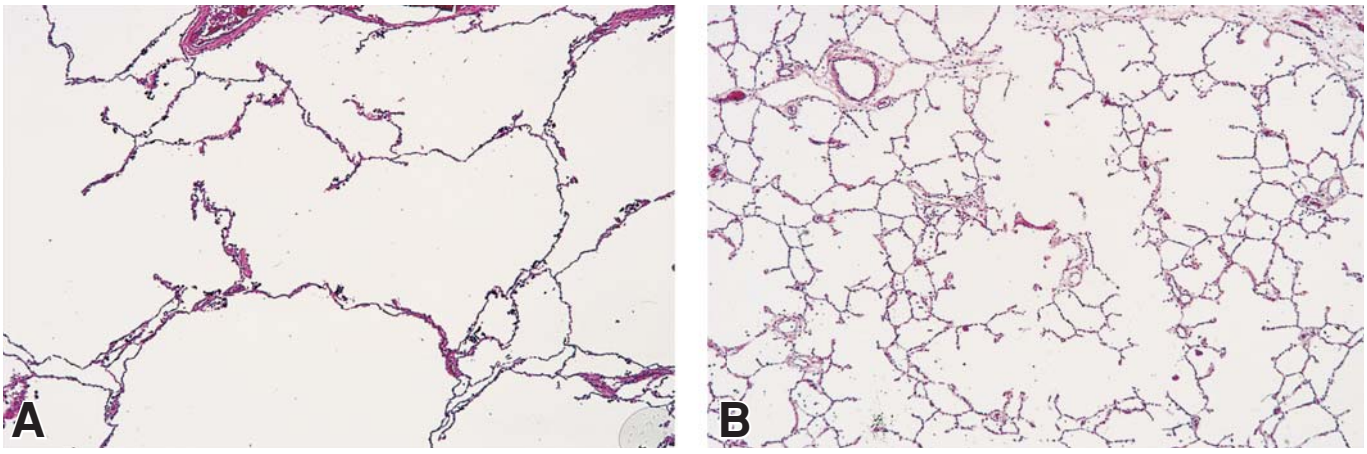

FIGURE 18-46. Panacinar emphysema. A. This lung, from a patient with α_1-antitrypsin deficiency, shows large, irregular airspaces and a markedly reduced number of alveolar walls. **B.** Extensive loss of alveolar walls in **A** is emphasized by comparison with this section of normal lung at the same magnification.

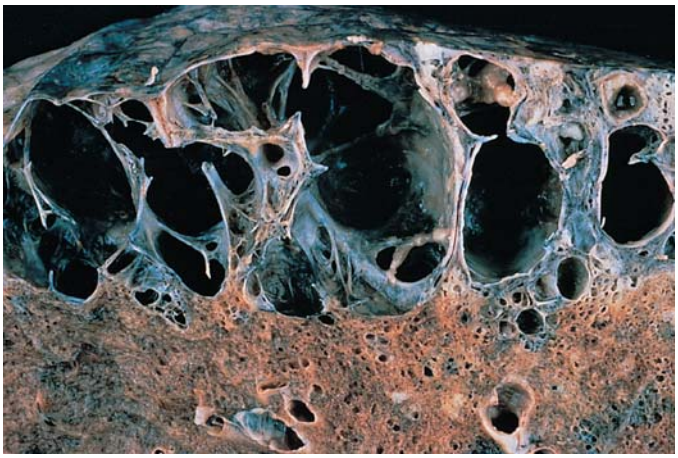

FIGURE 18-47. Localized emphysema. The subpleural parenchyma shows markedly enlarged airspaces owing to the loss of alveolar tissue.

nonproductive cough. They have lost weight and use accessory muscles of respiration to breathe. Weight loss is probably due less to lack of calories than to the increased work of breathing. Tachypnea and a prolonged expiratory phase are typical. Radiologically, the lungs are overinflated: they are enlarged, diaphragms are depressed and the posteroanterior diameter is increased (barrel chest). Bronchovascular markings do not reach the peripheral lung fields. Since these patients have increased respiratory rates and minute volumes, they can maintain arterial hemoglobin saturation at near-normal levels and so are called "pink puffers." Unlike patients with predominantly chronic bronchitis, those with emphysema are not at higher risk for recurrent pulmonary infections and are not so prone to develop cor pulmonale. Emphysema entails an inexorable decline in respiratory function and progressive dyspnea, for which no treatment is adequate.

In Asthma a Number of Stimuli Trigger Episodic Airflow Obstruction

Asthmatic patients typically have paroxysms of wheezing, dyspnea and cough. Attacks may alternate with asymptomatic periods or be superimposed on a background of chronic airway obstruction. Severe acute asthma that is unresponsive to therapy is **status asthmaticus**. Most asthmatic patients, even when apparently well, have some persistent airflow obstruction and morphologic lesions.

In the United States, bronchial asthma affects up to 10% of children and 5% of adults. The prevalence of asthma in the United States has doubled since 1980. Initial asthma attacks may occur at any age, but half of cases begin in patients under age 10, and they are twice as common in boys as in girls. By age 30, both sexes are affected equally.

ETIOLOGIC FACTORS: Asthma was once divided into **extrinsic (allergic)** and **intrinsic (idiosyncratic)** forms, depending on inciting factors. Asthma is now described in terms of the different inciting factors and the common effector pathways.

Bronchial hyperresponsiveness in asthma generally reflects inflammatory reactions to diverse stimuli. After exposure to an inciting factor (e.g., allergens, drugs, cold, exercise), inflammatory mediators released by activated macrophages, mast cells, eosinophils and basophils trigger bronchoconstriction, increased vascular permeability and mucous secretion. Resident inflammatory cells release chemotactic factors, which in turn recruit more effector cells and amplify the response of the airways. Inflammation of bronchial walls also may injure the epithelium, stimulating nerve endings and initiating neural reflexes that further aggravate and propagate the bronchospasm.

Many inflammatory mediators and chemotactic factors may participate in the bronchospasm and mucous hypersecretion of asthma. The relative contributions of the different substances probably vary with the inciting stimulus. The best-studied situation associated with the induction of asthma is inhaled allergens.

In a sensitized person, an inhaled allergen interacts with T_H2 cells and IgE antibody bound to the surface of mast cells, which are interspersed among the bronchial epithelial cells (Fig. 18-48). The T_H2 cells and mast cells release mediators of type I (immediate) hypersensitivity, including histamine, bradykinin, leukotrienes, prostaglandins, thromboxane A_2 and platelet-activating factor (PAF), as well as cytokines such as interleukin (IL)-4 and IL-5. These inflammatory mediators lead to (1) **smooth muscle contraction,** (2) **mucous secretion** and (3) **increased vascular permeability and edema.** Each of these effects is a potent, albeit reversible, cause of airway obstruction. IL-5 causes terminal differentiation of eosinophils in the bone marrow. Chemotactic factors, including leukotriene B_4 and neutrophil and eosinophil chemotactic factors, attract neutrophils, eosinophils and platelets to the bronchial wall. Eosinophils then release leukotriene B_4 and PAF, aggravating bronchoconstriction and edema. Discharge of eosinophil granules containing eosinophil cationic protein and major basic protein into the bronchial lumen further impairs mucociliary function and damages epithelial cells. Epithelial cell injury is suspected to stimulate nerve endings in the mucosa, initiating autonomic discharge that contributes to airway narrowing and mucus secretion. Leukotriene B_4 and PAF recruit more eosinophils and other effector cells, and thus act to prolong and amplify the attack.

Bronchial epithelium also plays a role in the pathogenesis of various asthma phenotypes. The barrier function of the bronchial epithelium is impaired, with disruption of tight junctions and increased permeability. The mucosal epithelium itself also secretes various cytokines and chemokines that participate in regulating cells of the immune system. Since the bronchial mucosa is the first structure to come into contact with inhaled allergens and infectious agents, the importance of epithelial cells in the pathogenesis of asthma has recently been emphasized.

ALLERGIC ASTHMA: This is the most common form of asthma and is usually seen in children. One third to one half of all patients with asthma have known or suspected reactions to such allergens as pollens, animal hair or fur and house dust contaminated with mites. Allergic asthma correlates strongly with skin-test reactivity. Half of children with asthma have substantial or complete remission of symptoms by age 20, but in many, asthma may recur after age 30.

INFECTIOUS ASTHMA: A common precipitating factor in childhood asthma is a viral respiratory tract infection rather than an allergic stimulus. In children under 2 years of age, RSV is the usual agent; in older children, rhinovirus,

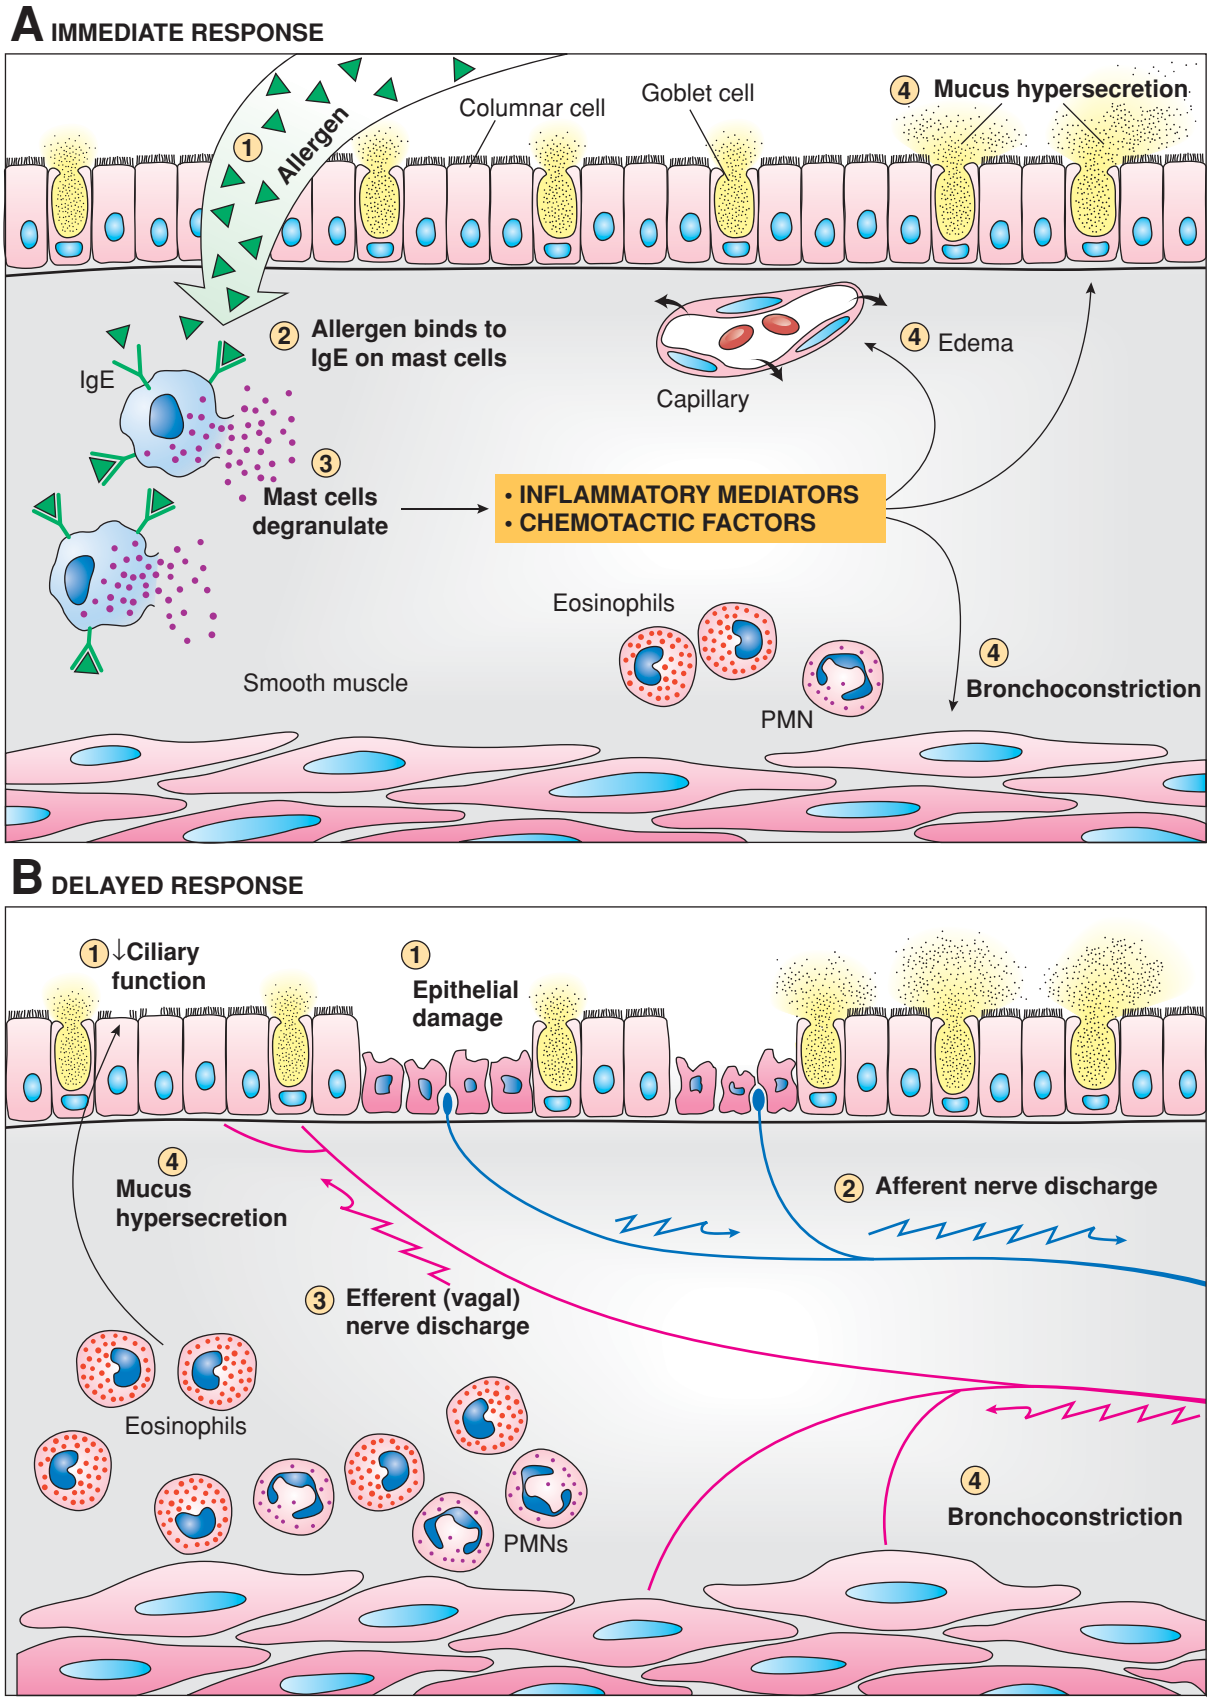

FIGURE 18-48. Pathogenesis of asthma. A. Immunologically mediated asthma. Allergens interact with immunoglobulin E (IgE) on mast cells, either on the surface of the epithelium or, when there is abnormal permeability of the epithelium, in the submucosa. Released mediators may react locally or by vagal reflexes. **B.** Discharge of eosinophilic granules further impairs mucociliary function and damages epithelial cells. Epithelial cell injury stimulates nerve endings (*in red*) in the mucosa, initiating an autonomic discharge that contributes to airway narrowing and mucus secretion. *PMNs* = polymorphonuclear neutrophils.

influenza and parainfluenza are common inciting organisms. Inflammatory responses to viral infection in susceptible people may trigger the episode of bronchoconstriction. In support of this hypothesis, bronchial hyperreactivity may persist for as long as 2 months after a viral infection in nonasthmatics.

EXERCISE-INDUCED ASTHMA: Exercise can precipitate bronchospasm in more than half of all asthmatics. In some patients, it may be the only inciting factor. Exercise-induced asthma is related to the magnitude of heat or water loss from airway epithelium. The more rapid the ventilation (severity of exercise) and the colder and drier the air breathed, the more likely is an attack of asthma. Thus, an asthmatic playing hockey on an outdoor rink in Canada in winter is more likely to have an attack than one swimming slowly in Texas during the summer. The mechanisms underlying exercise-induced asthma are unclear. It may be related to mediator release or vascular congestion secondary to rewarming of bronchi after the exertion.

OCCUPATIONAL ASTHMA: More than 80 different occupational exposures have been linked to asthma. Some substances may provoke allergic asthma via IgE-related hypersensitivity (e.g., in animal handlers, bakers and workers exposed to wood and vegetable dusts, metal salts, pharmaceutical agents and industrial chemicals). Occupational asthma may also result from direct release of mediators of smooth muscle contraction after contact with an offending agent, as is postulated in byssinosis ("brown lung"), an occupational lung disease of cotton workers. Some occupational exposures affect the autonomic nervous system directly. For instance, organic phosphorus insecticides act as anticholinesterases and produce overactivity of the parasympathetic nervous system. Substances such as toluene diisocyanate and western red cedar dust are thought to operate through hypersensitivity mechanisms, although specific IgE antibodies to these substances have not been identified.

DRUG-INDUCED ASTHMA: Drug-induced bronchospasm occurs mostly in patients with known asthma. The best-known offender is aspirin, but other nonsteroidal anti-inflammatory agents also have been implicated. Up to 10% of adult asthmatics may be sensitive to aspirin. Immediate hypersensitivity does not seem to be involved, and these patients can be desensitized by daily administrations of small doses of aspirin. Rhinitis and nasal polyps are also common in these individuals. β-Adrenergic antagonists consistently induce bronchoconstriction in asthmatics and are contraindicated in such patients.

AIR POLLUTION: Massive air pollution, usually occurring during temperature inversions, may cause bronchospasm in patients with asthma and other preexisting lung diseases. Gasses such as SO_2, nitrogen oxides and ozone are commonly implicated, but particulate carbon, carrying toxic chemicals in diesel exhaust, may also participate.

EMOTIONAL FACTORS: Psychological stress can aggravate or precipitate attacks of bronchospasm in as many as half of asthmatics. Vagal efferent stimulation is thought to be the underlying mechanism.

PATHOLOGY: The pathology of asthma has been studied in autopsies of patients who died in status asthmaticus, where the most severe lesions are described. Grossly, the lungs are highly distended with air, and airways are filled with thick, tenacious, adherent mucous plugs. Microscopically, these plugs (Fig. 18-49A) contain strips of epithelium and many eosinophils. Charcot-Leyden crystals, derived from phospholipids of the eosinophil cell membrane, are also seen (Fig. 18-24B). In some

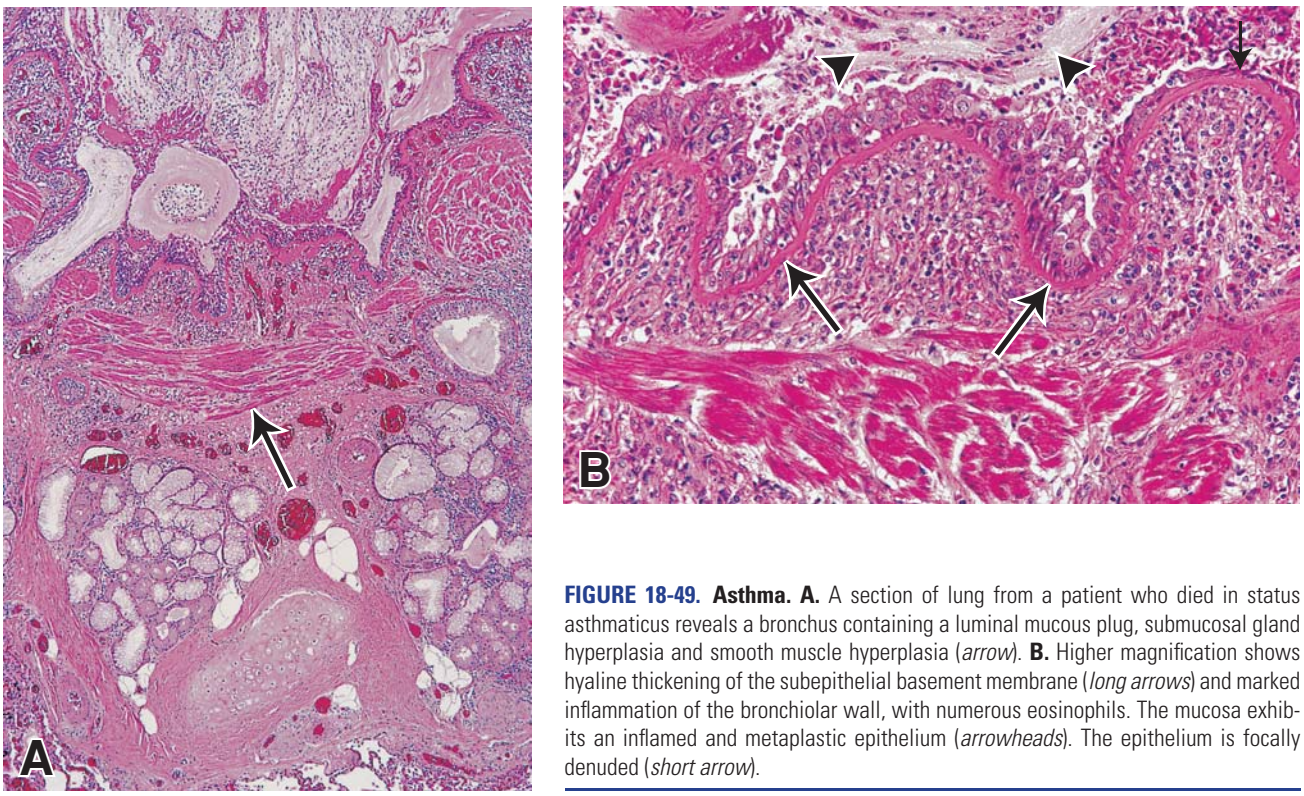

FIGURE 18-49. Asthma. A. A section of lung from a patient who died in status asthmaticus reveals a bronchus containing a luminal mucous plug, submucosal gland hyperplasia and smooth muscle hyperplasia (*arrow*). **B.** Higher magnification shows hyaline thickening of the subepithelial basement membrane (*long arrows*) and marked inflammation of the bronchiolar wall, with numerous eosinophils. The mucosa exhibits an inflamed and metaplastic epithelium (*arrowheads*). The epithelium is focally denuded (*short arrow*).

cases, mucoid casts of the airways (Curschmann spirals) may be expelled with coughing, as may compact clusters of epithelial cells (Creola bodies).

One of the most characteristic features of status asthmaticus is hyperplasia of bronchial smooth muscle. Bronchial submucosal mucous glands are also hyperplastic (Fig. 18-49A). The submucosa is edematous, with a mixed inflammatory infiltrate containing variable numbers of eosinophils. The epithelium does not show the normal pseudostratified appearance and may be denuded, with only basal cells remaining (Fig. 18-49B). The basal cells are hyperplastic, and squamous metaplasia and goblet cell hyperplasia are seen. Bronchial epithelial basement membranes are thickened, owing to an increase in collagen deep to the true basal lamina.

CLINICAL FEATURES: A typical attack of asthma begins with tightness in the chest and nonproductive cough. Inspiratory *and* expiratory wheezes appear, respiratory rate increases and the patient becomes dyspneic. The expiratory phase is particularly prolonged. The attack often ends with fits of severe coughing and expectoration of thick, mucus-containing Curschmann spirals, eosinophils and Charcot-Leyden crystals.

Status asthmaticus is severe bronchoconstriction that does not respond to drugs that usually abort the acute attack. It is serious and requires hospitalization. Patients in status asthmaticus have hypoxemia and often hypercapnia. They require oxygen and other pharmacologic interventions. Severe episodes may be fatal. The cornerstone of asthma treatment includes administration of β-adrenergic agonists, inhaled corticosteroids, cromolyn sodium, methylxanthines and anticholinergic agents. Systemic corticosteroids are reserved for status asthmaticus or resistant chronic asthma. The inhalation of bronchodilators often provides dramatic relief.

PNEUMOCONIOSES

Pneumoconioses are pulmonary diseases caused by mineral dust inhalation. Over 40 inhaled minerals cause lung lesions and radiographic abnormalities. Most, like tin, barium and iron, are innocuous and simply accumulate in the lung. However, some lead to crippling lung diseases. The specific types of pneumoconioses are named by the substance inhaled (e.g., silicosis, asbestosis, talcosis). Sometimes, the offending agent is uncertain, and the occupation is simply cited (e.g., "arc welder's lung"), as before etiologies were identified, some occupations were known to predispose to lung disease. Thus, "knife grinder's lung" was used before the disease was recognized as silicosis.

ETIOLOGIC FACTORS: ***The key factor in the genesis of symptomatic pneumoconioses is the capacity of inhaled dusts to stimulate fibrosis*** (Fig. 18-50). Thus, small amounts of silica produce extensive fibrosis, whereas coal and iron are only weakly fibrogenic.

In general, lung lesions produced by inorganic dusts reflect the dose and size of inhaled particles. The dose is a function of the concentration of dust in the air and the duration of exposure. As inhaled particles are often irregular, their size should be expressed as aerodynamic particle diameter, a parameter that describes the particle's motion in inspired air and that determines where inhaled dusts deposit in the lung (Fig. 18-2, Chapter 8). The most dangerous particles are those that reach the farthest periphery (i.e., the smallest bronchioles and acini). Particles 2.5–10 μm in diameter deposit on bronchi and bronchioles and are removed by mucociliary action. Smaller particles (<2.5 μm) reach acini, and the tiniest ones (<100 nm) may penetrate alveolar walls and enter the bloodstream.

Alveolar macrophages ingest inhaled particles and are the main defenders of the alveolar space. Most phagocytosed particles ascend to the mucociliary carpet, to be coughed up or swallowed. Others migrate into the lung interstitium, and thence into lymphatics. Many ingested particles accumulate in and about respiratory bronchioles and terminal bronchioles. Others are not phagocytosed but migrate through epithelial cells into the interstitium.

Silicosis Is Caused by Inhaled Silicon Dioxide (Silica)

The earth's crust is composed largely of silicon and its oxides, and silicosis is one of the oldest recorded diseases, possibly having begun in the Paleolithic period when humans began to fashion flint instruments. Dyspnea in metal diggers was reported by Hippocrates, and early Dutch pathologists wrote that the lungs of stone cutters sectioned like a mass of sand. The 19th-century English literature provided numerous descriptions of silicosis, and the disease remained the major cause of death in workers exposed to silica dust for the first half of the 20th century.

Silicosis was first described as a disease of sandblasters, but exposure to silica occurs in many occupations, including mining, stone cutting, polishing and sharpening of metals, ceramic manufacturing, foundry work and cleaning of boilers. The use of air-handling equipment and face masks has substantially reduced the incidence of silicosis.

ETIOLOGIC FACTORS: The biological effects of silica particles depend on a number of factors, some involving the particle itself and others related to the host response. Crystalline silica (quartz) is more toxic than amorphous forms, and its biological activity is related to its surface properties. Particles of 0.2–2.0 μm are the most dangerous. Removal of the soluble surface layer by acid washing or creation of new surfaces by sandblasting enhances the biological activity of silica particles.

After their inhalation, silica particles are ingested by alveolar macrophages. Silicon hydroxide groups on the particles' surface form hydrogen bonds with phospholipids and proteins. This interaction damages cellular membranes and so kills the macrophages. The dead cells release free silica particles and fibrogenic factors. The released silica is then reingested by macrophages and the process is amplified.

PATHOLOGY:

SIMPLE NODULAR SILICOSIS: This is the most common form of silicosis and is almost inevitable in any worker with long-term exposure to silica. Twenty to 40 years (but sometimes only 10 years) after initial exposure to silica, the lungs contain silicotic nodules less than 1 cm in diameter (usually 2–4 mm). Histologically, they have

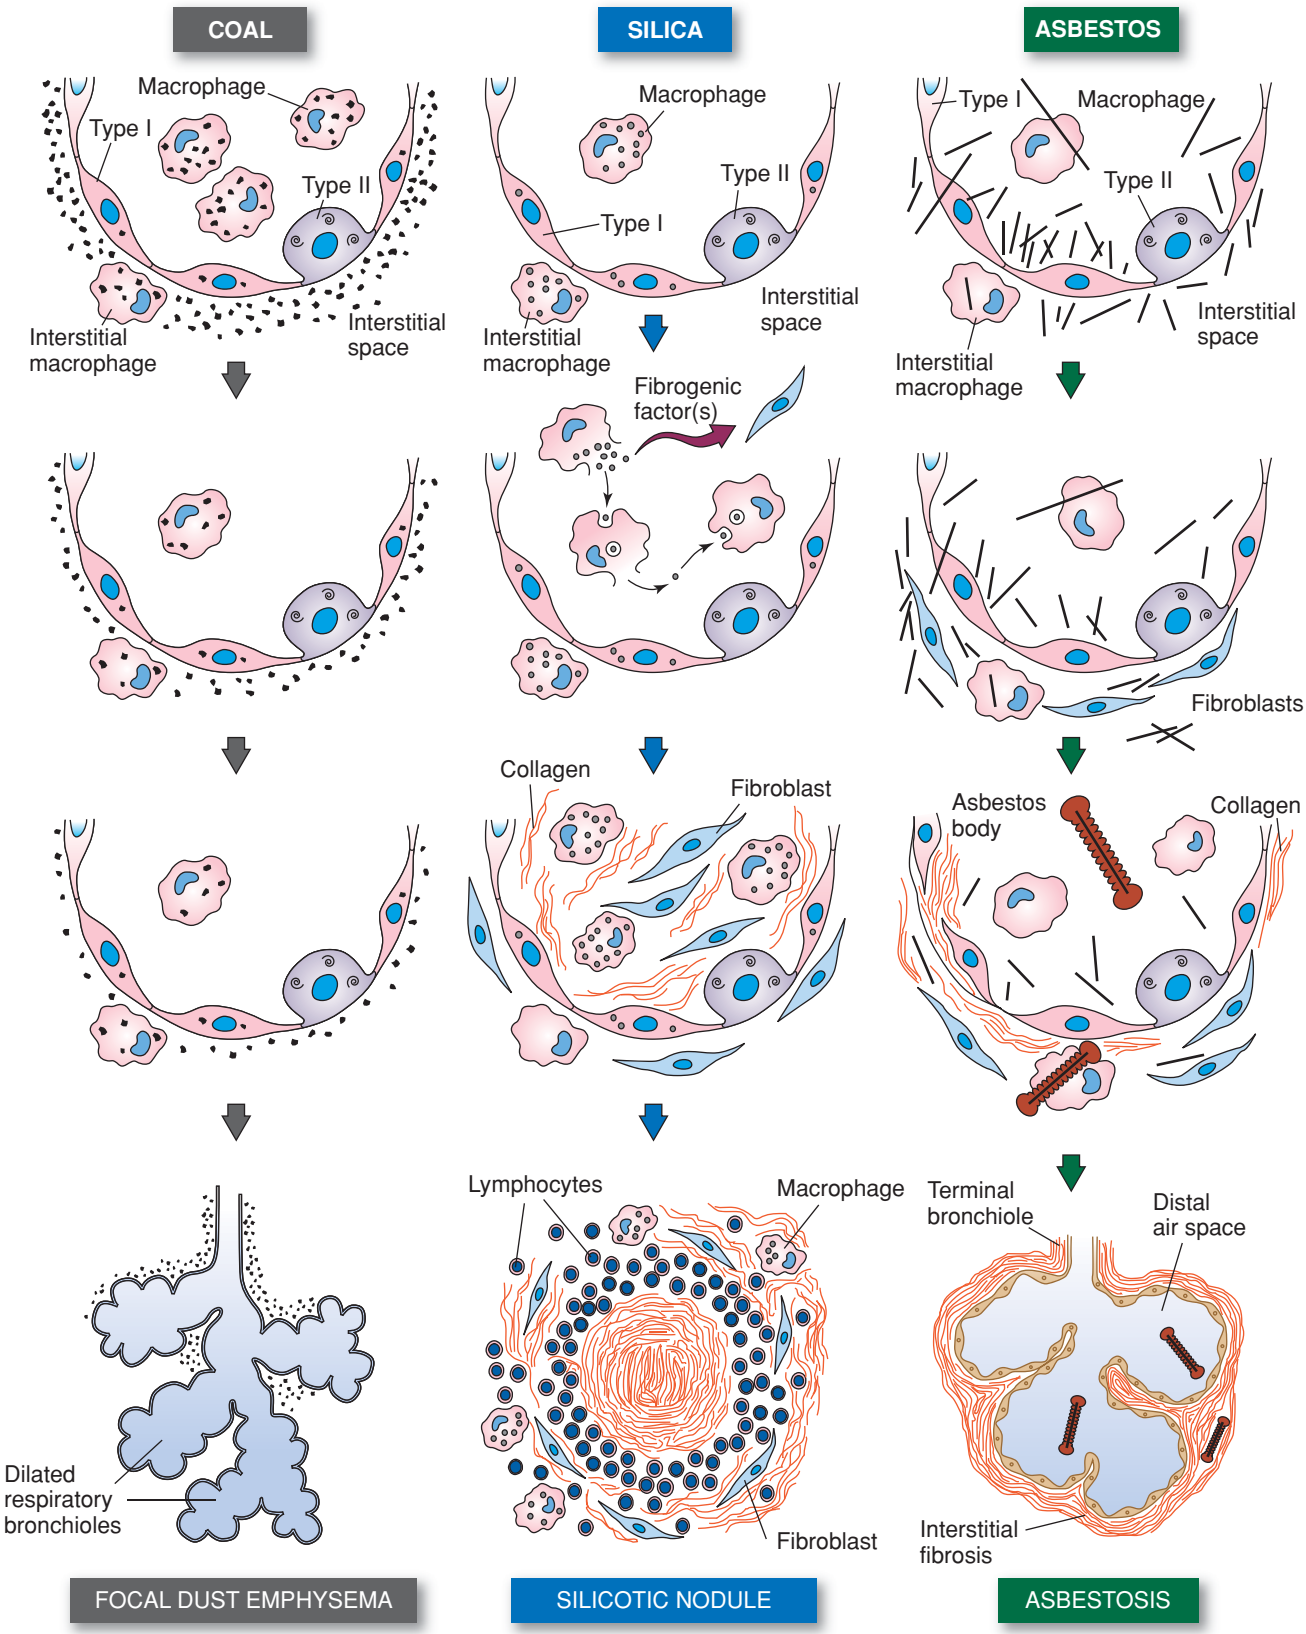

FIGURE 18-50. Pathogenesis of pneumoconioses. The three most important pneumoconioses are illustrated. In simple coal workers' pneumoconiosis, massive amounts of dust are inhaled and engulfed by macrophages. The macrophages pass into the interstitium of the lung and aggregate around respiratory bronchioles, which subsequently dilate. In silicosis, silica particles are toxic to macrophages, causing them to die and release a fibrogenic factor. In turn, the released silica is again phagocytosed by other macrophages. The result is a dense fibrotic nodule, the silicotic nodule. Asbestosis is characterized by considerable interstitial fibrosis. Asbestos bodies are the classic features.

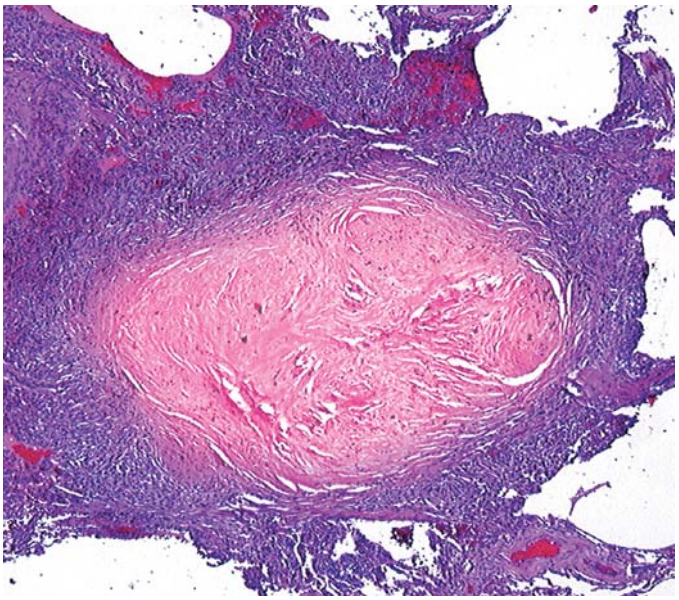

FIGURE 18-51. Silicosis. A silicotic nodule is composed of concentric whorls of dense, sparsely cellular collagen.

a characteristic whorled appearance, with concentrically arranged collagen forming the largest part of the nodule (Fig. 18-51). At the periphery are aggregates of mononuclear cells, mostly lymphocytes and fibroblasts. Polarized light reveals doubly refractile needle-shaped silicates within the nodule.

Hilar nodes may be enlarged and calcified, often at their edges ("eggshell calcification"). Simple silicosis does not usually impair respiration significantly.

PROGRESSIVE MASSIVE FIBROSIS: Radiographically, progressive massive fibrosis signifies nodular masses greater than 2 cm in diameter, in a background of simple silicosis. These larger lesions, most of which are 5–10 cm across, represent coalescence of smaller nodules and are usually in the upper zones of the lungs bilaterally (Fig. 18-52). The lesions often exhibit central cavitation. Progressive massive fibrosis is related to the amount of silica in the lung. Disability is caused by destruction of lung tissue that was incorporated into the nodules.

ACUTE SILICOSIS: Now uncommon, acute silicosis results from heavy exposure to finely particulate silica during sandblasting or boiler scaling. It is associated with diffuse fibrosis of the lung. Silicotic nodules are not found. Dense eosinophilic material accumulates in alveolar spaces to produce an appearance resembling alveolar lipoproteinosis **(silicoproteinosis)**. The disease progresses rapidly over a few years, unlike other forms of silicosis in which progression is measured in decades. On radiologic examination, acute silicosis shows diffuse linear fibrosis and reduced lung volume. Clinically, there is a severe restrictive defect.

CLINICAL FEATURES: Simple silicosis is usually a radiologic diagnosis without significant symptoms. Dyspnea on exertion and later at rest suggests progressive massive fibrosis or other complications of silicosis. In acute silicosis, dyspnea may become rapidly disabling, after which respiratory failure ensues.

It is well recognized that **tuberculosis** is much more common in patients with silicosis than in the general population. The incidence of tuberculosis in patients with silicosis is higher in acute silicosis and among populations with a high prevalence of tuberculosis. Although the incidence of tuberculosis in the general population has declined, the association with silicosis persists.

Coal Workers' Pneumoconiosis Is Due to Inhalation of Carbon Particles

ETIOLOGIC FACTORS: Coal dust is composed of amorphous carbon and other constituents of the earth's surface, including variable amounts of silica. Anthracite (hard) coal contains significantly more quartz than does bituminous (soft) coal. Workers who inhale large amounts of quartz particles, such as those who work within mines, are at greater risk than those working above ground or loading coal for transport. In this context, amorphous carbon by itself is not fibrogenic. It does not kill alveolar macrophages, but is simply a nuisance dust that causes innocuous anthracosis. By contrast, silica is highly fibrogenic, and inhaled anthracotic particles may thus lead to **anthracosilicosis** (Fig. 18-53).

PATHOLOGY: Coal workers' pneumoconiosis (CWP) is typically divided into **simple CWP** and **complicated CWP** (a.k.a. progressive massive fibrosis). The typical lung lesions of simple CWP include nonpalpable **coal-dust macules** and palpable **coal-dust nodules,** both of which are multiple and scattered throughout the lung as 1–4-mm black foci. Microscopically, coal-dust macules contain many carbon-laden macrophages, which

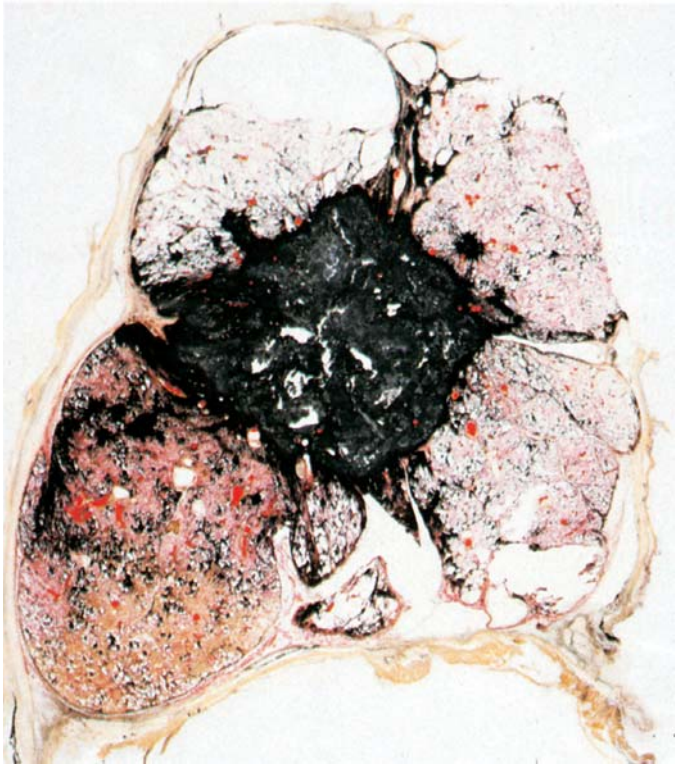

FIGURE 18-52. Progressive massive fibrosis. A whole mount of a silicotic lung from a coal miner shows a large area of dense fibrosis containing entrapped carbon particles.

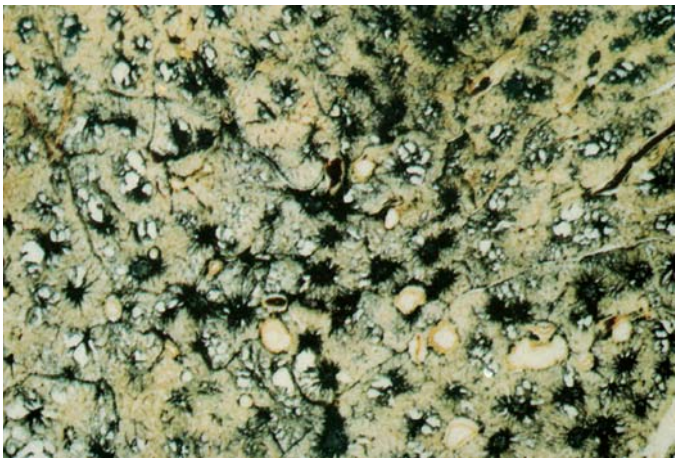

FIGURE 18-53. Anthracosilicosis. A whole mount of the lung of a coal miner demonstrates scattered, irregular, pigmented nodules throughout the parenchyma.

surround distal respiratory bronchioles, extend to fill adjacent alveolar spaces and infiltrate peribronchiolar interstitial spaces. Respiratory bronchioles may be mildly dilated (focal dust emphysema), probably owing to atrophy of smooth muscle.

Nodules are round or irregular, may or may not be associated with bronchioles and consist of dust-laden macrophages associated with a fibrotic stroma. They occur when coal is admixed with fibrogenic dusts such as silica, and are more properly classified as anthracosilicosis (Fig. 18-53). Coal-dust macules and nodules appear on chest radiographs as small nodular densities. Simple CWP was once thought to cause severe disability, but it is now clear that at worst it causes minor impairment of lung function. If coal miners have severe airflow obstruction, it is usually due to smoking. **Complicated CWP** occurs on a background of simple CWP and is defined as a lesion 2.0 cm or greater in size. It may cause significant respiratory impairment.

Caplan syndrome was first described as rheumatoid nodules **(Caplan nodules)** in the lungs of coal miners with rheumatoid arthritis. However, it now also refers to the association of pulmonary rheumatoid nodules with other pneumoconioses, such as silicosis or asbestosis. The nodular lesions are large (1–10 cm), multiple, bilateral and usually peripheral. Microscopically, they resemble rheumatoid nodules associated with inhaled dust deposits. Rheumatoid nodules are large, central, necrotic areas with a border of chronic inflammation and palisading macrophages (see Chapters 11 and 30). Caplan nodules are not identical to rheumatoid nodules and may represent a combination of silicotic and rheumatoid nodules.

Asbestos-Related Diseases May Be Reactive or Neoplastic

Asbestos (Greek, "unquenchable") includes a group of fibrous silicate minerals that occur as thin fibers. It has been used for diverse purposes for over 4000 years, since early Finns fashioned pottery from it. Roman vestal virgins used it to manufacture oil-lamp wicks, and Marco Polo remarked that asbestos-containing Chinese cloth resisted fire. More recently, asbestos has been used in insulation, construction materials and automative brake linings. Asbestos mining proceeded exponentially in the 20th century until its deleterious effects eventually elicited alarm.

There are six natural types of asbestos, which can be divided into two mineralogic groups. **Chrysotile** accounts for the bulk of commercially used asbestos. The **amphiboles** include amosite, crocidolite, tremolite, actinolite and anthophyllite. Of the amphiboles, only amosite and crocidolite have been used commercially to any significant extent. Erionite, a fibrous zeolite, is found in Turkey and adjacent areas. It has pathogenic properties similar to the amphiboles. Exposure to asbestos can cause asbestosis, benign pleural effusion, pleural plaques, diffuse pleural fibrosis, rounded atelectasis and mesothelioma (Table 18-4). All commercially used forms of asbestos are associated with lung diseases, but the amphiboles, and crocidolite in particular, have a much greater propensity to produce disease than does chrysotile.

ASBESTOSIS: Asbestosis is diffuse interstitial fibrosis resulting from inhalation of asbestos fibers. Development of asbestosis requires heavy exposure to asbestos of the type historically seen in asbestos miners, millers and insulators.

ETIOLOGIC FACTORS: Asbestos fibers may be long (up to 100 μm) but thin (0.5–1 μm), so their aerodynamic particle diameter is small. They deposit in distal airways and alveoli, particularly at bifurcations of alveolar ducts. The smallest particles are engulfed by macrophages, but many larger fibers penetrate into the interstitial space. The first lesion is an alveolitis that is directly related to asbestos exposure. Release of inflammatory mediators by activated macrophages and the fibrogenic character of the free asbestos fibers in the interstitium promote interstitial pulmonary fibrosis.

PATHOLOGY: Asbestosis is characterized by bilateral, diffuse interstitial fibrosis and asbestos bodies in the lung (Figs. 18-54 and 18-55). In early stages, fibrosis occurs in and around alveolar ducts and respiratory bronchioles, and in the periphery of the acinus. When the fibers deposit in bronchioles and respiratory bronchioles, they incite a fibrogenic response that leads to mild chronic airflow obstruction. Thus, asbestos may produce obstructive as well as restrictive defects. As the disease progresses, fibrosis spreads beyond the peribronchiolar location and eventually results in an end-stage or "honeycomb" lung. Asbestosis is usually more severe in the lower zones of the lung.

Interstitial Lung Disease
Asbestosis
Malignant Mesothelioma
Carcinoma of the lung (in smokers)

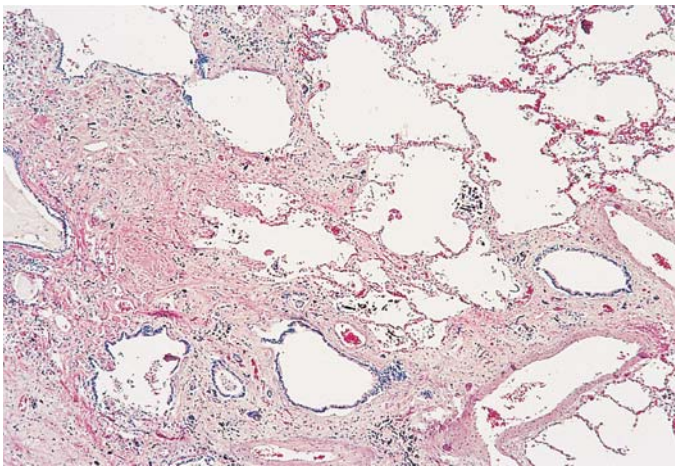

FIGURE 18-54. Asbestosis. The lung shows patchy, dense, interstitial fibrosis.

Asbestos bodies are found in the walls of bronchioles or within alveolar spaces, often engulfed by alveolar macrophages. The particles have a distinctive morphology, consisting of a clear, thin asbestos fiber (10–50 µm long) surrounded by a beaded iron–protein coat. By light microscopy, they are golden brown (Fig. 18-55) and react strongly with the Prussian blue stain for iron. The fibers are only partly engulfed by macrophages because they are too large for a single cell. The macrophages coat the asbestos fiber with protein, proteoglycans and ferritin.

Finding asbestos bodies incidentally at autopsy does not warrant a diagnosis of asbestosis; the lungs must also show diffuse interstitial fibrosis. Digests and concentrates of autopsy lungs demonstrate asbestos bodies to varying degrees in the lungs of virtually all adults.

BENIGN PLEURAL EFFUSION: Benign pleural effusion associated with asbestos inhalation is diagnosed by (1) a history of asbestos exposure, (2) identification of a pleural effusion with radiographs or thoracentesis, (3) absence of other diseases that could cause effusion and (4) no malignant tumor after 3 years of follow-up. Pleural effusions often occur within 10 years of initial exposure and are seen in about 3% of workers exposed to asbestos.

PLEURAL PLAQUES: Pleural plaques, mainly on parietal and diaphragmatic pleura, occur 10–20 years after exposure to asbestos. They may be found in up to 15% of the general population, and half of all patients with plaques at autopsy may not have a known history of asbestos exposure. Plaques occur most often on the parietal pleura, in the posterolateral regions of the lower thorax and on the domes of the diaphragm.

FIGURE 18-55. Asbestos bodies. These ferruginous bodies are golden brown and beaded, with a central, colorless, nonbirefringent core fiber. Asbestos bodies are encrusted with protein and iron.

FIGURE 18-56. Pleural plaque. The dome of the diaphragm is covered by a pearly white, nodular plaque.

Grossly, pleural plaques are pearly white and have a smooth or nodular surface (Fig. 18-56). They are usually bilateral, but not necessarily symmetric. Plaques may measure over 10 cm in diameter and become calcified. Histologically, they consist of acellular, dense, hyalinized fibrous tissue, with numerous slit-like spaces in a parallel fashion ("basket-weave pattern"). Pleural plaques are not predictors of asbestosis, nor do they evolve into mesotheliomas.

DIFFUSE PLEURAL FIBROSIS: Fibrosis limited to the pleura is usually detected at least 10 years after the initial exposure and should be distinguished from asbestosis, in which fibrosis affects the interstitium of the underlying lung diffusely.

ROUNDED ATELECTASIS: Asbestosis exposure occasionally leads to pleural fibrosis and adhesions associated with atelectasis, which has a rounded appearance on chest radiograph. Radiographically, rounded atelectasis is characterized by a pleural-based, rounded or oval, 2.5–5-cm shadow, which usually lies along the posterior surface of a lower lobe. Pathologically, the lung shows pleural fibrosis or plaques, with curved pleural invaginations extending several centimeters into the underlying parenchyma. The condition is clinically benign.

MESOTHELIOMA: The relation between asbestos exposure and malignant mesothelioma is firmly established. Sometimes exposure is indirect and slight (e.g., wives of asbestos workers who wash their husbands' clothes). More often, mesothelioma is seen in workers with heavy occupational exposure to asbestos, mainly crocidolite and amosite. This malignancy is discussed below with diseases of the pleura.

CARCINOMA OF THE LUNG: There are reports that lung cancer is more common in nonsmoking asbestos workers than in similar workers not exposed to asbestos, but data are limited and no firm conclusion is possible at this point. However, in asbestos workers who smoke, the incidence of carcinoma of the lung is vastly increased: up to 40–60 times that of the general nonsmoking population. The link between asbestos and lung cancer is most convincingly supported in the presence of asbestosis (diffuse interstitial fibrosis).

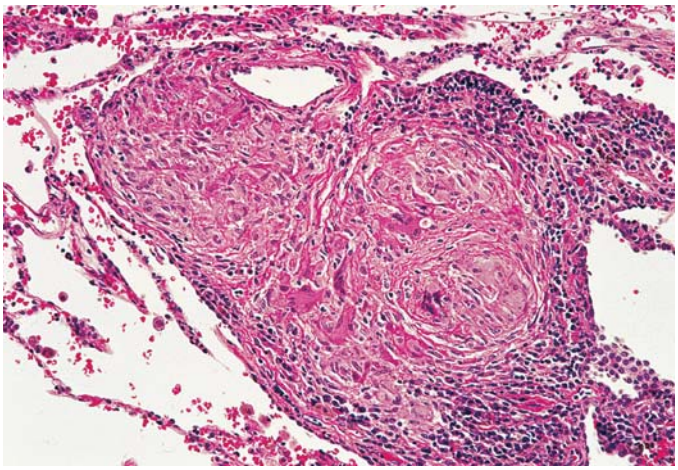

FIGURE 18-57. Berylliosis. A noncaseating granuloma consists of a nodular collection of epithelioid macrophages and multinucleated giant cells.

Berylliosis Is Characterized by Noncaseating Granulomas

Berylliosis refers to the pulmonary disease that follows the inhalation of beryllium. Today this metal is used principally in structural materials in aerospace, industrial ceramics and nuclear industries. Exposure to beryllium may also occur in those who mine and extract beryllium ores.

PATHOLOGY: Berylliosis may occur as an acute chemical pneumonitis or a chronic pneumoconiosis. In the acute form, symptoms begin within hours or days after inhalation of metal particles and manifest pathologically as diffuse alveolar damage. Of all patients with acute beryllium pneumonitis, 10% progress to chronic disease, although chronic berylliosis is often observed in workers without any history of an acute illness.

Chronic berylliosis differs from other pneumoconioses in that exposure may be brief and minimal. The lesion is thus suspected to be a hypersensitivity reaction. Pulmonary lesions are indistinguishable from those of sarcoidosis (see below). Multiple noncaseating granulomas are distributed along the pleura, septa and bronchovascular bundles (Fig. 18-57). The beryllium lymphocyte proliferation test (demonstration of beryllium sensitization by proliferation of isolated peripheral blood lymphocytes incubated with beryllium) may aid in separating these two entities. The disease may progress to end-stage fibrosis and **honeycomb lung** (see below). Patients with chronic berylliosis have an insidious onset of dyspnea 15 or more years after the initial exposure. The disease appears to be associated with an increased risk of lung cancer.

Talcosis Results from Prolonged and Heavy Exposure to Talc Dust

Talc consists of magnesium silicates that are used in several industries as lubricants, and in cosmetics and pharmaceuticals. Occupational exposure to talc occurs among workers engaged in mining and milling the mineral and in the leather, rubber, paper and textile industries. Industrial talcs may include other minerals such as tremolite or silica. Cosmetic talc is more than 90% pure and rarely causes lung disease.

PATHOLOGY: Talcosis lesions vary from tiny nodules to severe fibrosis. Foreign body granulomas associated with birefringent plate-like talc particles are scattered throughout the parenchyma, which displays fibrotic nodules and interstitial fibrosis. Associated minerals such as silica may contribute to the fibrotic changes.

People who inject illicit drugs that include talc as a carrier may develop vascular and interstitial granulomas in the lung and variable fibrosis. Arterial changes of pulmonary hypertension are common and may be associated with cor pulmonale.

INTERSTITIAL LUNG DISEASE

Many pulmonary disorders are characterized by interstitial inflammatory infiltrates and have similar clinical and radiologic presentations, and so are grouped as interstitial, infiltrative or restrictive diseases. These may be acute or chronic and of known or unknown etiology and vary from minimally symptomatic to severely incapacitating and lethal interstitial fibrosis. Restrictive lung diseases are characterized by decreased lung volume and decreased oxygen-diffusing capacity on pulmonary function studies.

Hypersensitivity Pneumonitis Is a Response to Inhaled Antigens

Inhalation of many antigens leads to hypersensitivity pneumonitis (also called extrinsic allergic alveolitis), with acute or chronic interstitial inflammation in the lung. Most such antigens are encountered in occupational settings, and resulting diseases are labeled accordingly: **farmer's lung** occurs in people exposed to *Micropolyspora faeni* from moldy hay; **bagassosis** results from exposure to *Thermoactinomyces sacchari* in moldy sugar cane; **maple bark–stripper's disease** follows exposure to the fungus *Cryptostroma corticale* in moldy maple bark; and **bird fancier's lung** affects bird keepers with long-term exposure to proteins from bird feathers, blood and excrement. Other causes of hypersensitivity pneumonitis include inhalation of pituitary snuff **(pituitary snuff taker's disease),** moldy cork **(suberosis)** and moldy compost **(mushroom worker's disease)**. Hypersensitivity pneumonitis may also be caused by fungi that grow in stagnant water in air conditioners, swimming pools, hot tubs and central heating units. Skin tests and serum precipitating antibodies are often used to confirm the diagnosis. Often, especially in chronic hypersensitivity pneumonitis, an inciting antigen is never identified. In acute cases, the diagnosis is usually established clinically, so lung biopsies are performed only in chronic cases.

PATHOPHYSIOLOGY: Acute hypersensitivity pneumonitis is characterized by neutrophilic infiltrates in alveoli and respiratory bronchioles; chronic lesions show mononuclear cells and granulomas, typical of delayed hypersensitivity. Most cases have serum IgG precipitating antibodies against the offending

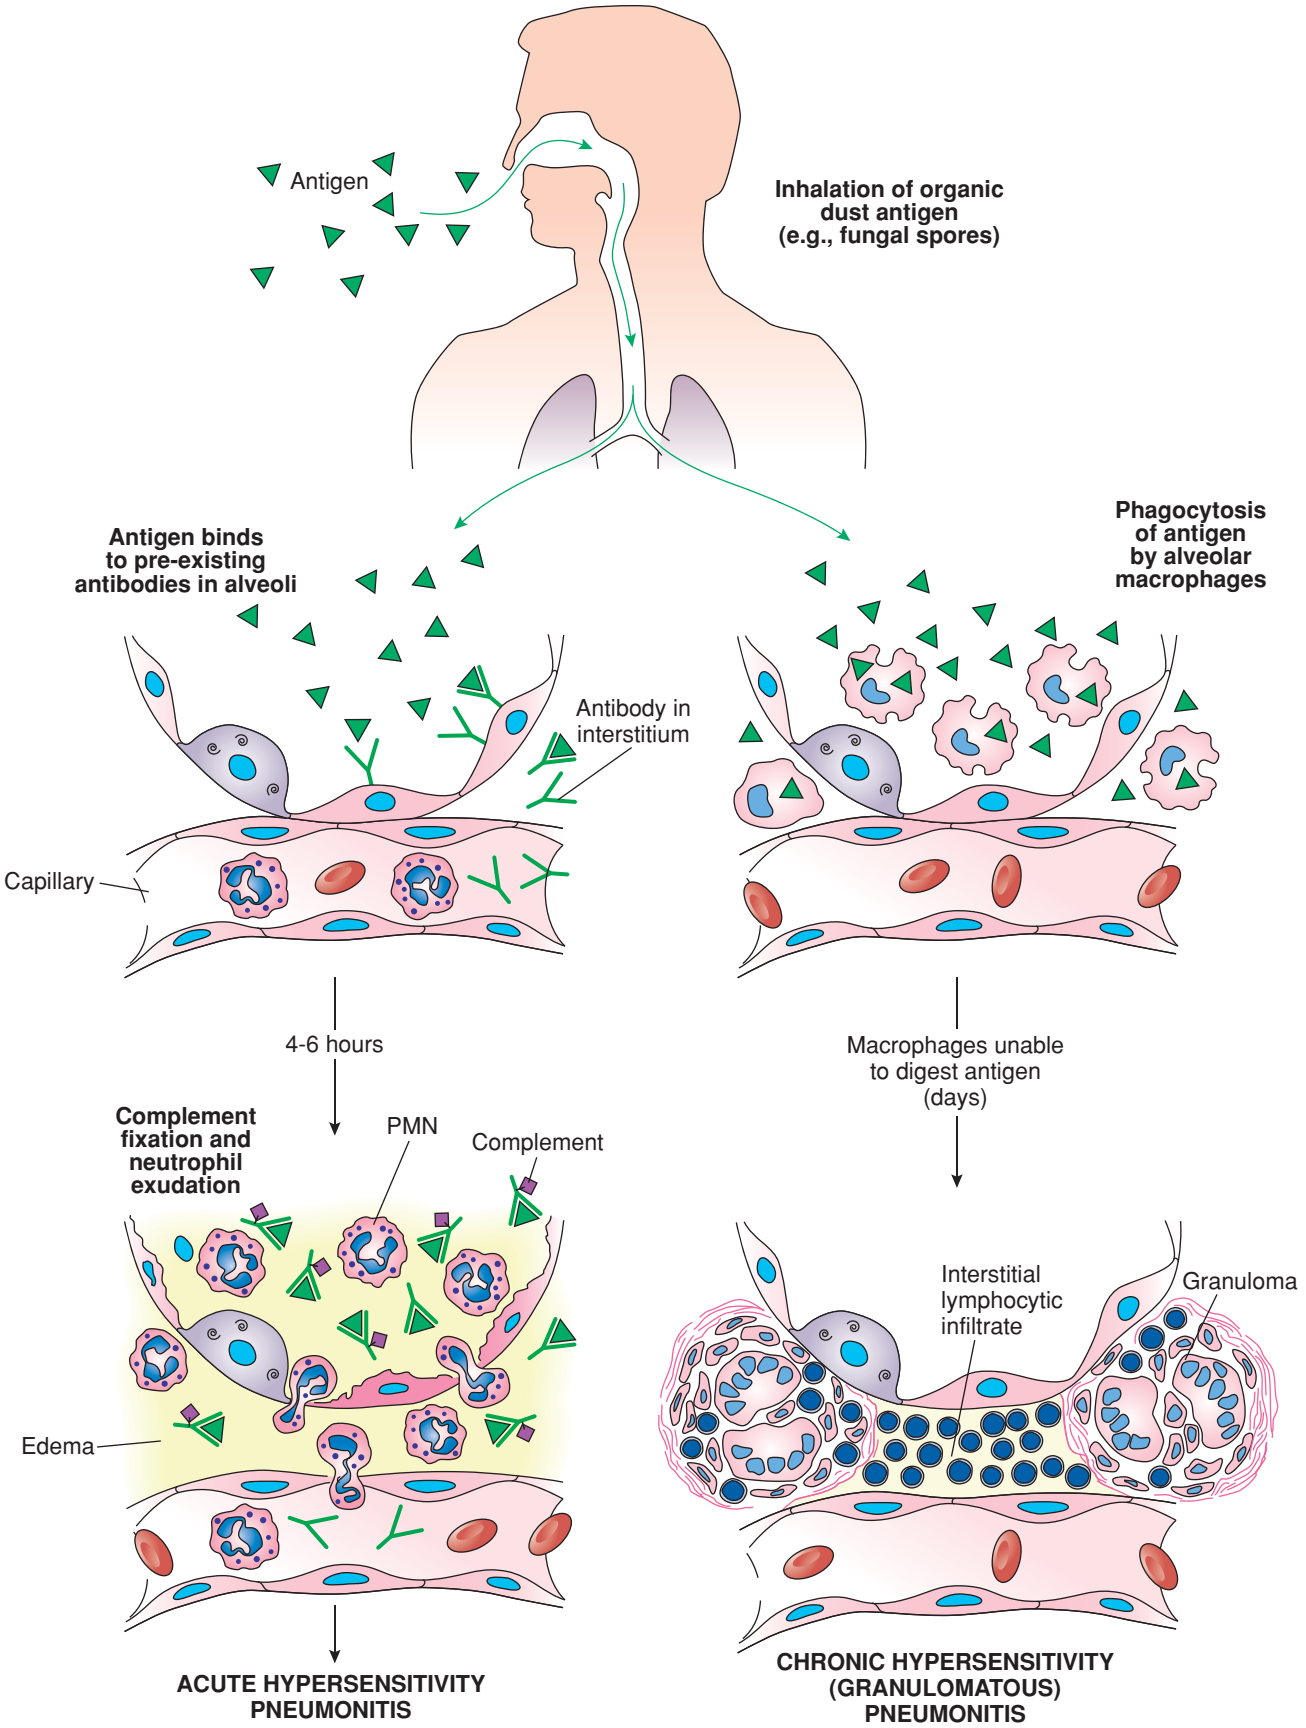

FIGURE 18-58. Hypersensitivity pneumonitis. An antigen–antibody reaction occurs in the acute phase and leads to acute hypersensitivity pneumonitis. If exposure is continued, this is followed by a cellular or subacute phase, with formation of granulomas and chronic interstitial pneumonitis. *PMN* = polymorphonuclear neutrophil.

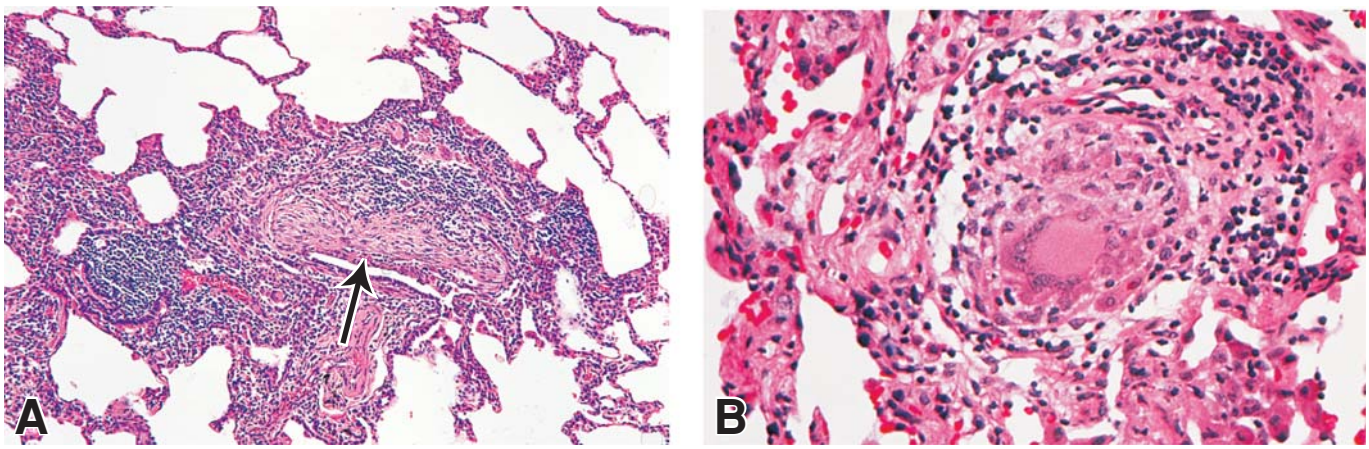

FIGURE 18-59. Hypersensitivity pneumonitis. A. A lung biopsy specimen shows a mild peribronchiolar chronic inflammatory interstitial infiltrate, with a focus of intraluminal organizing fibrosis (*arrow*). **B.** Focal poorly formed granulomas were scattered in the lung biopsy specimen.

agent. Hypersensitivity pneumonitis represents a combination of immune complex–mediated (type III) and cell-mediated (type IV) hypersensitivity reactions, although the precise contribution of each is still debated (Fig. 18-58). Importantly, most people who have serum precipitins to inhaled antigens do not develop hypersensitivity pneumonitis, suggesting a genetic component in host susceptibility.

PATHOLOGY: The histology in florid cases of chronic hypersensitivity pneumonitis is virtually diagnostic. However, in subtle cases, the diagnosis may require careful clinical and radiologic correlation, and even then it may remain tentative. Microscopic features of chronic hypersensitivity pneumonitis are bronchiolocentric cellular interstitial pneumonia, noncaseating granulomas and organizing pneumonia (Fig. 18-59A,B). The bronchiolocentric cellular interstitial infiltrate consists of lymphocytes, plasma cells and macrophages and varies from severe to subtle; eosinophils are uncommon. Poorly formed noncaseating granulomas are seen in two thirds of cases (Fig. 18-59B), as is organizing pneumonia (Fig. 18-59A). In the end stage, interstitial inflammation recedes, leaving pulmonary fibrosis, which may resemble usual interstitial pneumonia.

CLINICAL FEATURES: Hypersensitivity pneumonitis may present as acute, subacute or chronic pulmonary disease, depending on the frequency and intensity of exposure to the offending antigen. Farmer's lung is the prototype of hypersensitivity pneumonitis, caused by inhaling thermophilic actinomycetes from moldy hay. Typically, a farm worker enters a barn where hay has been stored for winter feeding. After a lag period of 4–6 hours, he or she rapidly develops dyspnea, cough and mild fever. Symptoms remit within 24–48 hours but return on reexposure; with time, the disorder becomes chronic. Patients with chronic hypersensitivity pneumonitis have a more nonspecific presentation, with a gradual onset of dyspnea and cor pulmonale.

Pulmonary function studies show a restrictive pattern, with decreased compliance, reduced diffusion capacity and hypoxemia. In the chronic stage, airway obstruction may be troublesome. Bronchoalveolar fluid has increased T lymphocytes, mostly $CD8^+$ suppressor/cytotoxic cells. Removing the offending antigen is the only adequate treatment for hypersensitivity pneumonitis. Steroid therapy may be effective in acute forms and for some chronically affected patients.

Sarcoidosis Is a Granulomatous Disease of Unknown Etiology

In sarcoidosis, the lung is the organ most often involved, but lymph nodes, skin, eye and other organs are also common targets (Fig. 18-60).

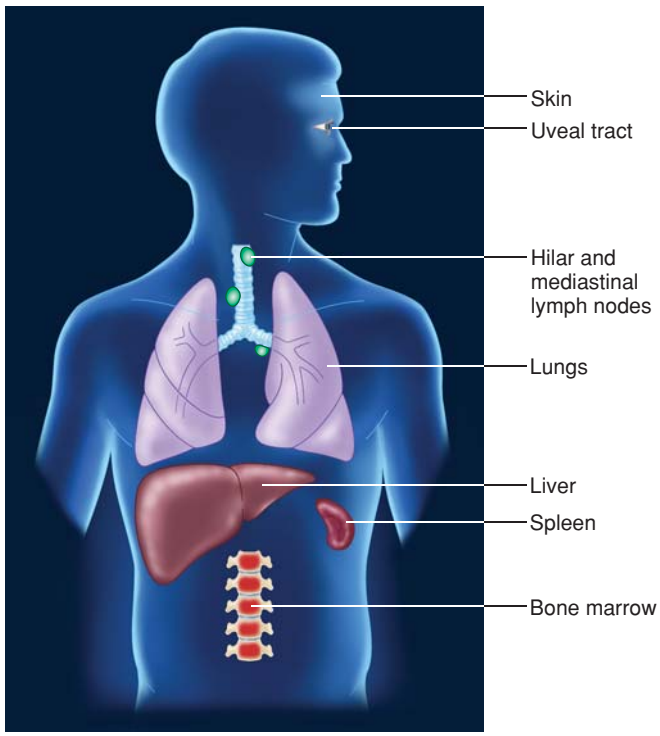

FIGURE 18-60. Organs commonly affected by sarcoidosis. Sarcoidosis involves many organs, most commonly the lymph nodes and lung.

EPIDEMIOLOGY: Sarcoidosis occurs worldwide and affects all races and both sexes, but with strong racial and ethnic predilections. In North America, it is much more common among blacks than whites (15:1), but it is uncommon in tropical Africa. In Scandinavian countries, its prevalence is 64 in 100,000, but is 10 in 100,000 in France and 3 in 100,000 in Poland; among Irish women in London, its prevalence is an astonishing 200 in 100,000. Sarcoidosis is distinctly uncommon in China.

PATHOPHYSIOLOGY: The pathogenesis of sarcoidosis remains obscure, but there is a consensus that helper/inducer T-lymphocyte responses to exogenous or autologous antigens are exaggerated. These cells accumulate in affected organs, where they secrete lymphokines and recruit macrophages, which help form noncaseating granulomas. $CD4^+$:$CD8^+$ T-cell ratios are 10:1 in organs with sarcoid granulomas, but are 2:1 in uninvolved tissues. Why helper/inducer T lymphocytes accumulate is unclear. A defect in suppressor cell function may permit unopposed helper cell proliferation. Inherited or acquired differences in immune response genes may favor one type of T-cell response over another. Nonspecific polyclonal activation of B cells by T-helper cells leads to hyperglobulinemia, a characteristic feature of active sarcoidosis.

PATHOLOGY: Pulmonary sarcoidosis most often affects the lungs and hilar lymph nodes, although either involvement may occur separately. Radiologically, a diffuse reticulonodular infiltrate is typical, but occasional cases may show larger nodules. Histologically, multiple sarcoid granulomas are scattered in the interstitium of the lung (Fig. 18-61). The distribution is distinctive—along the pleura and interlobular septa and around bronchovascular bundles (Fig. 18-61A). Frequent bronchial or bronchiolar submucosal infiltration by sarcoid granulomas accounts for the high diagnostic yield (≅90%) on bronchoscopic biopsy. Granulomas in airways may occasionally be so prominent as to lead to airway obstruction (endobronchial sarcoid).

The granulomatous phase of sarcoidosis can progress to a fibrotic phase. Fibrosis often begins at the periphery of a granuloma and may show an onion-skin pattern of lamellar fibrosis around the giant cells. Significant necrosis is uncommon, but one third of open lung biopsies show small foci of necrosis. Interstitial chronic inflammation tends to be inconspicuous. Granulomatous vasculitis is seen in two thirds of open lung biopsies from patients with sarcoidosis. Although **asteroid bodies** (star-shaped crystals) (Fig. 18-61B) and **Schaumann bodies** (small lamellar calcifications) are commonly encountered, they are not specific for sarcoidosis and may be seen in most granulomatous processes.

Interstitial fibrosis is not prominent in pulmonary sarcoidosis. However, progressive pulmonary fibrosis leads to a honeycomb lung, respiratory insufficiency and cor pulmonale.

CLINICAL FEATURES: Sarcoidosis is most common in young adults of both sexes. **Acute sarcoidosis** has an abrupt onset, usually followed by spontaneous remission within 2 years and an excellent response to steroids. **Chronic sarcoidosis** begins insidiously, and patients are more likely to have persistent or progressive disease. Sarcoidosis causes several chest radiographic patterns, the most classic of which is bilateral hilar adenopathy, with or without interstitial pulmonary infiltrates. It may also affect the skin (erythema nodosum), mostly in women. Black patients tend to have more severe uveitis, skin disease and lacrimal gland involvement. Cough and dyspnea are the major respiratory complaints. However, the disease can be mild and may be discovered as an incidental finding on a chest radiograph in an asymptomatic patient.

No laboratory test is specific for the diagnosis of sarcoidosis. Transbronchial lung biopsy via a fiberoptic bronchoscope often reveals granulomas. Occasionally, the diagnosis is made by mediastinoscopy, identifying multiple noncaseating granulomas in a mediastinal lymph node. Bronchoalveolar lavage often shows an increase in the proportion of $CD4^+$ T lymphocytes. Increased uptake of gallium-67, a material phagocytosed by activated macrophages, can demonstrate granulomatous areas. Serum angiotensin-converting enzyme (ACE) levels are elevated in two thirds of patients with active sarcoidosis, and 24-hour urine calcium

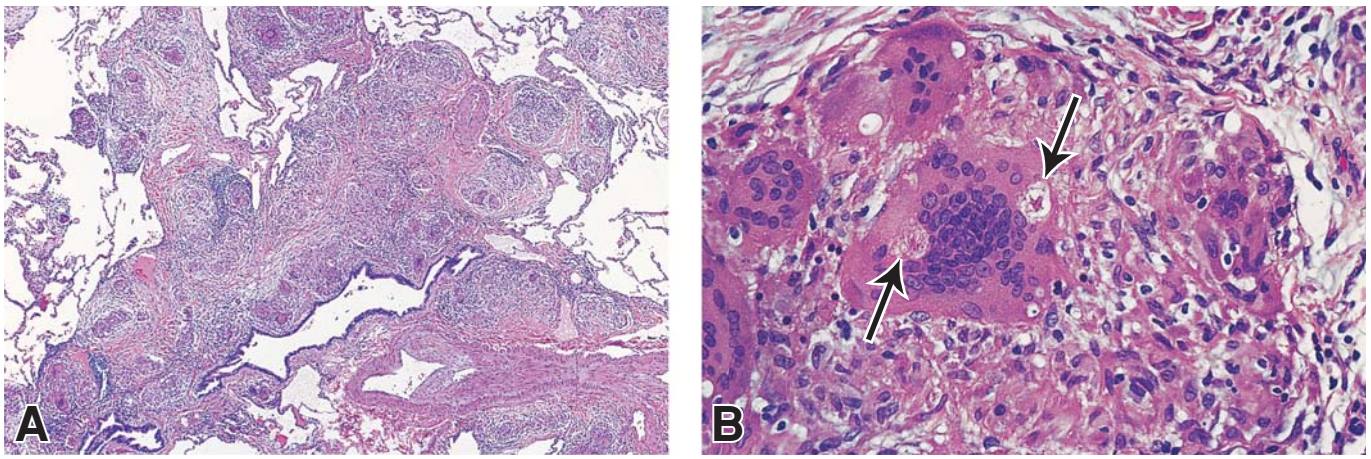

FIGURE 18-61. Sarcoidosis. A. Multiple noncaseating granulomas are present along the bronchovascular interstitium. **B.** Noncaseating granulomas consist of tight clusters of epithelioid macrophages and multinucleated giant cells. Several asteroid bodies are present (*arrows*).

is frequently increased. These laboratory data, together with supportive clinical and radiologic findings, allow the diagnosis of sarcoidosis to be made with a high probability.

Other organs commonly involved include the skin, eye (uveal tract), heart, central nervous system, extrathoracic lymph nodes, spleen and liver (Fig. 18-60). These are discussed separately in individual chapters.

The prognosis in pulmonary sarcoidosis is favorable; most patients do not develop clinically significant sequelae. In 60% of patients, pulmonary sarcoidosis resolves, but this is less likely in older patients and those with extrathoracic disease, particularly in the bone and skin. In up to 20% of cases, sarcoidosis does not remit or recurs at intervals, but it leads to death in only 10% of cases. Corticosteroid therapy is effective for active sarcoidosis.

Usual Interstitial Pneumonia Is the Most Common Histology Seen in Clinical Idiopathic Pulmonary Fibrosis

Usual interstitial pneumonia (UIP) is one of the most common types of interstitial pneumonia, with an annual incidence of 6–14 cases per 100,000 people. It has a slight male predominance and a mean age at onset of 50–60 years. UIP is the histologic pattern present on biopsy, and the clinical term **idiopathic pulmonary fibrosis** (IPF) is applied when the disease is determined to be of unknown origin.

ETIOLOGIC FACTORS: The etiology of IPF is unknown, but immunologic, viral and genetic factors probably contribute. Some patients have histories of flu-like illnesses, suggesting viral involvement. Familial clusters of IPF, and association of UIP-like diseases in patients with inherited disorders such as neurofibromatosis and Hermansky-Pudlak syndrome, indicate that genetic factors contribute. Mutations in telomerase genes, particularly telomerase reverse transcriptase (TERT), surfactant protein C and MUC5B, are common in familial IPF but involve less than 1/3 of cases; the genetic abnormality is unknown in most patients.

UIP histology accompanies autoimmune diseases, including rheumatoid arthritis, systemic lupus erythematosus and progressive systemic sclerosis, in 20% of cases, suggesting impaired immunity. It also occurs with autoimmune disorders like Hashimoto thyroiditis, primary biliary cirrhosis, autoimmune hepatitis, idiopathic thrombocytopenic purpura and myasthenia gravis. Autoantibodies (e.g., antinuclear antibodies and rheumatoid factor) and immune complexes are often found in blood, inflamed alveolar walls and bronchoalveolar lavage fluids. No antigen has yet been identified. Activated alveolar macrophages may release cytokines, which recruit neutrophils. These in turn damage alveolar walls, stimulating a series of events that culminates in interstitial fibrosis.

PATHOLOGY: UIP is a histologic pattern that occurs in several clinical settings (e.g., collagen vascular disease, chronic hypersensitivity pneumonitis, drug toxicity and asbestosis). Many cases have no identifiable etiology and are so considered idiopathic (IPF). The lungs are small in UIP, and fibrosis tends to be worse in the lower lobes, in the subpleural regions and along interlobular septa. Retraction of the scars, especially of lobular septa, gives the pleural surface of the lung a hobnail appearance, reminiscent of cirrhosis of the liver. Fibrosis is often patchy, with areas of dense scarring and honeycomb cystic change (Fig. 18-62A).

The histologic hallmark of UIP is patchy interstitial fibrosis, with areas of normal lung adjacent to fibrotic areas (Fig. 18-62B). The fibrosis is of different ages, which has been called **"temporal heterogeneity."** Areas of loose fibroblastic tissue **(fibroblast foci)** may be adjacent to dense collagen (Fig. 18-62C). The fibrosis is most pronounced beneath the pleura and adjacent to interlobular septa (Fig. 18-62B).

Bronchiolar epithelium grows into the dilated airspaces, which may be damaged but unrecognizable proximal respiratory bronchioles (Fig. 18-63). The areas of dense scarring fibrosis cause remodeling of the lung architecture, leading to alveolar wall collapse and formation of cystic spaces (Fig. 18-62A). These spaces are typically lined by bronchiolar or cuboidal epithelium and contain mucus, macrophages or neutrophils. If such changes are extensive, the term **"honeycomb lung"** may be used to describe the gross cystic changes. Interstitial chronic inflammation is mild or moderate. Lymphoid aggregates, sometimes containing germinal centers, are occasionally noted, particularly in UIP associated with a collagen vascular disease such as rheumatoid arthritis. Extensive vascular changes of intimal fibrosis and medial thickening may be associated with pulmonary hypertension.

CLINICAL FEATURES: UIP begins insidiously, with gradual onset of dyspnea on exertion and dry cough, usually for 1–3 years. Patients have restrictive lung disease by pulmonary function testing. Finger clubbing is common, especially late in the disease. In half of patients, CT scans show distinctive peripheral, subpleural reticular opacities, traction bronchiectasis and honeycombing, mostly in posterior lower lobes.

The classic auscultatory finding is late inspiratory crackles and fine ("Velcro") rales at the lung bases. Tachypnea at rest, cyanosis and cor pulmonale eventually follow. The prognosis is bleak, with a mean survival of 4–6 years. Patients are treated with corticosteroids and sometimes cyclophosphamide, but lung transplantation generally offers the only hope of survival.

Nonspecific Interstitial Pneumonia Has Multiple Etiologies

Nonspecific interstitial pneumonia (NSIP) is a histologic pattern that reflects diverse potential etiologies (infection, collagen vascular disease, hypersensitivity pneumonitis, drug reaction) or it may be idiopathic.

PATHOLOGY: NSIP shows a spectrum of **cellular** and **fibrosing patterns**. Unlike the patchy distribution and temporal heterogeneity of UIP, lung changes in NSIP are diffuse and uniform. In the **cellular form,** alveolar septa are diffusely involved by a mild to moderate lymphocytic infiltrate. In the **fibrosing form,** septa show diffuse fibrosis, with or without significant associated inflammation. Honeycombing and fibroblastic foci are inconspicuous or absent.

CLINICAL FEATURES: In NSIP, shortness of breath and cough develop over months to years. Computed tomography is variable but mostly

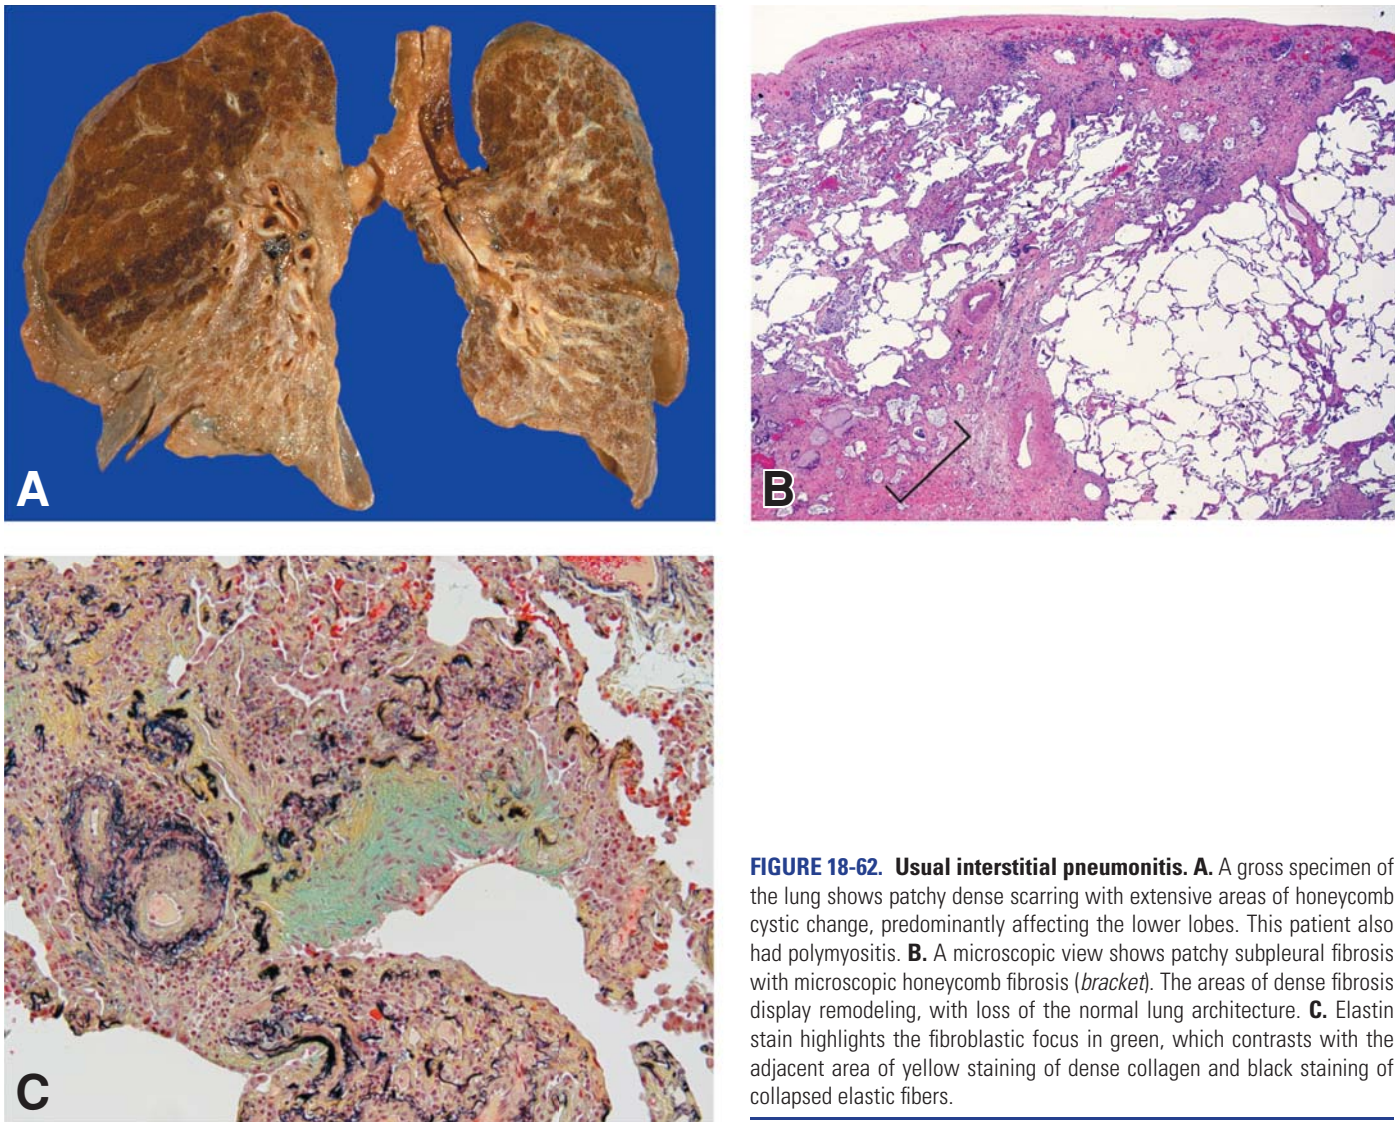

FIGURE 18-62. Usual interstitial pneumonitis. A. A gross specimen of the lung shows patchy dense scarring with extensive areas of honeycomb cystic change, predominantly affecting the lower lobes. This patient also had polymyositis. **B.** A microscopic view shows patchy subpleural fibrosis with microscopic honeycomb fibrosis (*bracket*). The areas of dense fibrosis display remodeling, with loss of the normal lung architecture. **C.** Elastin stain highlights the fibroblastic focus in green, which contrasts with the adjacent area of yellow staining of dense collagen and black staining of collapsed elastic fibers.

shows bilateral lower lobe "ground glass" changes or reticulation with traction bronchiectasis. The prognosis of idiopathic NSIP is favorable compared to IPF; 5-year survival is 80%.

Desquamative Interstitial Pneumonia Is a Diffuse Lung Disease Seen Mostly in Smokers

Interstitial fibrosis is minimal in desquamative interstitial pneumonia (DIP) (Fig. 18-64A,B). The term "desquamative" reflected the misconception that the intra-alveolar cells were desquamated epithelial cells, but they are now recognized as macrophages. In DIP, unlike UIP, alveolar architecture is preserved, and the disorder lacks the patchy scarring and remodeling of lung parenchyma of UIP. The macrophages contain a fine golden-brown pigment. Alveolar walls in DIP may, however, be mildly thickened by chronic inflammation and interstitial fibrosis (Fig. 18-64B). Scattered lymphoid aggregates also may be present. Hyperplasia of type II pneumocytes is often prominent.

DIP occurs almost exclusively in cigarette smokers, typically in the fourth or fifth decade, and is twice as common in men as in women. Probably, DIP and respiratory bronchiolitis–interstitial lung disease (see below) are a spectrum of disease related to cigarette smoking, although the mechanism is unclear. The radiographic picture of DIP is not specific but is most often bilateral lower lobe ground glass infiltrates. DIP has a much better prognosis than UIP, with an overall 10-year survival between 70% and 100%. Most patients respond well to steroid therapy and smoking cessation.

Respiratory Bronchiolitis–Interstitial Lung Disease Occurs in Smokers

Respiratory bronchiolitis (RB) is a histologic lesion that occurs in cigarette smokers. It is most often an incidental histologic finding, but it may rarely be the sole cause of interstitial lung disease (ILD), and the clinical term **respiratory bronchiolitis–interstitial lung disease** (RB-ILD) is appropriate in this setting.

PATHOLOGY: RB is a patchy accumulation of pigmented macrophages in airspaces, centered on bronchioles (Fig. 18-65). These macrophages are

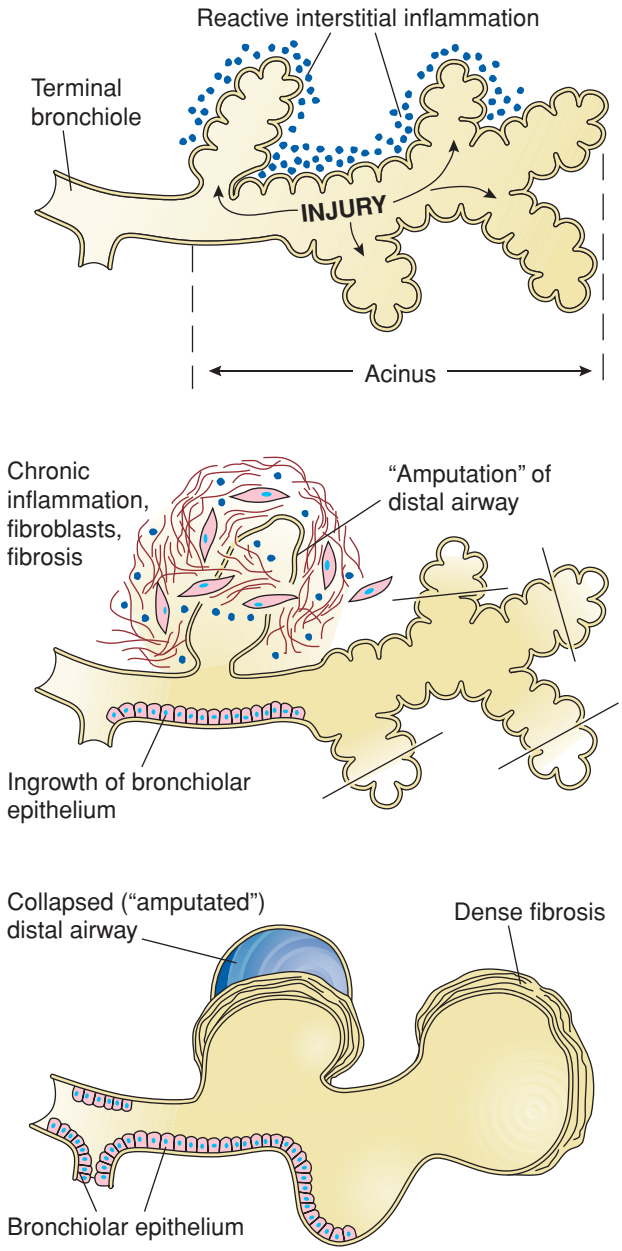

FIGURE 18-63. Pathogenesis of honeycomb lung. Honeycomb lung is the result of a variety of injuries. Interstitial and alveolar inflammation destroys ("amputates") the distal part of the acinus. The proximal parts dilate and become lined by bronchiolar epithelium.

present in bronchiolar lumens and adjacent alveoli. Bronchiolar walls show mild chronic inflammation and fibrosis. However, interstitial fibrosis does not extend into the surrounding lung. Macrophages usually contain finely granular, brown pigment. The lesions in RB are bronchiolocentric and patchy.

CLINICAL FEATURES: Patients have mild respiratory dysfunction. Upper lobes are most affected, with thickening of peripheral bronchioles.

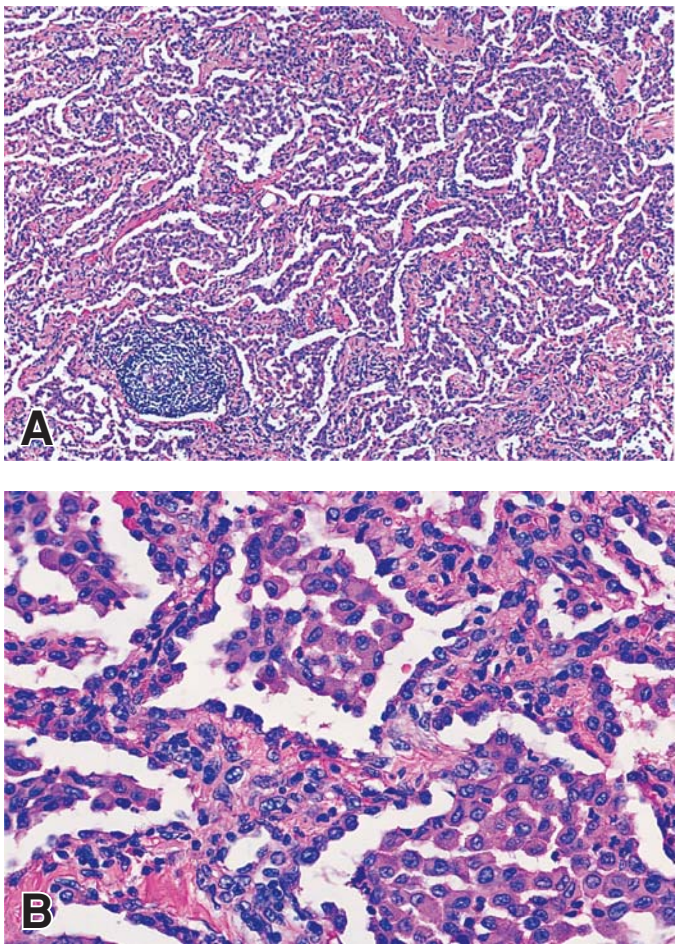

FIGURE 18-64. Desquamative interstitial pneumonia (DIP). A. A diffuse process in the lungs is characterized by accumulation of alveolar macrophages, preservation of alveolar architecture and lymphoid aggregates. **B.** In addition to alveolar macrophage accumulation, there is mild alveolar septal fibrosis, type II pneumocyte hyperplasia and mild interstitial chronic inflammation.

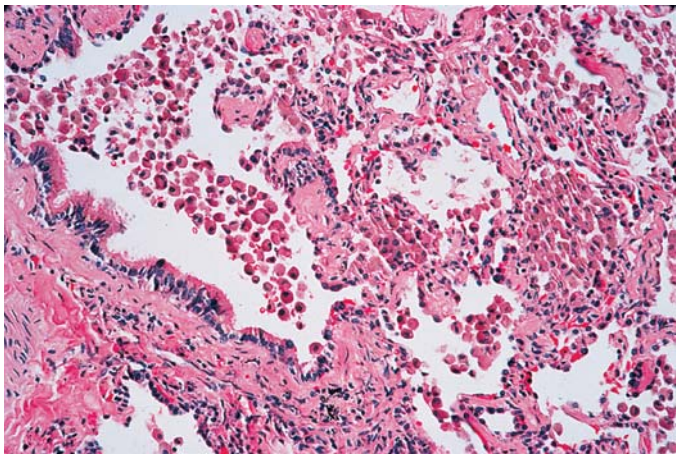

FIGURE 18-65. Respiratory bronchiolitis. There is marked accumulation of macrophages within bronchioles and surrounding airspaces. Mild fibrotic thickening and chronic inflammation of the bronchiolar wall are present.

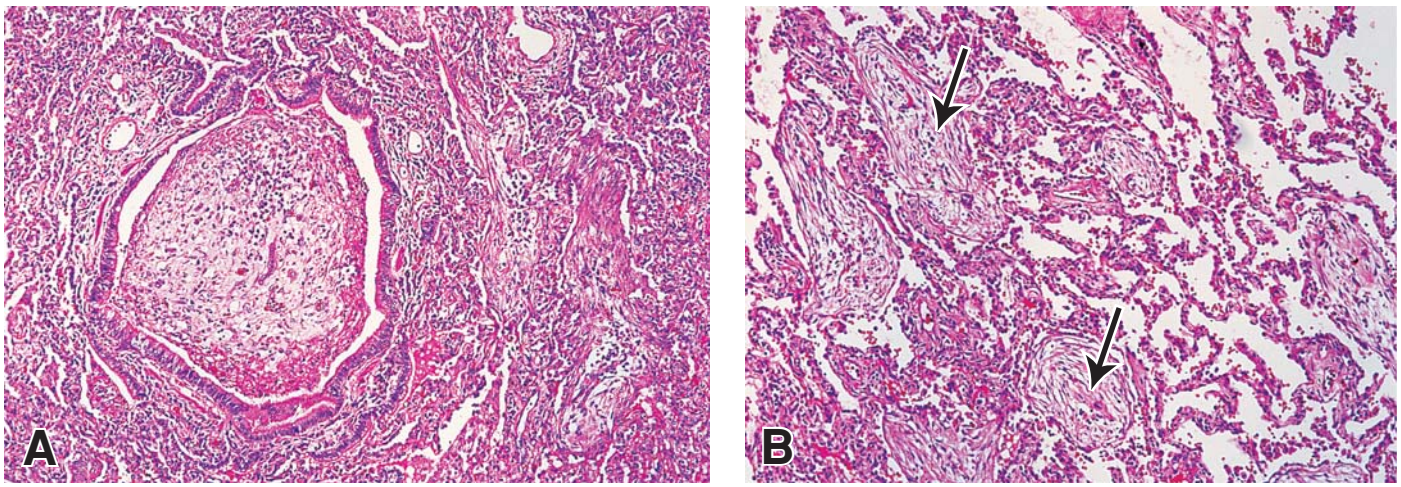

FIGURE 18-66. Organizing pneumonia pattern. A. Polypoid plugs of loose fibrous tissue are present in a bronchiole and adjacent alveolar ducts and alveoli. **B.** Alveolar spaces contain similar plugs of loose organizing connective tissue (*arrows*).

Patients with RB-ILD have an excellent prognosis, and the symptoms usually resolve after smoking cessation.

In Organizing Pneumonia Pattern (Cryptogenic Organizing Pneumonia) Polypoid Plugs of Tissue Fill Alveolar Spaces, Alveolar Ducts and Bronchiolar Lumens

Organizing pneumonia pattern, previously called "bronchiolitis obliterans–organizing pneumonia" (BOOP), is not specific for any etiologic agent, and its cause cannot be determined from the histopathology. Thus, it is seen in many settings, including respiratory tract infections (particularly viral bronchiolitis), inhalation of toxic materials, after administration of a number of drugs and various inflammatory processes (e.g., collagen vascular diseases). ***A substantial number of cases are idiopathic and are called cryptogenic organizing pneumonia (or idiopathic BOOP).***

PATHOLOGY: Organizing pneumonia pattern has patchy areas of loose organizing fibrosis and chronic inflammatory cells in distal airways, adjacent to normal lung. Plugs of organizing fibroblastic tissue occlude bronchioles (bronchiolitis obliterans), alveolar ducts and surrounding alveoli (organizing pneumonia; Fig. 18-66). Alveolar organizing pneumonia predominates; bronchiolitis obliterans may not be seen in all cases. Lung architecture is preserved, without honeycombing. Obstructive or endogenous lipid pneumonia may develop if there is significant bronchiolitis obliterans due to occlusion of the distal airways. Alveolar septa are only slightly thickened with chronic inflammatory cells, and type II pneumocyte hyperplasia is mild.

CLINICAL FEATURES: The average age at presentation is 55. The onset is acute, with fever, cough and dyspnea, often with a history of a flu-like illness 4–6 weeks previously. Some patients may have predisposing conditions. Chest radiographs reveal localized opacities or bilateral interstitial infiltrates, which may migrate over time. Pulmonary function studies demonstrate a restrictive ventilatory pattern. Corticosteroid therapy is effective, and some patients recover within weeks to months even without therapy.

Acute Interstitial Pneumonia Is Idiopathic Diffuse Alveolar Damage

Acute interstitial pneumonia (AIP) is a clinical term for diffuse alveolar damage of unknown cause. The diagnosis requires exclusion of clinical and pathologic causes such as infection, collagen vascular disease and drug toxicity.

PATHOLOGY: The pathology is identical to DAD associated with known causes (see above), but histologic features such as necrosis, acute pneumonia, eosinophilia, vasculitis or hemorrhage, which suggest specific etiologies, must be excluded. In AIP, the pattern is usually of organizing DAD, so hyaline membranes may be inconspicuous; mainly, organizing loose connective tissue causes thickening of alveolar walls.

CLINICAL FEATURES: AIP has a mean age at onset of 50 with a wide range and no sex predominance. It usually begins after an illness that resembles an upper respiratory tract infection with myalgias, arthralgias, fever, chills and malaise. Patients develop severe exertional dyspnea over several days and usually present less than 3 weeks after experiencing the first symptoms. CT scan shows widespread consolidation. Mortality is approximately 50%, and those who survive may either recover completely or follow a course with recurrences and progressive interstitial lung disease.

Lymphoid Interstitial Pneumonia Often Accompanies Autoimmune Diseases

Lymphoid interstitial pneumonia (LIP) is a rare disease with lymphoid infiltrates distributed diffusely in interstitial spaces.

PATHOLOGY: The hallmark of LIP is diffuse lymphocytic infiltration of alveolar septa and peribronchiolar spaces, with plasma cells and macrophages

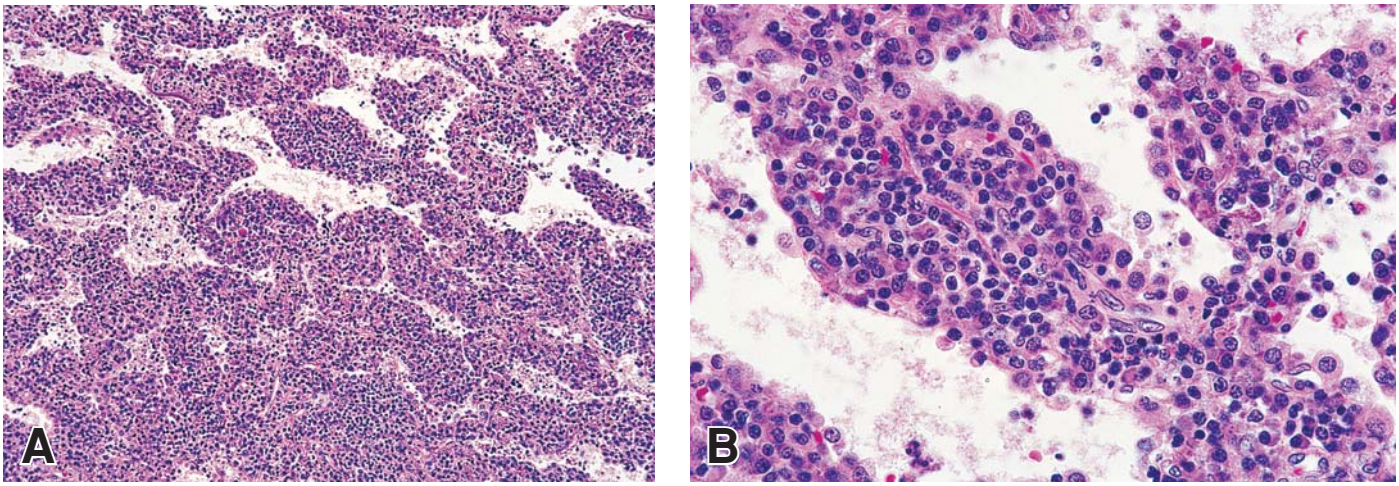

FIGURE 18-67. Lymphocytic interstitial pneumonia (LIP). A. The walls of the alveolar septa are diffusely infiltrated by chronic inflammation. **B.** The inflammatory infiltrate is composed of lymphocytes and plasma cells.

(Fig. 18-67). Alveolar architecture is preserved without scarring or remodeling. Marked type II pneumocyte hyperplasia may be seen, and inconspicuous foci of organizing interstitial fibrosis are occasionally present. Noncaseating sarcoid-like granulomas are often seen. Alveolar spaces tend to contain a proteinaceous exudate. Occasionally, scattered lymphoid aggregates are present, some containing germinal centers. Hyperplasia of peribronchiolar lymphoid tissue may be prominent.

CLINICAL FEATURES: LIP may be idiopathic but often occurs in patients with collagen vascular disease (especially Sjögren syndrome), dysproteinemia or HIV infection (Table 18-5). It is largely a disease of adults, but pediatric cases are recorded. In children, LIP is a defining criterion for the diagnosis of AIDS. Associated autoimmune manifestations include increased or reduced serum γ-globulins, various dysproteinemias and increased circulating autoantibodies, such as rheumatoid factor and antinuclear antibodies. Lymphoma may rarely develop in patients with LIP, particularly in patients with Sjögren syndrome and AIDS.

Symptoms of LIP include cough and progressive dyspnea. The disease varies from an indolent condition to one that progresses to end-stage lung and respiratory failure. Corticosteroids and cytotoxic agents have been of some benefit.

Langerhans Cell Histiocytosis Entails Diverse Histiocyte Proliferations

Different presentations of Langerhans cell histiocytosis (LCH) have been called **eosinophilic granuloma, Hand-Schüller-Christian disease** and **Letterer-Siwe disease** (see Chapter 26). LCH can affect the lung as a distinctive form of interstitial lung disease. In adults, LCH is ***primarily seen in cigarette smokers*** and may occur as an isolated lesion (previously **pulmonary eosinophilic granuloma**) or as diffuse cystic lung disease. Extrapulmonary manifestations such as bone lesions or diabetes insipidus occur in 10%–15% of cases. In children, lung involvement may occur in association with the multisystemic Letterer-Siwe disease or Hand-Schüller-Christian disease.

PATHOLOGY: Histologically, pulmonary LCH appears as scattered nodular infiltrates with a stellate border extending into the surrounding interstitium (Fig. 18-68A). These lesions are frequently subpleural or centered on bronchioles. They contain varying proportions of Langerhans cells admixed with lymphocytes, eosinophils and macrophages. Langerhans cells are round to oval,

The nodular interstitial infiltrate has a stellate shape, with extension of cells into adjacent alveolar septa. **B.** Higher-power view shows Langerhans cells with moderate amount of eosinophilic cytoplasm and prominently grooved nuclei. Eosinophils are present.

with a moderate amount of eosinophilic cytoplasm and prominently grooved nuclei with small inconspicuous nucleoli (Fig. 18-68B). As the disease progresses, lesions cavitate and become fibrotic, and honeycomb fibrosis may result. Parenchyma adjacent to the nodular lesions may show marked accumulation of intra-alveolar macrophages, owing to respiratory bronchiolitis caused by smoking.

Langerhans cells are distinctive: they show cytoplasmic Birbeck granules (on electron microscopy), C3, IgG-F_c receptors, CD1a and human leukocyte antigen (HLA)-DR and S-100 protein expression. Whether pulmonary LCH is a neoplastic proliferation or an abnormal immunologic response to antigens within cigarette smoke is unclear. Recently, BRAF mutations have been reported in a subset of pulmonary LCH.

CLINICAL FEATURES: Pulmonary LCH usually affects patients in their third and fourth decades. The most common presenting symptoms are nonproductive cough, dyspnea on exertion and spontaneous pneumothorax, but 25% of patients are asymptomatic at the time of diagnosis. Chest radiographs show diffuse, bilateral, reticulonodular lesions, usually in the upper lobes. The lesions frequently undergo cavitation. Although most patients have a good prognosis, some develop chronic pulmonary dysfunction. In a few cases, progressive pulmonary fibrosis can lead to death. Cessation of smoking is beneficial in early stages of the disease.

In Lymphangioleiomyomatosis Abnormal Smooth Muscle Proliferates in the Lung and Lymphatics

Lymphangioleiomyomatosis (LAM) is a rare interstitial lung disease that occurs almost exclusively in women of child-bearing age and is characterized by widespread abnormal proliferation of smooth muscle in the lung, mediastinal and retroperitoneal lymph nodes and major lymphatic ducts. Its etiology is unknown, but clinical responses to oophorectomy and progesterone therapy suggest that the smooth muscle proliferation is under hormonal control. Its occurrence in patients with tuberous sclerosis and its association with renal angiomyolipomas suggest that LAM may be a forme fruste of **tuberous sclerosis**. LAM is also associated with tuberous sclerosis gene complex (TSC) mutations, whether or not the patient has fully developed tuberous sclerosis. LAM cells are thought to be derived from perivascular epithelioid cells similar to other lesions associated with tuberous sclerosis, such as angiomyolipoma and clear cell tumor.

PATHOLOGY: The lungs show bilateral, diffuse enlargement, with extensive cystic changes as in emphysema (Fig. 18-69A). Many cystic spaces are lined by focal nodules or bundles of abnormal smooth muscle cells. These round or spindle-shaped cells (LAM cells) resemble immature smooth muscle cells but lack the parallel orientation of normal smooth muscle around airways and blood vessels (Fig. 18-69B). This proliferation typically follows a lymphatic distribution in the lung, around blood vessels and bronchioles and along pleura and interlobular septa. Blood vessel walls, especially in small pulmonary veins, may also be infiltrated, causing microscopic hemorrhage and hemosiderin accumulation in alveolar macrophages. Immunostaining for HMB-45 (a melanoma antigen) specifically identifies LAM cells and distinguishes them from other lung smooth muscle cells. They usually also express estrogen or progesterone receptors.

CLINICAL FEATURES: Patients with LAM have shortness of breath, spontaneous pneumothorax, hemoptysis, cough and chylous effusions. In early stages, the chest radiograph may be normal, but may show a diffuse interstitial reticular or cystic pattern as the disease progresses. Pleural effusions, marked hyperinflation of the lungs and pneumothorax may ensue. Pulmonary function tests show markedly increased total lung capacity, decreased diffusing capacity and obstructive or restrictive features. Some patients have an indolent clinical course, but many die of progressive respiratory failure. Hormonal ablation through oophorectomy, as well as antiestrogen (tamoxifen) and progesterone therapy, showed initial promise but has not proven to be effective therapy over time. Mutations of the TSC genes lead to activation of the mammalian target of rapamycin (mTOR) pathway, and as such, sirolimus is currently under investigation as a potential therapy.

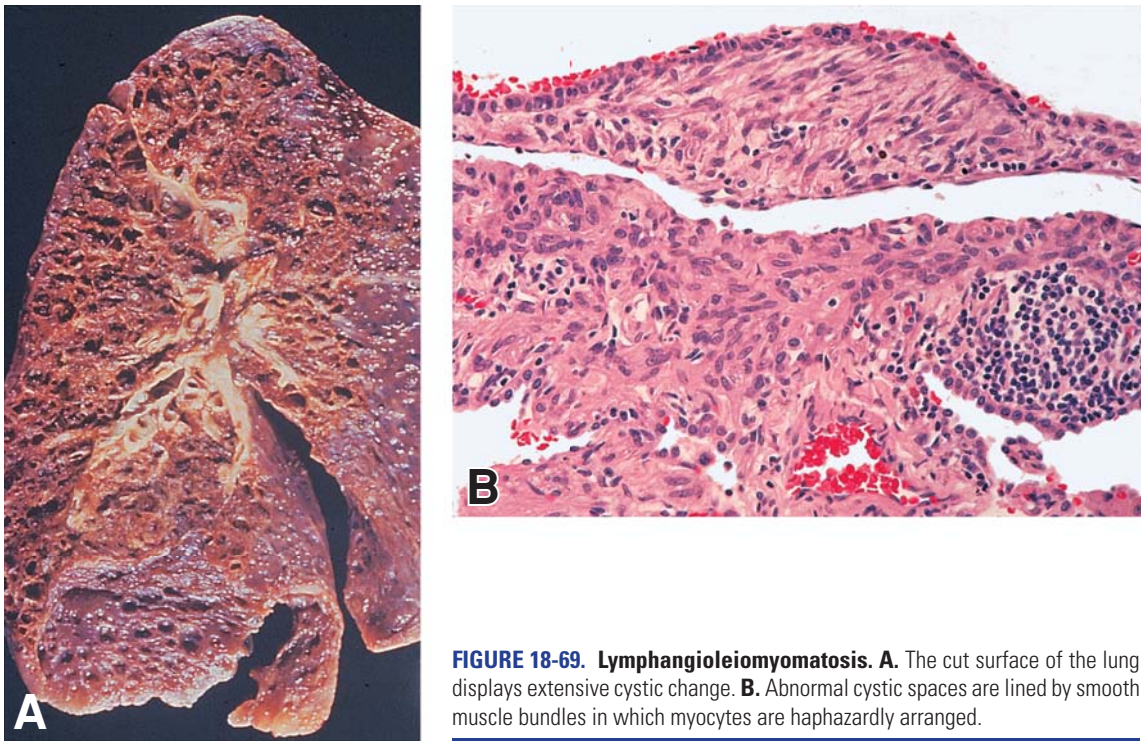

FIGURE 18-69. Lymphangioleiomyomatosis. A. The cut surface of the lung displays extensive cystic change. **B.** Abnormal cystic spaces are lined by smooth muscle bundles in which myocytes are haphazardly arranged.

LUNG TRANSPLANTATION

Patients who undergo lung transplantation are prone to acute and chronic rejection and infection. The histology of acute rejection includes perivascular infiltrates of small round lymphocytes, plasmacytoid lymphocytes, macrophages and eosinophils. In severe cases, inflammation may involve adjacent alveoli, and hyaline membranes may be seen. The major pattern of chronic rejection is bronchiolitis obliterans, characterized by bronchiolar inflammation and varying degrees of fibrosis. The latter can take the form of polypoid plugs of intraluminal granulation tissue or concentric mural fibrosis, with the pattern of constrictive bronchiolitis (Fig. 18-70). Bronchiectasis is common in long-term survivors of lung transplants, perhaps related to poor perfusion of the airways, denervation and/or recurrent airway infection.

Opportunistic infections, including bacteria, fungi, viruses and *Pneumocystis*, are common in transplant patients. The most common fungal pathogens are *Candida* and *Aspergillus* spp. CMV is the most common cause of viral pneumonia. Of lung transplant patients who survive more than 30 days, 3%–8% develop **lymphoproliferative disorders,** owing to uncontrolled proliferation of Epstein-Barr virus (EBV)–infected B lymphocytes as a result of immunosuppression by cyclosporine.

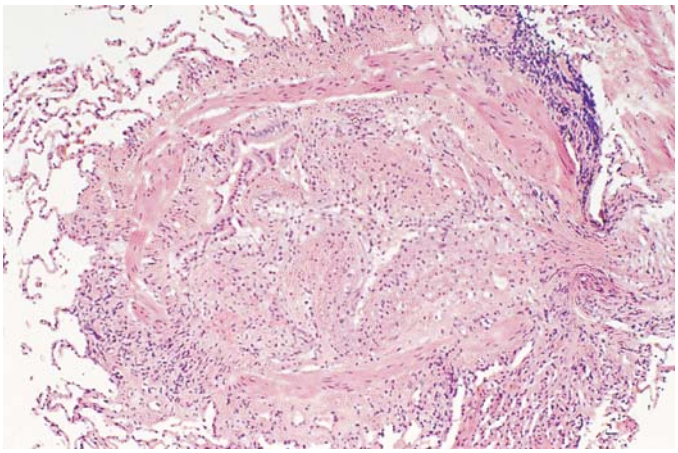

FIGURE 18-70. Obliterative bronchiolitis, chronic rejection in lung transplantation. The lumen of this bronchiole is virtually obliterated by concentric fibrosis.

VASCULITIS AND GRANULOMATOSIS

Many pulmonary conditions result in vasculitis, most of which are secondary to other inflammatory processes, such as necrotizing granulomatous infections. Only a few primary idiopathic vasculitis syndromes affect the lung, the most important of which are granulomatosis with polyangiitis (GPA, formerly Wegener granulomatosis), microscopic polyangiitis, eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg-Strauss granulomatosis) and necrotizing sarcoid granulomatosis.

Granulomatosis with Polyangiitis Has Aseptic, Necrotizing Granulomas and Vasculitis

GPA (formerly called Wegener granulomatosis) is a disease of unknown cause. Blood vessels affected by the disease are small and medium sized. It chiefly affects upper and lower respiratory tracts and the kidneys (see Chapters 16, 22 and 29), but many cases also involve the eyes, joints, skin and peripheral nerves. Here, we deal only with pulmonary manifestations of GPA.

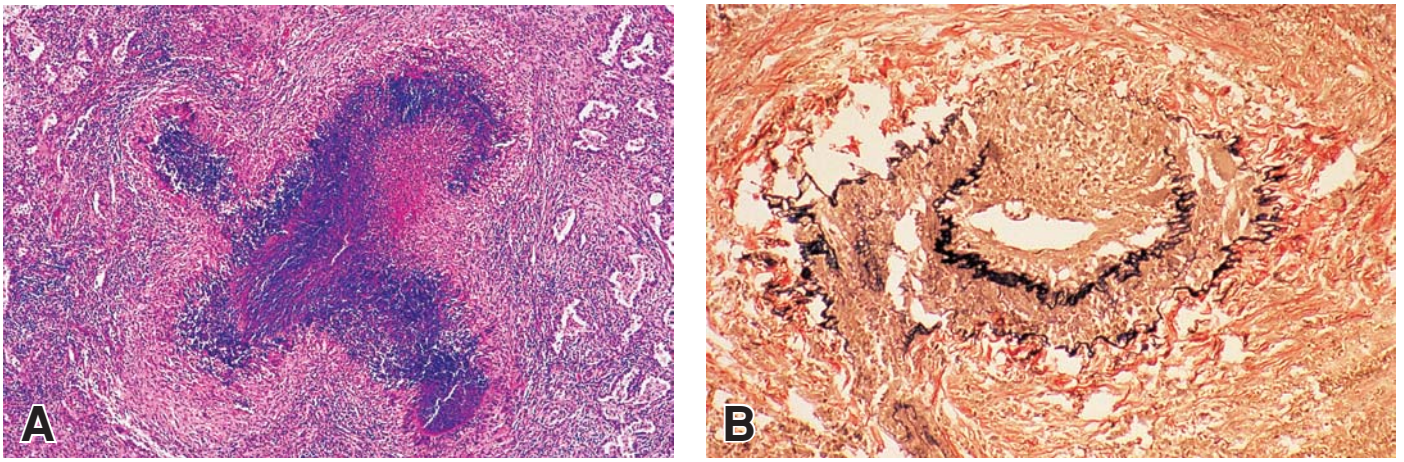

FIGURE 18-71. Granulomatosis with polyangiitis (formerly Wegener granulomatosis). A. This large area of necrosis has a "geographical" pattern with serpiginous borders and a basophilic center. **B.** Vasculitis in this artery is characterized by a focal, eccentric, transmural chronic inflammatory infiltrate that destroys the inner and outer elastic laminae (elastic stain).

PATHOLOGY: GPA in the lung is characterized by necrotizing granulomatous inflammation, parenchymal necrosis and vasculitis. Most cases show multiple bilateral nodules, averaging 2–3 cm, with irregular edges, tan-brown or hemorrhagic cut surfaces and frequent central cavitation.

Nodules of parenchymal consolidation show (1) tissue necrosis; (2) granulomatous inflammation with a mixture of lymphocytes, plasma cells, neutrophils, eosinophils, macrophages and giant cells; and (3) fibrosis. Necrosis may feature neutrophilic microabscesses or large basophilic zones of "geographical" necrosis with irregular serpiginous borders (Fig. 18-71A). Patterns of GPA granulomas include palisading macrophages along the border of the large necrotic zones, loosely clustered multinucleated giant cells and scattered giant cells. Vasculitis may affect arteries (Fig. 18-71B), veins or capillaries and may show acute, chronic or granulomatous inflammation. Organizing pneumonia is common at the edges of the nodules of inflammatory consolidation. The lungs often show acute or chronic alveolar hemorrhage. "Neutrophilic capillaritis," with neutrophils in alveolar walls, is common.

CLINICAL FEATURES: GPA mostly affects the head and neck, then the lung, kidney and eye. Respiratory manifestations include cough, hemoptysis and pleuritis. Chest radiographs often show multiple intrapulmonary nodules, although single nodules may also be seen. Head and neck manifestations include sinusitis, nasal disease, otitis media, hearing loss, subglottic stenosis, ear pain, cough and oral lesions. Systemic symptoms include arthralgias, fever, skin lesions, weight loss, peripheral neuropathy, central nervous system abnormalities and pericarditis.

Diffuse pulmonary hemorrhage, an important complication of GPA, is a fulminant life-threatening crisis with severe respiratory failure. It is usually accompanied by acute renal failure.

It is currently thought that ANCAs are responsible for the inflammation in GPA. Serum ANCAs are a useful marker for GPA and other vasculitis syndromes. This test yields two major immunofluorescence patterns: cytoplasmic (C-ANCA) and perinuclear (P-ANCA). C-ANCAs reacting with proteinase 3 occur in more than 85% of patients with active generalized GPA. Most P-ANCAs are specific for myeloperoxidase and are seen with idiopathic necrotizing and crescentic glomerulonephritis, polyarteritis nodosa or Churg-Strauss syndrome.

Most patients with GPA are treated effectively with corticosteroids and cyclophosphamide, and 5-year survival is now almost 90%. Some patients respond to trimethoprim-sulfamethoxazole, suggesting a possible bacterial infection.

Microscopic Polyangiitis

Microscopic polyangiitis is a pauci-immune vasculitis involving arterioles, venules and capillaries. Almost all patients also show evidence of glomerulonephritis, and microscopic polyangiitis has emerged as one of the more common causes of "pulmonary-renal syndrome." Joints and muscle, upper respiratory tract and skin may also be involved. Over 80% of patients have a positive ANCA, most often of the "perinuclear" type (P-ANCA), directed against myeloperoxidase. Microscopic polyangiitis may occur at any age and is of equal incidence in both males and females. Lung biopsies show alveolar hemorrhage with neutrophilic capillaritis (Fig. 18-72). Immunoglobulin deposition is not seen.

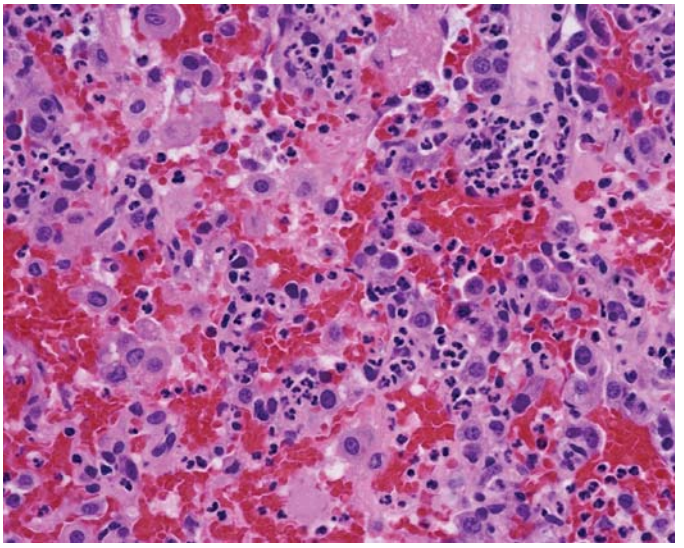

FIGURE 18-72. Microscopic polyangiitis. Alveolar walls are thickened owing to prominent infiltration by neutrophils.

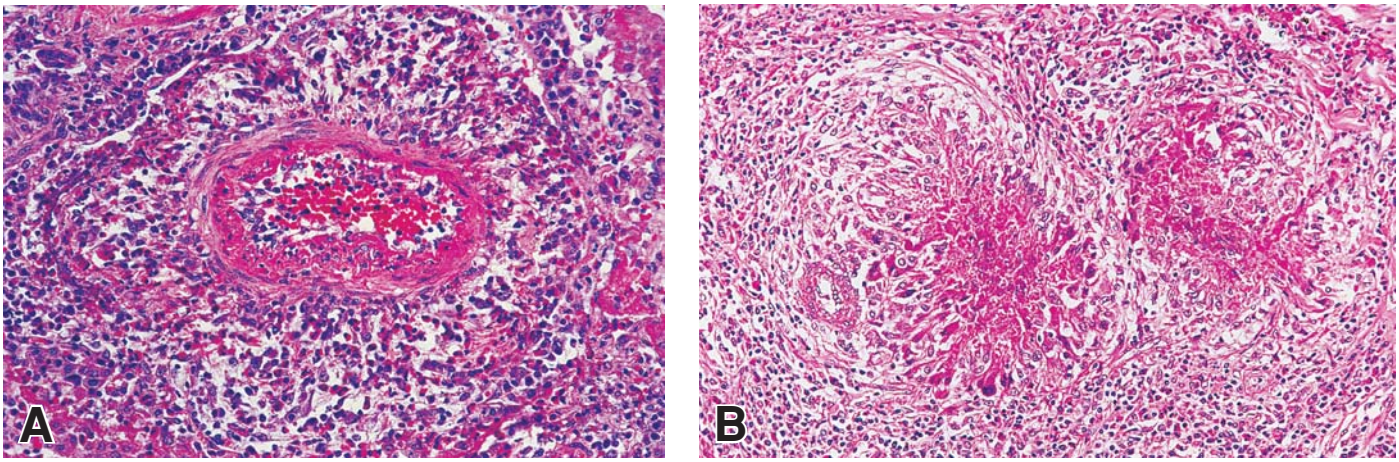

FIGURE 18-73. Allergic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome). A. An artery shows severe vasculitis consisting of a dense infiltrate of chronic inflammatory cells and eosinophils. **B.** A necrotic ("allergic") granuloma has a central eosinophilic area of necrosis surrounded by palisading macrophages and giant cells.

Eosinophilic Granulomatosis with Polyangiitis Is a Disorder of Unknown Etiology, Defined by Asthma, Eosinophilia and Vasculitis

PATHOLOGY: The lungs of patients with EGPA (formerly Churg-Strauss syndrome or allergic angiitis and granulomatosis) show changes of asthmatic bronchitis or bronchiolitis (see above), including eosinophilic pneumonia, vasculitis (Fig. 18-73A), parenchymal necrosis (Fig. 18-73B) and granulomatous inflammation. Infiltrates of eosinophils may be seen in any anatomic compartment of the lung. Involvement of blood vessel walls causes vasculitis and damage to airway walls and results in bronchitis or bronchiolitis. The vasculitis includes eosinophils, lymphocytes, plasma cells, macrophages, giant cells and neutrophils (Fig. 18-73A). Necrotic foci have eosinophilic centers owing to accumulation of dead eosinophils (Fig. 18-73B).

CLINICAL FEATURES: EGPA has 3 clinical phases.

- **Prodrome:** Patients have one or more of the following: allergic rhinitis, asthma, peripheral eosinophilia and eosinophilic infiltrative disease (eosinophilic pneumonia or eosinophilic enteritis).
- **Systemic vasculitic phase:** Extrapulmonary vasculitic manifestations are present, such as cutaneous leukocytoclastic vasculitis or peripheral neuropathy.
- **Postvasculitic phase:** Asthma, allergic rhinitis and complications of neuropathy and hypertension may persist. Cardiovascular manifestations are common and include pericarditis, hypertension and cardiac failure. Renal disease and sinus involvement are usually less severe than those in GPA.

The cause of EGPA is obscure. An autoimmune mechanism is likely, in view of the hypergammaglobulinemia, increased IgE, rheumatoid factor and ANCA.

Patients with EGPA usually are positive for P-ANCA in the vasculitic phase. Most patients respond to corticosteroid therapy, but cyclophosphamide may be needed in severe cases. With treatment, the 5-year survival is 60%.

Necrotizing Sarcoid Granulomatosis Shows Large Zones of Necrosis and Vasculitis

Necrotizing sarcoid granulomatosis is a rare condition featuring nodular confluent sarcoidal granulomas (Fig. 18-74).

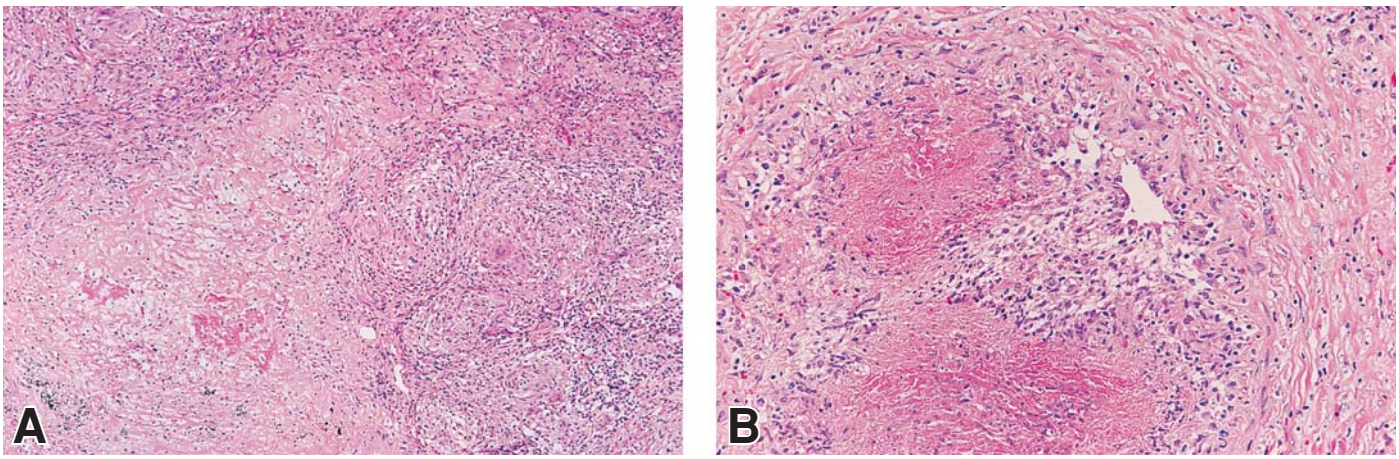

FIGURE 18-74. Necrotizing sarcoid granulomatosis. A. A large area of necrosis is surrounded by confluent sarcoid granulomas. **B.** The vasculitis consists of a necrotizing granuloma in the wall of an artery.

It is not a systemic vasculitis, but is usually limited to the lung. Giant cells and necrotizing granulomas (Fig. 18-74B) are seen, as is chronic inflammation with lymphocytes and plasma cells. Most patients are asymptomatic, and chest radiographs typically show multiple, well-circumscribed, pulmonary nodules. Extrapulmonary disease is uncommon, and localized lesions may be treated effectively by surgical removal. Corticosteroids are usually effective for patients with multiple lesions. The prognosis is excellent.

PULMONARY HYPERTENSION

In fetal life, pulmonary arterial walls are thick, as pulmonary arterial pressure is high. Blood is oxygenated through the placenta, not the lungs, and high fetal pulmonary arterial resistance helps to shunt right ventricular output through the ductus arteriosus into the systemic circulation. After birth, the ductus arteriosus closes and the lungs must oxygenate venous blood. The lungs must therefore adapt to accept the entire cardiac output, which demands the high-volume and low-pressure system of the mature lung. By the third day of life, pulmonary arteries dilate, their walls become thin and pulmonary arterial pressure declines.

Elevated pulmonary arterial pressure is defined as a mean pressure over 25 mm Hg at rest. Increased pulmonary blood flow or vascular resistance may lead to higher pulmonary arterial pressure. Whatever the cause, increased pulmonary artery pressure alters pulmonary artery histology (Fig. 18-75). The Heath and Edwards grading system was devised to determine if the arterial changes of pulmonary hypertension could be reversed with corrective cardiac surgery. Grades 1, 2 and 3 are generally reversible; grades 4 and above are generally not.

- **Grade 1:** Medial hypertrophy of muscular pulmonary arteries and appearance of smooth muscle in pulmonary arterioles.
- **Grade 2:** Intimal proliferation with increasing medial hypertrophy.
- **Grade 3:** Intimal fibrosis of muscular pulmonary arteries and arterioles, which may be occlusive (Fig. 18-76A).
- **Grade 4:** Plexiform lesions, dilation and thinning of pulmonary arteries. These nodular lesions are composed of irregular interlacing blood channels and further obstruct pulmonary blood flow (Fig. 18-76B).
- **Grade 5:** Plexiform lesions in combination with dilation or angiomatoid lesions. Rupture of dilated thin-walled vessel, with parenchymal hemorrhage and hemosiderosis, is also present.
- **Grade 6:** Fibrinoid necrosis of arteries and arterioles.

Even mild pulmonary atherosclerosis is uncommon if pulmonary arterial pressure is normal. However, atherosclerosis is seen in the largest pulmonary arteries with all grades of pulmonary hypertension. Increased pressure in the lesser circulation leads to hypertrophy of the right ventricle **(cor pulmonale)**.

Pulmonary Hypertension May Be Precapillary or Postcapillary in Origin

Whether the primary source of increased flow or resistance is proximal or distal to the pulmonary capillary bed may be used to understand the pathophysiology of pulmonary hypertension. Precapillary hypertension includes left-to-right cardiac shunts, primary pulmonary hypertension, thromboembolic pulmonary hypertension and hypertension due to fibrotic lung disease and hypoxia. Postcapillary hypertension includes pulmonary veno-occlusive disease and hypertension secondary to left-sided cardiac disorders, such as mitral stenosis and aortic coarctation.

Left-to-Right Shunts

Shunts from the systemic to the pulmonary circuit increase blood flow to the lungs. Most cases represent congenital left-to-right shunts (see Chapter 17). At birth, the pulmonary artery and the aorta have about the same number of elastic lamellae in their media. Normally, elastic lamellae in the pulmonary artery are lost after birth, but if pulmonary hypertension is present, the fetal pattern of elastic lamellation persists.

Primary Pulmonary Hypertension

Primary pulmonary hypertension is a rare precapillary disorder caused by increased pulmonary arterial tone. The

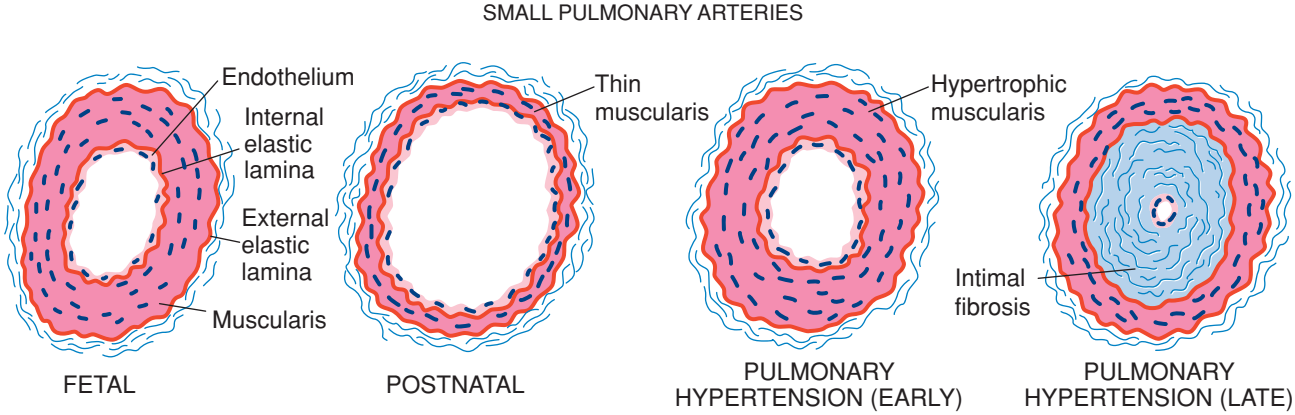

FIGURE 18-75. Histopathology of pulmonary hypertension. In late gestation, the pulmonary arteries have thick walls. After birth, the vessels dilate, and the walls become thin. Mild pulmonary hypertension is characterized by thickening of the media. As pulmonary hypertension becomes more severe, there is extensive intimal fibrosis and muscle thickening.

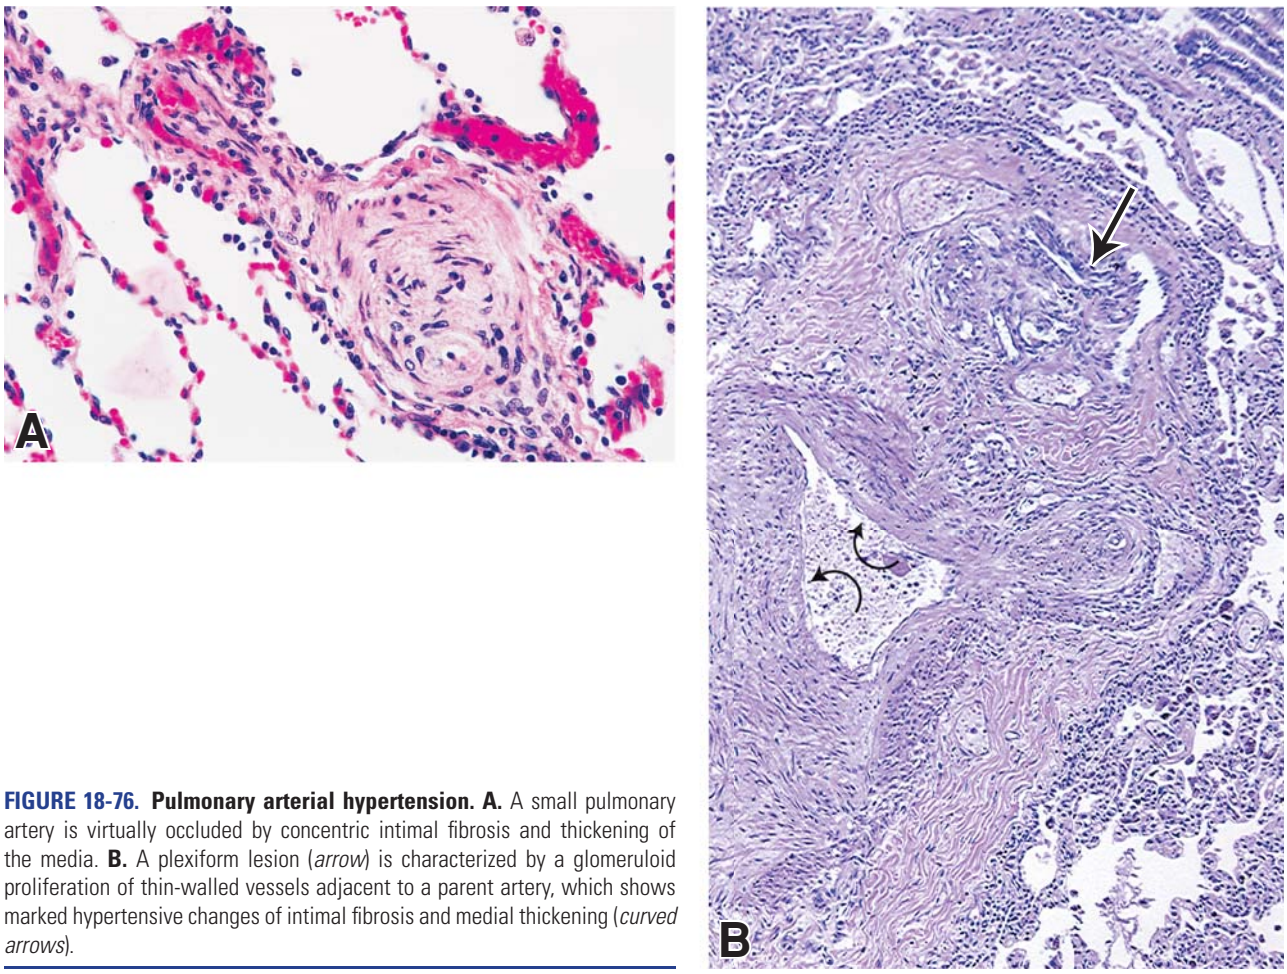

FIGURE 18-76. Pulmonary arterial hypertension. A. A small pulmonary artery is virtually occluded by concentric intimal fibrosis and thickening of the media. **B.** A plexiform lesion (*arrow*) is characterized by a glomeruloid proliferation of thin-walled vessels adjacent to a parent artery, which shows marked hypertensive changes of intimal fibrosis and medial thickening (*curved arrows*).

condition may be idiopathic, but some cases are hereditary and have been associated with mutations of bone morphogenetic protein receptor type 2 (*BMPR2*), activin receptor-like kinase 1 (*ALK1*) and endoglein. Pulmonary arterial hypertension may also be encountered in association with underlying collagen vascular diseases or may be induced by drugs or toxins (an example being the diet drug "phen-phen"). Pulmonary arterial hypertension occurs at all ages but is most common in young women in their 20s and 30s. It presents with insidious onset of dyspnea. Physical signs and radiologic abnormalities are initially slight but become more apparent with time. Severe pulmonary hypertension, typically associated with plexiform lesions histologically, eventually ensues, and patients die of cor pulmonale. Although medical treatment is mostly ineffective, recent use of prostacyclin analogs, endothelin receptor antagonists and phosphodiesterase-5 inhibitors have led to a 5-year survival of about 30%. Heart–lung transplantation is often indicated.

Recurrent Pulmonary Emboli

Multiple thromboemboli in smaller pulmonary vessels often result from asymptomatic, episodic showers of small emboli from the periphery. They gradually limit pulmonary circulation and lead to pulmonary hypertension. Some patients have peripheral venous thromboses, usually in leg veins, or a history of circumstances predisposing to venous thrombosis. In addition to the vascular lesions of pulmonary hypertension, organized thromboemboli are evidenced by fibrous bands ("webs") that extend across the lumina of small pulmonary arteries. If the condition is diagnosed during life, placement of a filter in the inferior vena cava usually prevents further embolization.

Any Disorder That Produces Hypoxemia Can Constrict Small Pulmonary Arteries and Lead to Pulmonary Hypertension

Predisposing conditions include chronic airflow obstruction (chronic bronchitis), interstitial lung disease and living at high altitude. Severe kyphoscoliosis or extreme obesity **(Pickwickian syndrome)** may impede ventilation and lead to hypoxemia and pulmonary hypertension.

Left Ventricular Failure Increases Pulmonary Venous Pressure and Secondarily Pulmonary Arterial Pressure

Both mitral stenosis and insufficiency can produce severe venous hypertension and significant pulmonary artery hypertension. In such cases, the lungs exhibit lesions of both pulmonary hypertension and chronic passive congestion (see Chapter 7).

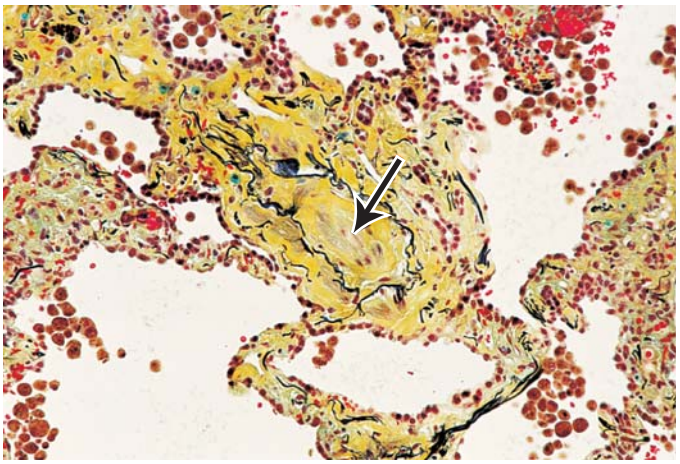

FIGURE 18-77. Veno-occlusive disease of the lung. This pulmonary vein is occluded by intimal fibrosis (*arrow;* Movat stain).

Pulmonary Veno-Occlusive Disease Involves Fibrotic Obstruction of Small Veins

Pulmonary veno-occlusive disease (PVOD) is a rare condition of uncertain etiology in which small pulmonary veins and venules are occluded by loose, sparsely cellular, intimal fibrosis (Fig. 18-77). Some large veins may also be involved, and in half of cases, similar but less severe lesions affect pulmonary arteries. The obstructive lesions may canalize, and so could represent organized thrombi, possibly due to endothelial damage. PVOD may follow viral infections, exposure to toxic agents and chemotherapy. More than half of cases occur in the first three decades of life. In children, girls and boys are affected similarly, but after age 15, it is more common in men.

PATHOLOGY: Pulmonary veno-occlusive disease produces severe pulmonary hypertension. Grossly, the lung shows brown induration and atherosclerosis of large pulmonary arteries. Microscopically, small veins and venules are partly or totally occluded and larger veins show eccentric intimal thickening. Moderate alveolar wall fibrosis and foci of hemosiderosis are common. Pulmonary arteries show recent thrombi and lesions of severe pulmonary hypertension.

CLINICAL FEATURES: The clinical presentation of progressive dyspnea is similar to that of primary pulmonary hypertension, but pulmonary veno-occlusive disease has a more fulminant course. Radiologic examination reveals scattered infiltrates in the lung, representing hemorrhage and hemosiderosis, which increase as the disease progresses. There is no effective therapy, and heart–lung transplantation should be contemplated.

Pulmonary Neoplasms

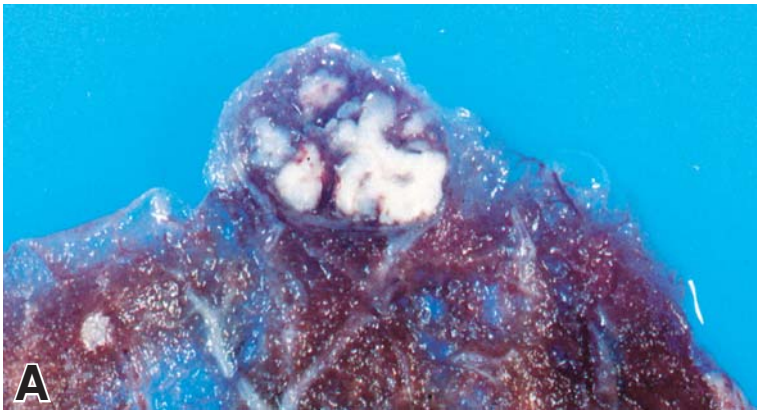
PULMONARY HAMARTOMA

The term "hamartoma" implies a malformation, but hamartomas are true tumors. They typically occur in adults, with a peak in the sixth decade of life, and account for 10% of "coin" lesions discovered incidentally on chest radiographs. A characteristic ("popcorn") pattern of calcification is often seen by x-ray.

PATHOLOGY: Grossly, pulmonary hamartomas are solitary, circumscribed, lobulated masses, averaging 2 cm in diameter, with a white or gray, cartilaginous cut surface (Fig. 18-78A). The tumor has elements usually present in the lung: cartilage, fibromyxoid connective tissue, fat, bone and occasionally smooth muscle (Fig. 18-78B), interspersed with clefts lined by respiratory epithelium. Hamartomas are benign and well circumscribed and shell out from the surrounding lung parenchyma. Most are seen in the periphery, but 10% occur in a central endobronchial location. The latter may cause symptoms due to bronchial obstruction.

CARCINOMA OF THE LUNG

EPIDEMIOLOGY: Regarded as a rare tumor as recently as 1945, lung cancer is the most common cause of cancer mortality worldwide. In the United States, where it is the leading cause of cancer death in both men and women, 85%–90% of lung cancers occur in cigarette smokers (see Chapter 8); conversely, the lifetime risk of developing lung cancer in smokers is 12%–17%. Smokers are



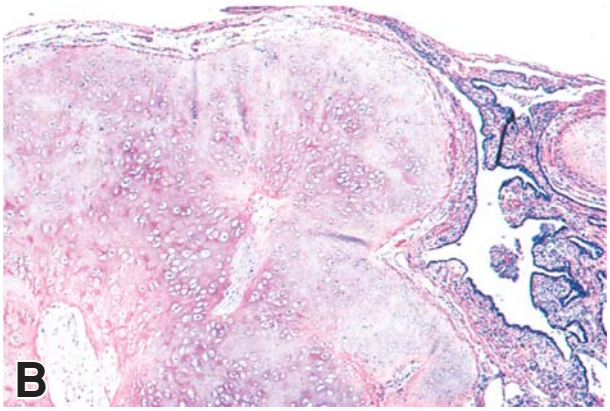


FIGURE 18-78. Pulmonary hamartoma. A. The cut surface of a sharply circumscribed, peripheral pulmonary nodule shows a lobulated structure. **B.** A photomicrograph reveals nodules of hyaline cartilage separated by connective tissue lined by respiratory epithelium.

TABLE 18-6
FREQUENCY OF LUNG CARCINOMA HISTOLOGIC TYPES BY GENDER (NCI SEER DATA, HISTOLOGICALLY CONFIRMED, 2006–2010)

Subtype	Males	Females	Males and Females
Adenocarcinoma	32.9	40.5	36.4
Squamous cell carcinoma	23.8	15.6	20
Small cell carcinoma	13.0	14.7	13.8
Large cell carcinoma	3.6	2.9	3.3
Other carcinomas	23.7	21.8	22.8
Carcinoid	2.0	3.5	2.7
Adenosquamous carcinoma	1.0	1.0	1.0

at risk for "non–small cell lung carcinomas" (NSCLCs)—encompassing squamous cell carcinoma, adenocarcinoma and large cell carcinoma (see also Pathology paragraph below)—and for small cell lung carcinoma (SCLC). Most of the never-smokers who develop lung cancer have an adenocarcinoma. In general, 80% of lung cancers are NSCLC and 17% are SCLC. The distribution of histologic subtypes of NSCLC according to gender is shown in Table 18-6. The peak age for lung cancer is between 60 and 70 years, with most patients between 50 and 80 years. The former male predominance is decreasing as smoking increases among women.

General Features of Lung Cancer

CLINICAL FEATURES: Lung cancer presents in early stages in 30% of patients where the primary treatment approach is surgical resection and pathology assessment is based on evaluation of the entire tumor. However, the remaining 70% of lung cancers present as advanced, unresectable disease. Then, diagnosis is based on nonresection specimens (small biopsies and cytology) and treatment is mostly chemotherapy and/or radiation.

Lung cancers were categorized as SCLCs and NSCLCs, with the latter encompassing squamous cell carcinoma, adenocarcinoma and large cell carcinoma. The reason for this was that small cell carcinomas responded to specific chemotherapies, but non–small cell tumors did not. Now, some NSCLCs can be treated with chemotherapy: lung adenocarcinoma patients whose tumors express endothelial growth factor receptor (*EGFR*) mutations or rearrangements involving the anaplastic lymphoma kinase gene (ALK, or CD246, not to be confused with ALK1, see above) show better progression-free survival if treated with tyrosine kinase inhibitors or crizotinib, respectively. Patients with advanced-stage adenocarcinoma—but not squamous cell carcinoma—respond to a folate antimetabolite, pemetrexed. Furthermore, patients with advanced squamous carcinoma are at risk for life-threatening hemorrhage.

Overall survival for all patients with NSCLC was 15% for the past few decades. However, advanced lung cancer patients with *EGFR* mutations or ALK rearrangements show improved 2-year progression-free survival, from 20% to 60%, with tyrosine kinase inhibitor and ALK therapy, respectively. The molecular landscape of lung cancer is evolving rapidly.

Small cell carcinomas have a dismal prognosis: 5-year survival of 5% or less. ***Tumor stage is the single most important predictor of prognosis.*** The staging system for lung carcinoma is based primarily on tumor size, extent of spread in the lung and chest, lymph node involvement and distant metastases or malignancy involving the pleural fluid. The staging system for lung cancer is summarized in Table 18-7.

LOCAL EFFECTS: Lung cancer can produce cough, dyspnea, hemoptysis, chest pain, obstructive pneumonia and pleural effusion. A lung cancer (usually squamous) in the apex of the lung **(Pancoast tumor)** may extend to involve the eighth cervical and first and second thoracic nerves, leading to shoulder pain that radiates down the arm in an ulnar distribution **(Pancoast syndrome)**. A Pancoast tumor also may paralyze cervical sympathetic nerves and cause **Horner syndrome** on the affected side with (1) depression of the eyeball (enophthalmos), (2) ptosis of the upper eyelid, (3) constriction of the pupil (miosis) and (4) absence of sweating (anhidrosis).

Most central endobronchial tumors produce symptoms related to bronchial obstruction: persistent cough, hemoptysis and obstructive pneumonia, or atelectasis. Effusions can result from tumor extension into the pleura or pericardium. Lymphangitic spread of the tumor within the lung may interfere with oxygenation. Tumors arising peripherally are more likely to be discovered on routine chest radiographs or after they have become advanced. The latter circumstance features invasion of the chest wall with resulting chest pain, superior vena cava syndrome and nerve entrapment syndromes.

MEDIASTINAL SPREAD: Tumor growth within the mediastinum can cause superior vena cava syndrome (owing to tumorous obstruction of this vein) and nerve entrapment syndromes.

METASTASES: Lung cancers metastasize most often to regional lymph nodes, particularly hilar and mediastinal nodes, and to the brain, bone and liver. Extranodal metastases often involve the adrenal gland, but adrenal insufficiency is uncommon.

PARANEOPLASTIC SYNDROMES: Disorders associated with lung cancer include acanthosis nigricans, dermatomyositis/polymyositis, clubbing of the fingers and myasthenic syndromes, such as Eaton-Lambert syndrome and progressive multifocal encephalopathy. Endocrine syndromes are also seen, for example, Cushing syndrome or the syndrome of inappropriate release of antidiuretic hormone (SIADH) in small cell carcinomas, and hypercalcemia (secretion of a parathormone-like substance) in squamous cell carcinomas. Small cell carcinomas may also be associated with a syndrome of paraneoplastic encephalomyelitis and sensory neuropathy associated with circulating anti-Hu antibodies.

MOLECULAR PATHOGENESIS: No single mutation determines the development of lung cancer, but some are common and may allow for targeted chemotherapy.

- ***EGFR:*** Activating mutations in the tyrosine kinase domain of this gene are of particular interest in lung adenocarcinomas,

TABLE 18-7
AMERICAN JOINT COMMISSION ON CANCER LUNG CANCER STAGING SYSTEM

T1	Tumor <3 cm surrounded by lung or visceral pleura and not involving the mainstem bronchus T1a: <2 cm T1b: 2–3 cm
T2	Tumor >3 cm but ≤7 cm OR tumor with any of the following features: Involves main bronchus, ≥2 cm distal to the carina Invades visceral pleura Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung T2a: >3 cm but ≤5 cm T2b: >5 cm but ≤7 cm
T3	Tumor >7 cm OR a tumor with involvement of any of the following: chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura, pericardium or main stem bronchus 2 cm from carina OR entire lung atelectasis OR separate tumor nodules in the same lobe
T4	Tumor with invasion of mediastinum, heart, great vessels, trachea, esophagus, vertebral body or carina OR separate tumor nodules in a different ipsilateral lobe
N0	No demonstrable metastasis to regional lymph nodes
N1	Ipsilateral hilar or peribronchial nodal involvement
N2	Metastasis to ipsilateral mediastinal or subcarinal lymph nodes
N3	Metastasis to contralateral mediastinal or hilar lymph nodes, ipsilateral or contralateral scalene or supraclavicular lymph nodes
M0	No distant metastasis
M1	Distant metastasis M1a: separate tumor nodule in contralateral lobe or separate pleural nodules or malignant pleural effusion M1b: distant metastasis

owing to the responsiveness of mutated tumors to tyrosine kinase inhibitor drugs targeted against this receptor, such as erlotinib and gefitinib. *EGFR* mutations are more common in adenocarcinomas in nonsmokers, Asians and women. These mutations occur in 10%–15% of lung adenocarcinomas in the United States, with higher percentages in nonsmokers and women, but 40%–60% of East Asians have *EGFR* mutations.

- ***K-ras:*** Mutations in this oncogene, particularly codons 12 and 13, occur in 25% of adenocarcinomas, 20% of large cell carcinomas and 5% of squamous carcinomas, but rarely in SCLCs. These mutations correlate with cigarette smoking and with a poor prognosis in patients with adenocarcinoma. No effective targeted molecular therapy is available for *K-ras* mutations.
- ***EML4-ALK* translocations:** Fusion between echinoderm microtubule-associated protein-like 4 (*EML4*) and anaplastic lymphoma kinase (*ALK*) is encountered in approximately 5% of advanced pulmonary adenocarcinomas, most frequently in nonsmokers. Adenocarcinomas harboring this translocation are responsive to targeted therapy with crizotinib.
- ***Myc:*** Overexpression of this oncogene occurs in 10%–40% of small cell carcinomas but is rare in other types.
- ***p53:*** Mutations of *p53* are identified in more than 80% of small cell carcinomas and 50% of non–small cell tumors.
- ***Rb:*** Mutations in the retinoblastoma (*Rb*) gene occur in over 80% of small cell cancers and 25% of non–small cell carcinomas.
- **Chromosome 3 (3p):** Deletions in the short arm of this chromosome are frequently found in all types of lung cancers.
- ***bcl-2:*** This protooncogene encodes a protein that inhibits apoptosis (see Chapter 1). It is expressed in 25% of squamous cell carcinomas and 10% of adenocarcinomas.
- ***PTEN:*** This tumor suppressor gene regulates cell survival signaling and is deficient by one of a number of mechanisms (loss of heterozygosity, mutation, promoter methylation, etc.) in many non–small cell lung cancers. Loss of PTEN is associated with poor prognosis and drug resistance.
- ***FGFR1*** (fibroblast growth factor receptor 1): Amplification of FGFR1 has been reported in 20% of squamous cell carcinoma, and FGFR inhibitors are currently the subject of clinical testing.
- **Other mutations:** Abnormalities of *BRAF, PIK3CA, ERBB2, ROS-1, RET* and others have been reported in small percentages of lung carcinoma and are the focus of ongoing efforts to identify effective targeted therapies.

PATHOLOGY: Squamous cell carcinoma, adenocarcinoma, large cell carcinoma and small cell carcinoma are the major forms of lung cancer. Although the term **bronchogenic** carcinoma was once used, about one fourth of primary lung cancers do not have an obvious bronchial origin, so this term is no longer recommended. Squamous cell carcinoma, adenocarcinoma and large cell carcinoma have traditionally been lumped together from a clinical standpoint as "non–small cell carcinoma" because of historically similar treatment; however, advances in chemotherapy and targeted therapies in particular have made subtyping of critical importance, and the usage of "non–small cell carcinoma" is discouraged.

Histologic subtyping of lung cancer is based on the best-differentiated component, unless an area of small cell carcinoma is present. However, the degree of differentiation is graded according to the worst-differentiated component. If a tumor is mostly poorly differentiated large cells but has foci of squamous cells or adenocarcinoma, it is classified as a poorly differentiated squamous cell carcinoma or adenocarcinoma, respectively. Any cancer with a component of small cell carcinoma is regarded as a subtype of that tumor (see below).

Histologic Subtypes of Lung Carcinoma

Squamous Cell Carcinoma

Squamous cell carcinoma is the second most common histologic type of lung cancer, accounting for 20% of all lung cancers in the United States, and is more common in men than in women (Table 18-6). After injury to the bronchial epithelium, such as occurs with cigarette smoking, regeneration from the pluripotent basal layer commonly entails squamous metaplasia. The metaplastic squamous mucosa follows the same sequence of dysplasia, carcinoma in situ and invasive tumor seen in other sites normally lined by squamous epithelium, such as the cervix or skin.

Most squamous cell carcinomas arise centrally in the lung, from major or segmental bronchi, although 10% originate in the periphery. They tend to be firm, gray-white, 3–5-cm ulcerated lesions that extend through the bronchial wall into the adjacent lung parenchyma (Fig. 18-79A). Central cavitation is frequent. On occasion, a central squamous carcinoma occurs as an endobronchial tumor.

These tumors vary widely in degrees of squamous differentiation. Many show overt keratinization or intercellular bridges. Well-differentiated tumors have keratin "pearls," small round nests of brightly eosinophilic aggregates of keratin surrounded by concentric ("onion skin") layers of squamous cells (Fig. 18-79B). Individual cell keratinization also occurs, in which the cytoplasm becomes glassy and intensely eosinophilic. Intercellular bridges in some well-differentiated squamous cancers are slender gaps between adjacent cells, traversed by fine strands of cytoplasm. By contrast, some squamous tumors are very poorly differentiated: they lack keratinization and are difficult to distinguish from large cell, small cell or spindle cell carcinomas.

Adenocarcinoma

Worldwide, adenocarcinoma has overtaken squamous cell carcinoma as the most common subtype of lung cancer in most countries, and it is the most common type in nonsmokers. In the United States, it accounts for 36% of all invasive lung malignancies and is more common in women (41% of all lung cancers) than in men (33% of all lung cancers) (Table 18-6). It tends to arise in the periphery and is often associated with pleural fibrosis and subpleural scars, which can lead to pleural puckering (Fig. 18-80). These cancers were once thought to arise in scars left by old tuberculosis or healed infarcts, but it is now recognized that such scars represent a desmoplastic response to the tumor. Adenocarcinoma classification has recently been revised. The term "bronchioloalveolar carcinoma" has been dropped because it was found to represent 5 different entities. Also, the term "mixed subtype adenocarcinoma" is no longer used.

Atypical adenomatous hyperplasia (AAH) is recognized as a putative precursor lesion for adenocarcinomas. AAH is a well-demarcated lesion, usually less than 5 mm, with atypical proliferation of epithelial cells along alveolar septa (Fig. 18-81). In a sequence similar to the "adenoma–carcinoma" sequence in colon cancers, lung adenocarcinomas are thought potentially to originate as AAH and progress to adenocarcinoma in situ and then to more aggressive invasive adenocarcinomas. The finding of progressive accumulation of mutations as the lesions advance supports this hypothesis. It remains unclear whether all foci of AAH will progress to carcinoma or if all adenocarcinomas arise via this sequence of events.

Adenocarcinoma in Situ

Adenocarcinoma in situ (AIS), once called bronchioloalveolar carcinoma, is a preinvasive form of adenocarcinoma in which tumor cells grow only along preexisting alveolar

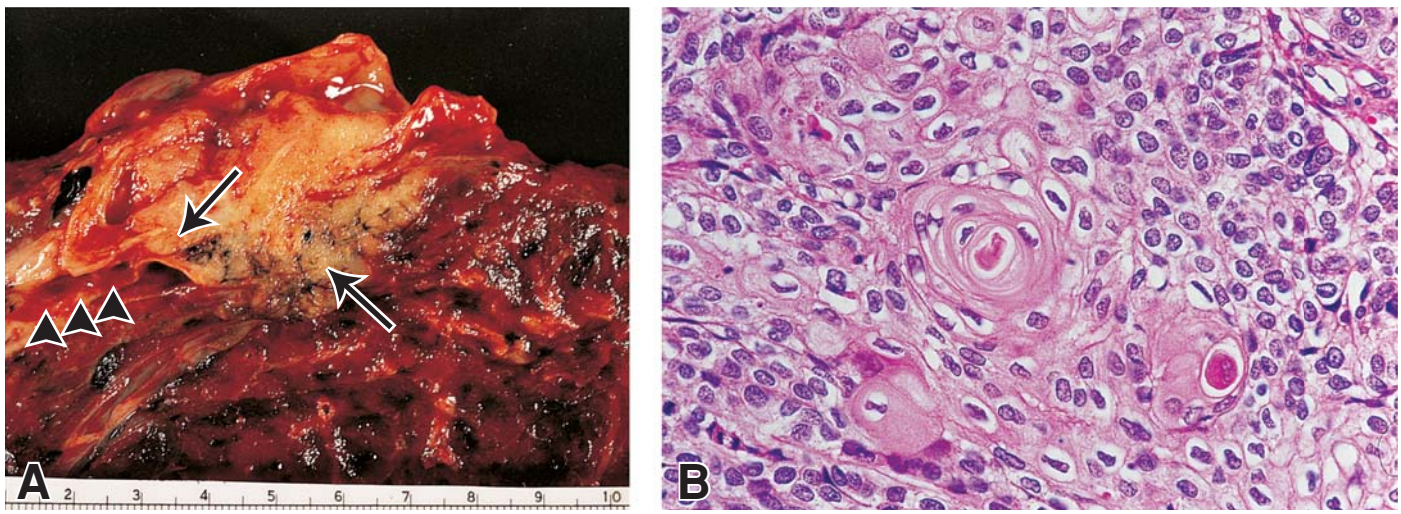

FIGURE 18-79. Squamous cell carcinoma of the lung. A. The tumor (*large arrow*) grows within the lumen of a bronchus (*arrowheads* highlight the course of the bronchus) and invades the adjacent intrapulmonary lymph node (*small arrow*). **B.** A photomicrograph shows well-differentiated squamous cell carcinoma with a keratin pearl composed of cells with brightly eosinophilic cytoplasm.

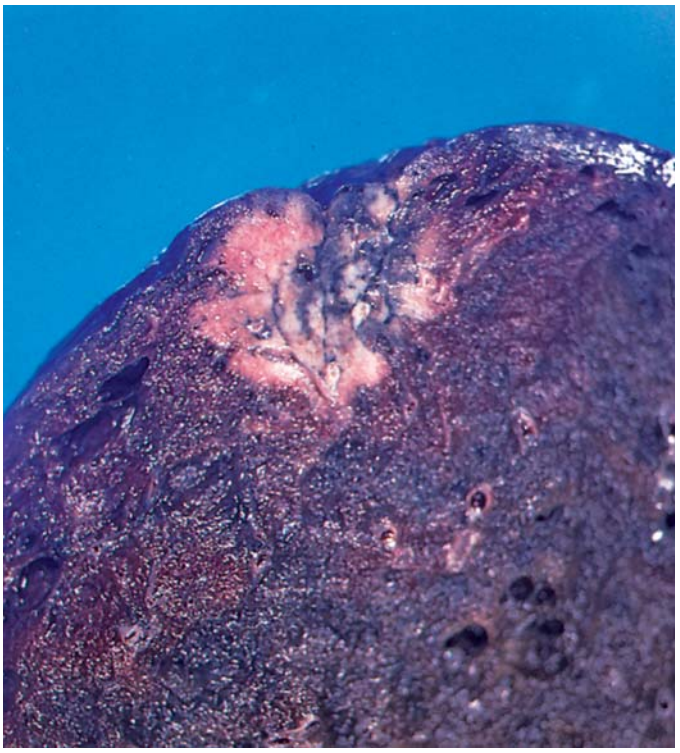

FIGURE 18-80. Invasive adenocarcinoma of the lung. A peripheral tumor of the right upper lobe has an irregular border and a tan or gray cut surface and causes puckering of the overlying pleura.

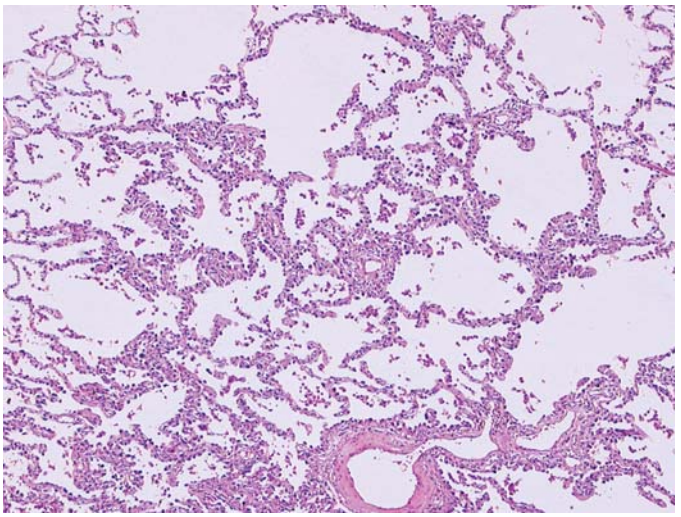

FIGURE 18-81. Atypical adenomatous hyperplasia. This millimeter-sized bronchioloalveolar proliferation is ill-defined with mild thickening of alveolar walls lined by hyperplastic pneumocytes that show minimal atypia.

walls (lepidic growth). It accounts for 1%–5% of lung adenocarcinomas. Patients with tumors meeting criteria for AIS have a 100% 5-year survival rate after resection.

Minimally Invasive Adenocarcinoma

For adenocarcinomas, a small amount of invasion in a tumor otherwise showing lepidic growth does not adversely affect prognosis. This has led to the introduction of a category of adenocarcinoma called minimally invasive adenocarcinoma (MIA, formerly bronchioloalveolar carcinoma), which has the same favorable prognosis as AIS. MIA is defined as a tumor with lepidic growth as seen in AIS, but with foci of invasive tumor measuring 5 mm or less in maximal diameter and lacking pleural or lymphovascular invasion and necrosis.

Both AIS and MIA may be seen radiographically as single peripheral nodules with a "ground glass" appearance or as multiple nodules. AIS shows pure ground glass changes radiographically, while MIA may show a small solid component. Grossly, both tumors should measure less than or equal to 3 cm and typically appear as ill-defined tan lesions, which may be difficult to distinguish from surrounding normal tissue.

Most AIS and MIA are nonmucinous, with club cells (formerly Clara cells) and/or type II pneumocytes. Only rarely

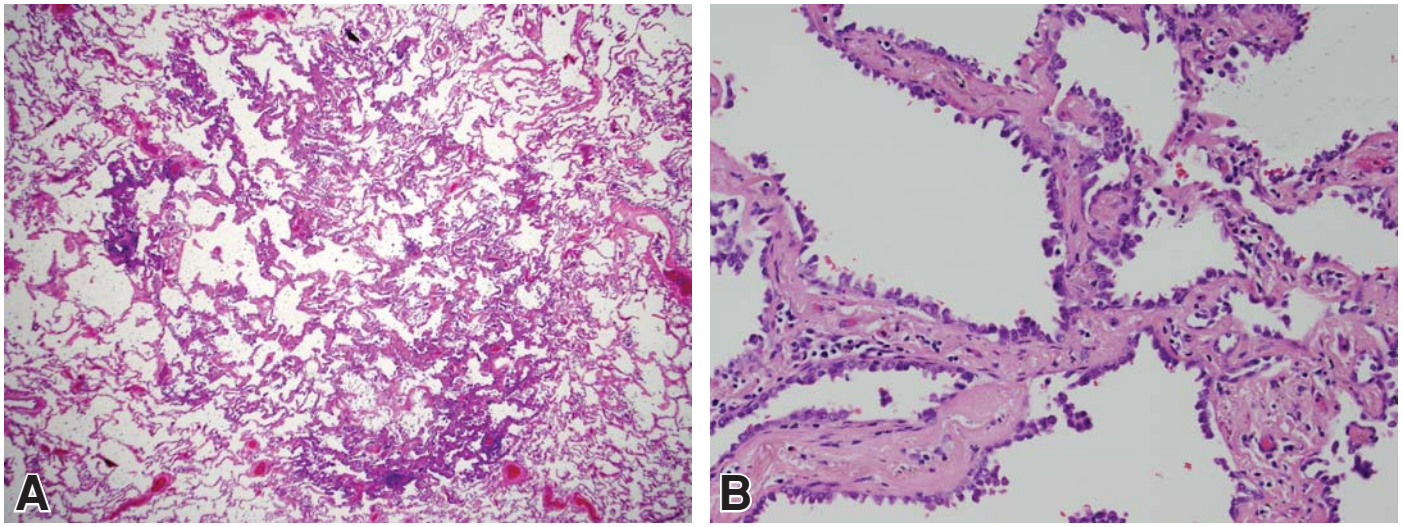

FIGURE 18-82. Adenocarcinoma in situ. A. This circumscribed nonmucinous tumor grows purely with a lepidic pattern. No foci of invasion or scarring are seen. **B.** A layer of atypical pneumocytes lines the alveolar walls.

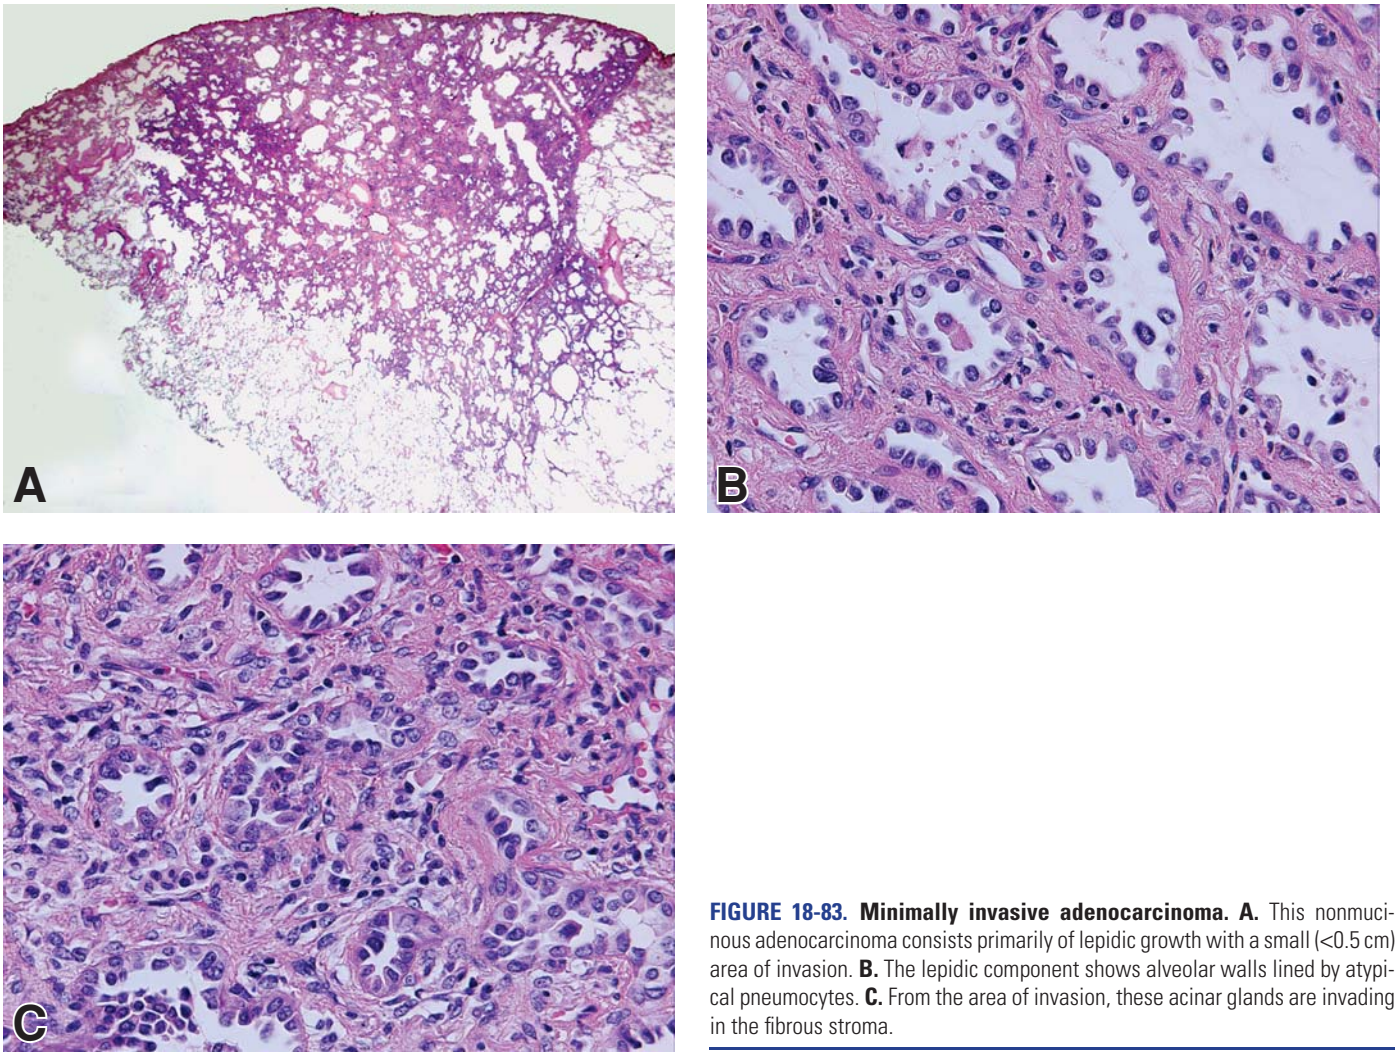

FIGURE 18-83. Minimally invasive adenocarcinoma. A. This nonmucinous adenocarcinoma consists primarily of lepidic growth with a small (<0.5 cm) area of invasion. **B.** The lepidic component shows alveolar walls lined by atypical pneumocytes. **C.** From the area of invasion, these acinar glands are invading in the fibrous stroma.

are they mucinous. AIS has a pure lepidic pattern without invasion. (Fig. 18-82A,B). MIA is lepidic-predominant adenocarcinoma with an invasive component less than or equal to 5 mm in maximal dimension (Fig. 18-83). In nonmucinous tumors, cuboidal cells grow along alveolar walls. Mucinous tumors contain columnar cells with abundant apical cytoplasm filled with mucus, sometimes with a goblet cell appearance. Particularly for mucinous tumors, the possibility that the tumor is metastatic from another site must be excluded.

Invasive Adenocarcinomas

AIS and MIA account for only 5% of adenocarcinomas. Most lung adenocarcinomas are more invasive. They are typically very heterogeneous and consist of a mixture of growth patterns. Invasive tumors are now classified based on the predominant growth pattern. Such patterns include lepidic, acinar, papillary, solid and micropapillary. Rarely, tumors will contain only a single growth pattern. For completely resected tumors, the predominant histologic subtype has prognostic significance. AIS and MIA have 100% 5-year disease-free survival. For stage I invasive adenocarcinomas, lepidic-predominant adenocarcinoma has excellent 5-year disease-free survival (>90%), with an intermediate survival for acinar and papillary types (80%–90%). The worst disease-free survival is for solid and micropapillary adenocarcinoma (60%–80%).

PATHOLOGY: Invasive lung adenocarcinomas appear mostly as irregular 2–5-cm masses but may be so large as to replace an entire lobe. On cut section, nonmucinous tumors are grayish white. Mucinous tumors may be glistening or gelatinous depending on the amount of mucin production. Central adenocarcinomas may grow mainly endobronchially and invade bronchial cartilage.

Most invasive adenocarcinomas contain heterogeneous mixtures of lepidic, acinar, papillary, micropapillary and solid patterns. Lepidic-predominant tumors are invasive lung adenocarcinomas in which lepidic growth is the most prominent pattern (Fig. 18-84A,B). The acinar pattern is distinguished by regular glands lined by cuboidal or columnar cells (Fig. 18-85A). Acinar-predominant adenocarcinomas are the most common category of invasive adenocarcinomas. Papillary adenocarcinomas exhibit a single cell layer on a core of fibrovascular connective tissue (Fig. 18-85B).

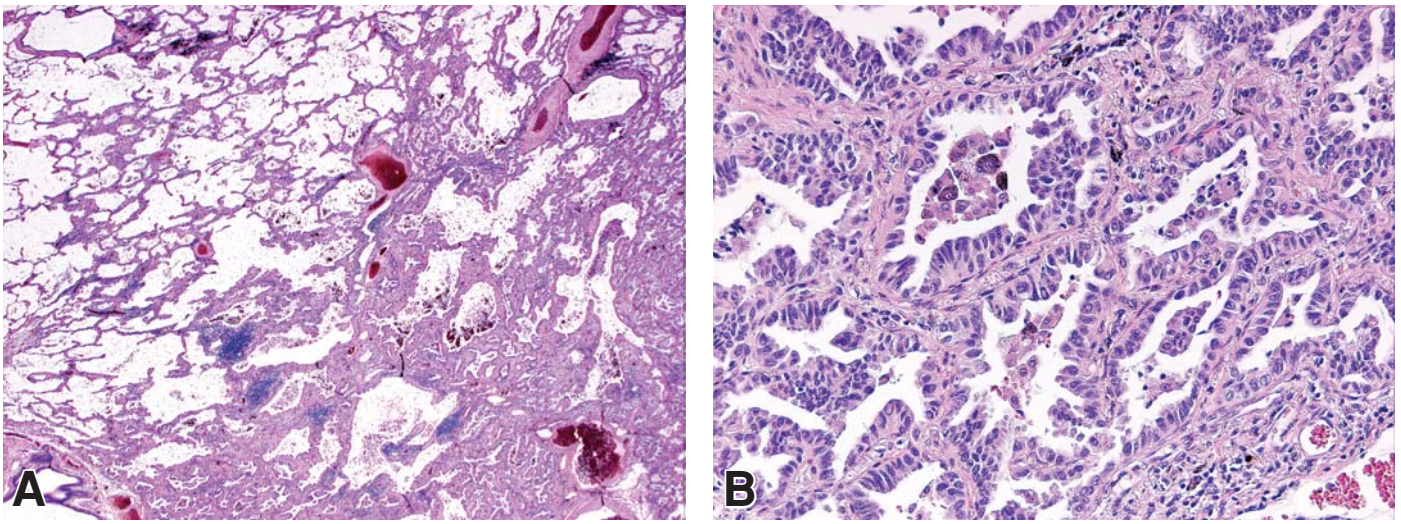

FIGURE 18-84. Adenocarcinoma with lepidic-predominant *pattern*. A. The tumor shows mostly lepidic growth and an area of invasive acinar adenocarcinoma. **B.** Lepidic pattern consists of a proliferation of type II pneumocytes and Clara cells along the surface alveolar walls.

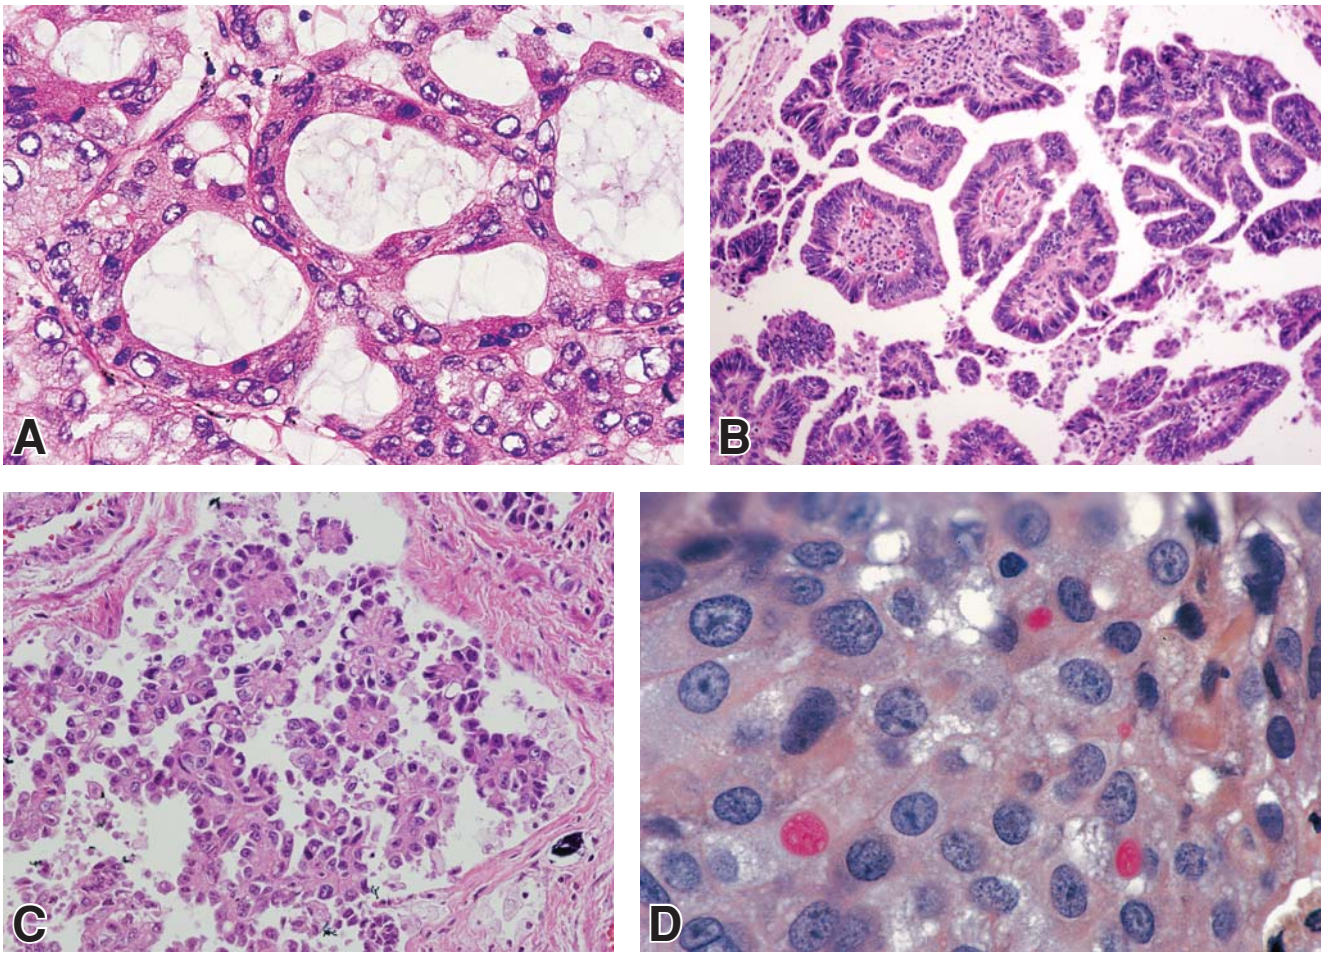

FIGURE 18-85. Invasive adenocarcinoma of the lung. A. Acinar adenocarcinoma composed of round to oval-shaped malignant glands. **B. Papillary adenocarcinoma** consists of malignant cuboidal to columnar tumor cells growing on the surface of fibrovascular cores. **C. Micropapillary adenocarcinoma** consists of small papillary clusters of glandular cells growing within this airspace, most of which do not show fibrovascular cores. **D.** Solid adenocarcinoma with mucin formation consists of solid sheets of tumor cells with several red intracytoplasmic mucin droplets that stain positively with the mucicarmine stain.

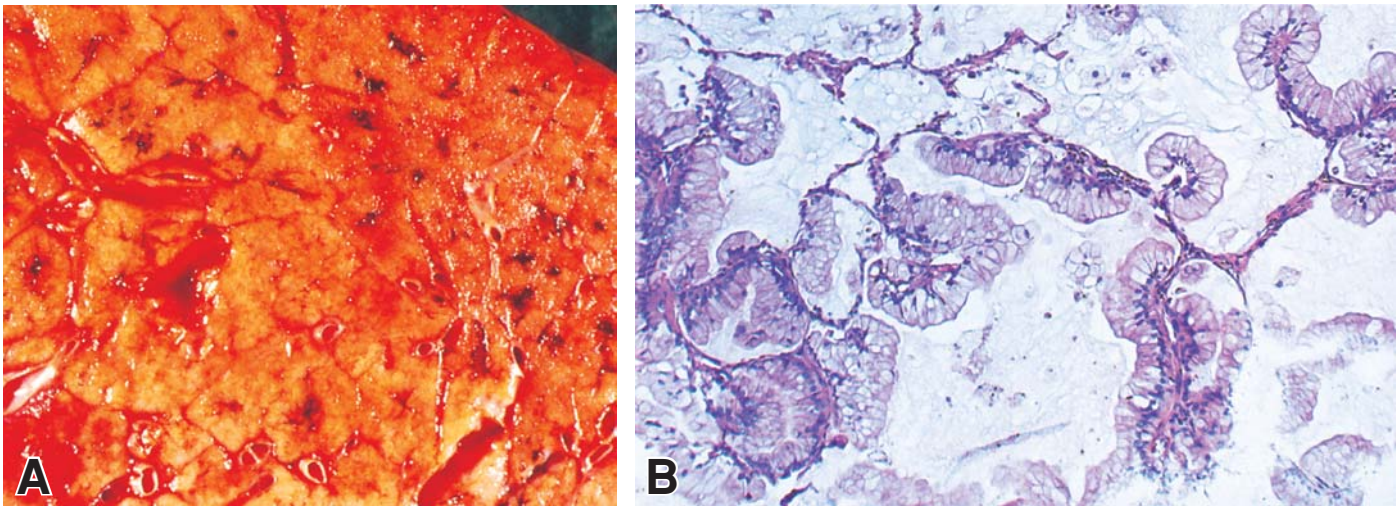

FIGURE 18-86. Invasive mucinous adenocarcinoma. A. The cut surface of the lung is solid, glistening and mucoid, an appearance that reflects a diffusely infiltrating tumor. **B.** Mucinous bronchioloalveolar carcinoma consists of tall columnar cells filled with apical cytoplasmic mucin that grow along existing alveolar walls.

Micropapillary carcinomas show small papillary tufts of tumor cells with no fibrovascular core. The cells may appear to float in alveolar spaces, glands or spaces in fibrous stroma (Fig. 18-85C). Solid adenocarcinomas with mucus formation are poorly differentiated tumors. They are different from large cell carcinomas by having mucin detected with mucicarmine or periodic acid–Schiff (with diastase digestion) stains (Fig. 18-85D). Invasive mucinous adenocarcinomas show solid mucoid cut surfaces (Fig. 18-86A) and have tall columnar cells with apical cytoplasmic mucin (Fig. 18-86B).

Large Cell Carcinoma

Large cell carcinoma is a diagnosis of exclusion: a poorly differentiated tumor lacking squamous or glandular differentiation that is not a small cell carcinoma (Fig. 18-87). This tumor type accounts for 30% of invasive lung tumors in the United States (Table 18-6). The cells are large and exhibit ample cytoplasm. Nuclei frequently show prominent nucleoli and vesicular chromatin.

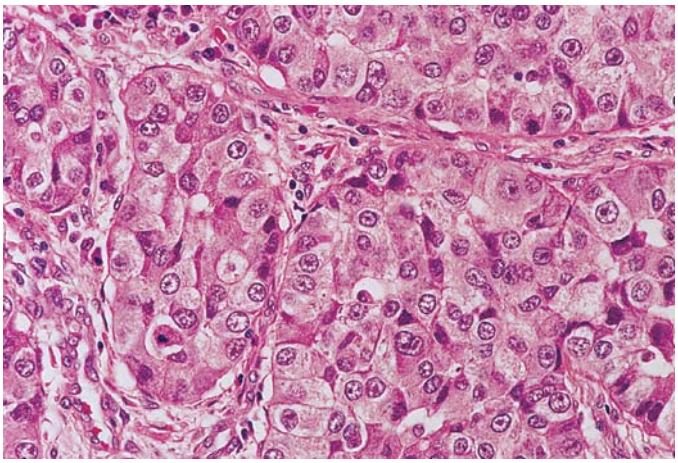

FIGURE 18-87. Large cell carcinoma of the lung. This poorly differentiated tumor is growing in sheets. Tumor cells are large and contain ample cytoplasm and prominent nucleoli.

Some large cell carcinomas called **large cell neuroendocrine carcinoma** grow like carcinoid tumors (see below), with an organoid pattern, trabecular growth, peripheral palisading of cells and rosette formation, and show evidence of neuroendocrine differentiation by immunohistochemistry or ultrastructure. Mitotic rates are high and necrosis is common. These are aggressive tumors with 5-year survival rates similar to small cell carcinoma.

Small Cell Carcinoma

Small cell carcinoma (formerly "oat cell" carcinoma) is a highly malignant epithelial tumor of the lung with neuroendocrine features. It accounts for 14% of all lung cancers in the United States (Table 18-6) and is strongly associated with cigarette smoking. SCLCs grow and metastasize rapidly: 70% of patients are first seen at advanced stages. These tumors often cause paraneoplastic syndromes, including **diabetes insipidus, ectopic adrenocorticotropic hormone (ACTH; corticotropin) syndrome** and **Eaton-Lambert syndrome**.

PATHOLOGY: SCLCs are usually perihilar masses, with extensive lymph node metastases. They are soft and white, often with extensive hemorrhage and necrosis. The tumor typically spreads along bronchi in a submucosal and circumferential fashion.

Small cell carcinomas have sheets of small, round, oval or spindle-shaped cells with scant cytoplasm. Their nuclei are distinctive, with finely granular nuclear chromatin and absent or inconspicuous nucleoli (Fig. 18-88). Most tumors express detectable neuroendocrine markers such as CD56, chromogranin or synaptophysin. Mitotic rates are very high, with 60–70 mitoses per 2-mm^2 area of tumor (10 high-power fields). Necrosis is frequent and extensive. Although there is no absolute measure for the size of the tumor cells, a useful rule of thumb in small cell carcinoma is the diameter of three small resting lymphocytes. Rarely, a small cell carcinoma may occur with a "non–small cell carcinoma." In such cases, tumor behavior and clinical outcome reflect the small cell component, so they are classified as combined small

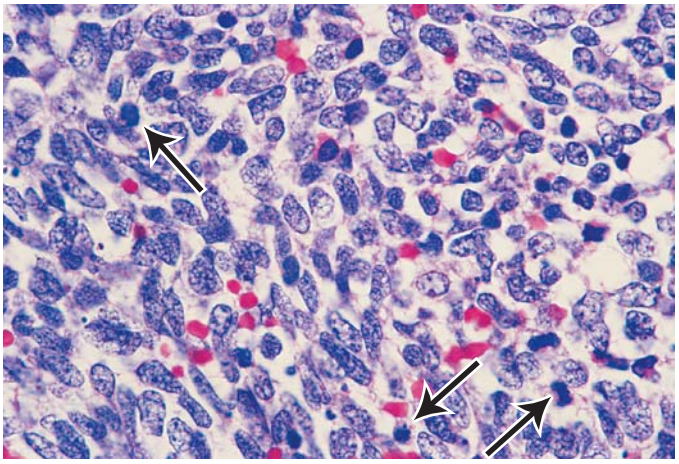

FIGURE 18-88. Small cell carcinoma of the lung. This tumor consists of small oval to spindle-shaped cells with scant cytoplasm, finely granular nuclear chromatin and conspicuous mitoses (*arrows*).

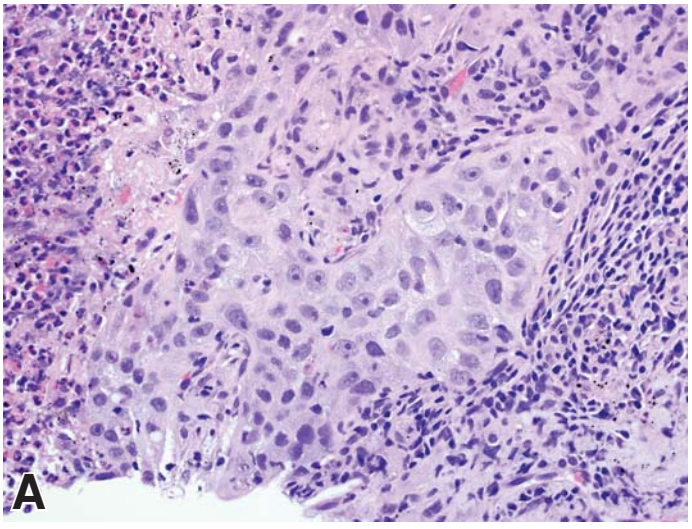
cell carcinoma plus the non–small cell type (e.g., combined small cell carcinoma and adenocarcinoma). Unlike other lung cancers, small cell tumors, at least initially, are very sensitive to chemotherapy, which is the mainstay of treatment for this tumor type.

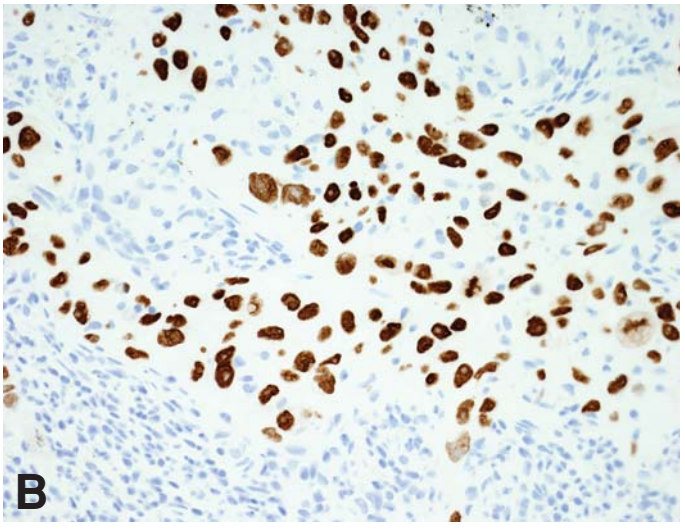
Lung Carcinomas with Combined Histology

Lung carcinomas may contain a combination of histologic subtypes within one tumor: small cell carcinomas may occur in combination with components of non–small cell carcinomas (known as "combined small cell carcinoma"), or different non–small cell subtypes may also occur in the same tumor, primarily exemplified by adenosquamous carcinomas. Combined small cell carcinomas are treated as small cell carcinomas.

Sarcomatoid tumors make up less than 1% of lung cancers. Most are pleomorphic carcinomas with at least 10% spindle and/or giant cell carcinoma in addition to other non–small cell carcinoma patterns such as adenocarcinoma or squamous cell carcinoma. If true sarcomatous components are present such as osteosarcoma, chondrosarcoma or rhabdomyosarcoma, these tumors are classified as carcinosarcomas. Their prognosis is poor, with a median survival of 9–12 months.

DIAGNOSIS OF LUNG CANCER IN SMALL BIOPSIES AND CYTOLOGY SPECIMENS: The diagnosis of small cell carcinoma is reliably made based on small biopsy and cytology specimens. However, in 20%–40% of advanced NSCLCs where the diagnosis is based on small biopsies or cytology, tumors may be difficult to further reclassify as adenocarcinoma or squamous cell carcinoma because they lack clear





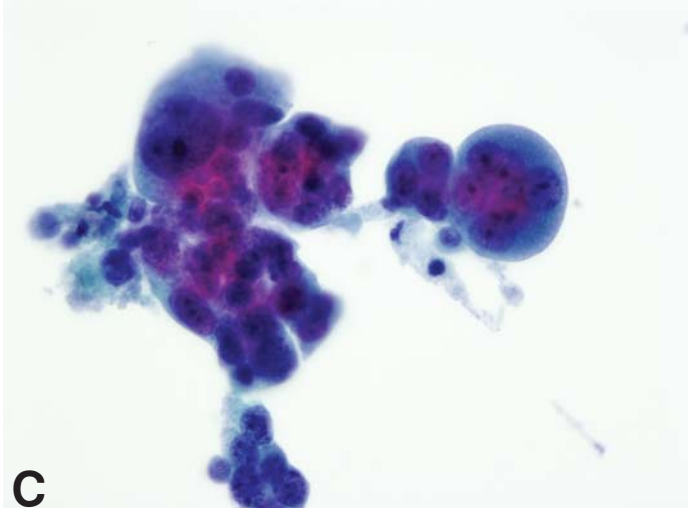


FIGURE 18-89. Non–small cell carcinoma, favor adenocarcinoma. A. This tumor shows features of a non–small cell carcinoma with large cell size, abundant cytoplasm and prominent nucleoli. **B.** Tumor cells show strong nuclear staining for the immunohistochemical marker thyroid transcription factor-1 (TTF-1), a marker not only for adenocarcinoma differentiation but also for lung origin. Staining for p40 was negative (not shown). **C.** Papanicolaou stain of fine needle aspiration shows malignant cells in clusters with glandular structures and large hyperchromatic nuclei with some nucleoli.

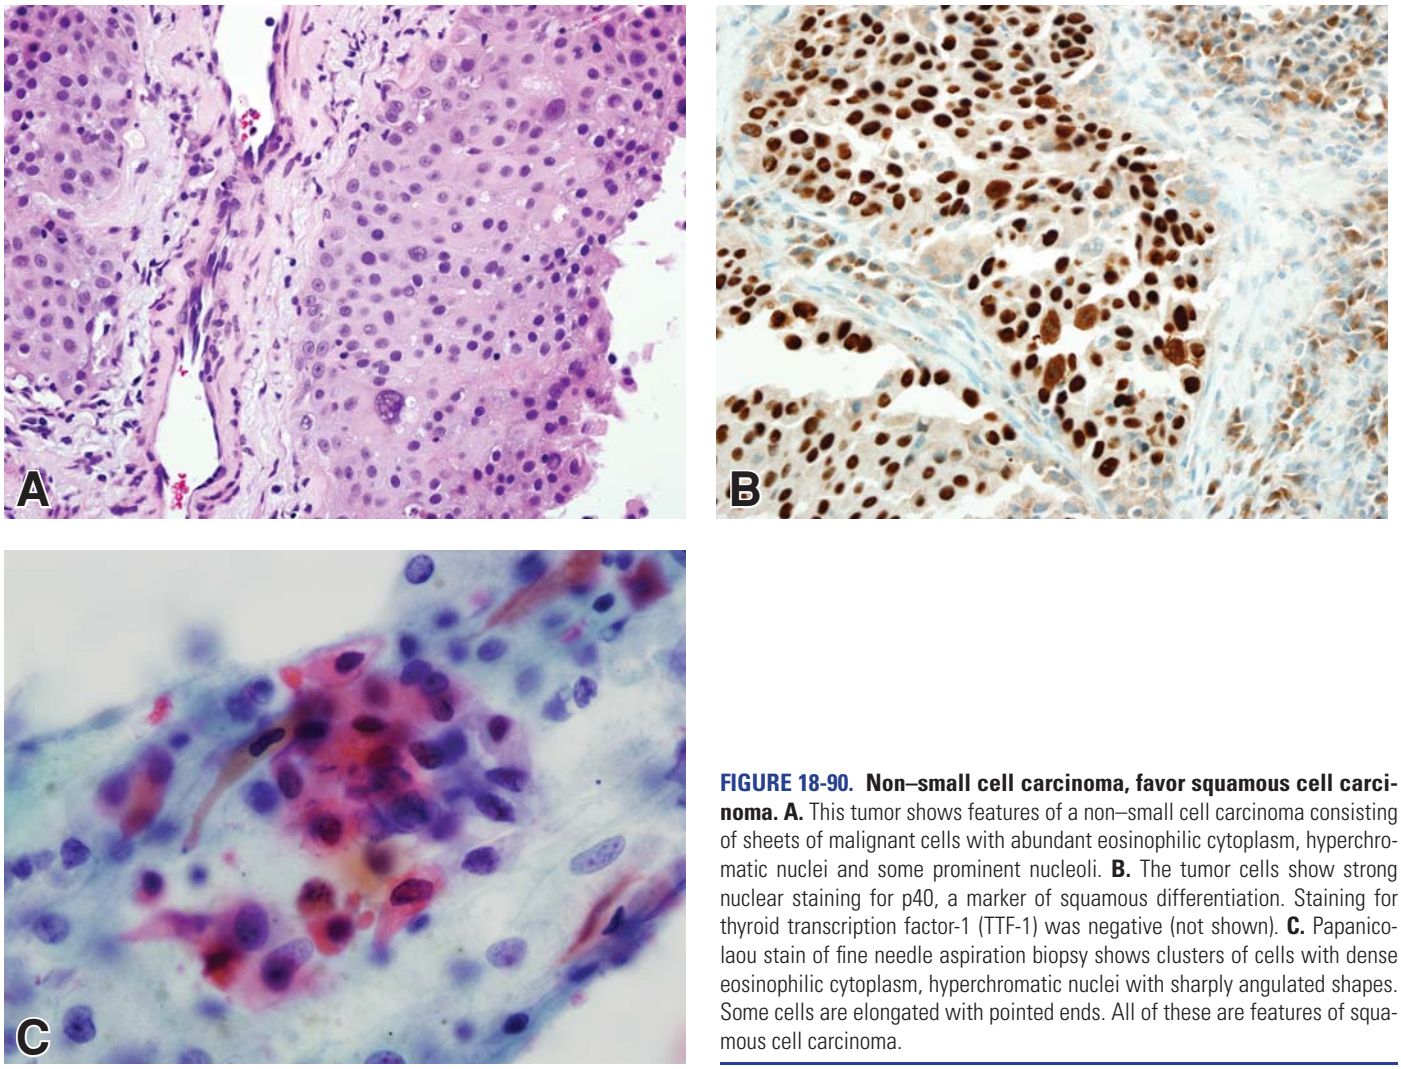

FIGURE 18-90. Non–small cell carcinoma, favor squamous cell carcinoma. A. This tumor shows features of a non–small cell carcinoma consisting of sheets of malignant cells with abundant eosinophilic cytoplasm, hyperchromatic nuclei and some prominent nucleoli. **B.** The tumor cells show strong nuclear staining for p40, a marker of squamous differentiation. Staining for thyroid transcription factor-1 (TTF-1) was negative (not shown). **C.** Papanicolaou stain of fine needle aspiration biopsy shows clusters of cells with dense eosinophilic cytoplasm, hyperchromatic nuclei with sharply angulated shapes. Some cells are elongated with pointed ends. All of these are features of squamous cell carcinoma.

patterns of differentiation. In such cases, the term "non–small cell carcinoma, not otherwise specified (NSCC-NOS)" has been used. As noted above, because targeted chemotherapy for advanced lung cancer patients is dependent on accurate histologic classification and knowledge of *EGFR* mutation or *ALK* rearrangement status, an initial NSCC-NOS pattern in small biopsies and cytology specimens prompts immunohistochemical analyses using a single adenocarcinoma marker such as thyroid transcription factor-1 (TTF-1) and a single squamous marker such as p40 to further classify these tumors. A histochemical stain for mucin may also be helpful. The recommended terminology and criteria for these tumors are summarized below:

- **Non–small cell carcinoma, favor adenocarcinoma:** An NSCC-NOS by light microscopy that is positive for adenocarcinoma markers (TTF-1 or mucin) and negative for squamous markers (Fig. 18-89)
- **Non–small cell carcinoma, favor squamous carcinoma:** An NSCC-NOS by light microscopy that is positive for squamous markers (p40 or p63) but negative for adenocarcinoma markers (Fig. 18-90)
- **Non–small cell carcinoma, not otherwise specified:** An NSCC-NOS by light microscopy either that is negative for adenocarcinoma and squamous markers or where the staining pattern is not clear (Fig. 18-91)

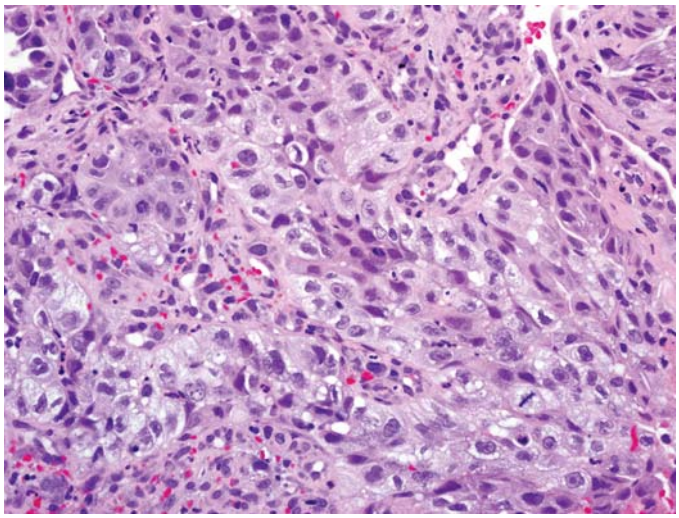

FIGURE 18-91. Non–small cell carcinoma, not otherwise specified. This tumor consists of sheets of large malignant cells with abundant eosinophilic cytoplasm and hyperchromatic and vesicular nuclei, many of which show prominent nucleoli.

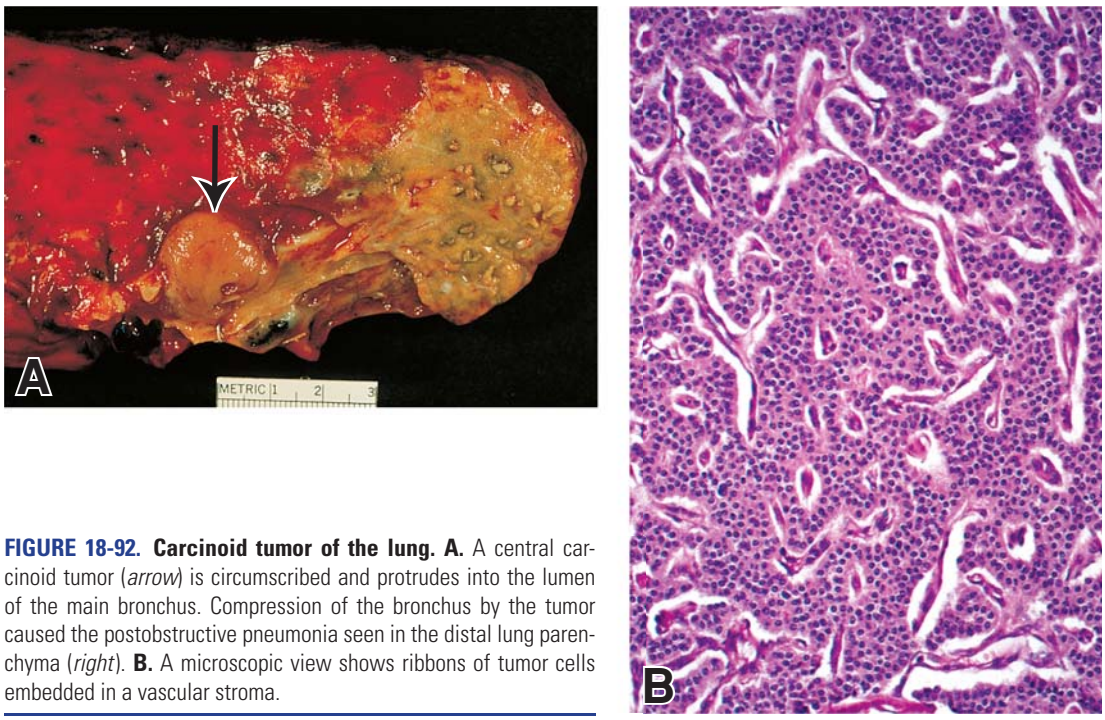

FIGURE 18-92. Carcinoid tumor of the lung. A. A central carcinoid tumor (*arrow*) is circumscribed and protrudes into the lumen of the main bronchus. Compression of the bronchus by the tumor caused the postobstructive pneumonia seen in the distal lung parenchyma (*right*). **B.** A microscopic view shows ribbons of tumor cells embedded in a vascular stroma.

This approach can reduce the percentage of NSCC-NOS from 20%–40% to less than 5%, allowing many patients to get a clear histologic diagnosis that defines eligibility for molecular testing for *EGFR* mutation and *ALK* rearrangement. It emphasizes the need to minimize use of special stains to further classify the tumor in small specimens and preserves tissue for molecular testing. All tumors classified as adenocarcinoma, NSCC-NOS and NSCC-NOS must be tested for *EGFR* mutation and *ALK* rearrangement. Treatments are given accordingly. If the tumor is negative for both, or if mutation status is unknown, patients are eligible for pemetrexed or bevacizumab-based regiments.

Evidence-based molecular targeted therapies are not yet established for squamous cell carcinomas. Thus, routine molecular testing for squamous cell carcinomas is not currently recommended.

Carcinoid Tumors

There are two subtypes of carcinoid tumors of the lung **(typical carcinoid and atypical carcinoid),** which are thought to arise from the resident neuroendocrine cells normally in the bronchial epithelium. Carcinoid tumors account for 2%–32% of all primary lung cancers in the United States (Table 18-6), show no sex predilection and are not related to cigarette smoking. Although neuropeptides are readily demonstrated in the tumor cells, most are endocrinologically silent. A small subset of cases is associated with an endocrinopathy, such as Cushing syndrome with ectopic ACTH production by tumor cells. The carcinoid syndrome (see Chapter 19) occurs in 1% of cases, usually in the setting of hepatic metastases. Nodular neuroendocrine proliferations less than 0.5 cm are called tumorlets. They may arise in the setting of interstitial fibrosis or small airway disorders and usually represent incidental findings of no clinical significance.

PATHOLOGY: One third of carcinoid tumors are central, 1/3 are peripheral (subpleural) and 1/3 are in the midportion of the lung. Central carcinoid tumors tend to have a large endobronchial component, with fleshy, smooth, polypoid masses protruding into bronchial lumens (Fig. 18-92A). The tumors average 3.0 cm in diameter, but range from 0.5 to 10 cm.

Carcinoid tumors are characterized by organoid growth patterns and uniform cytologic features: eosinophilic, finely granular cytoplasm and nuclei with finely granular chromatin (Fig. 18-92B). A variety of neuroendocrine patterns may be seen, including trabecular growth, peripheral palisading and rosettes.

Atypical carcinoid tumors differ from typical carcinoids by (1) increased mitoses, with 2–10 mitoses per 2 mm^2 of tumor; (2) tumor necrosis (Fig. 18-93); (3) areas of

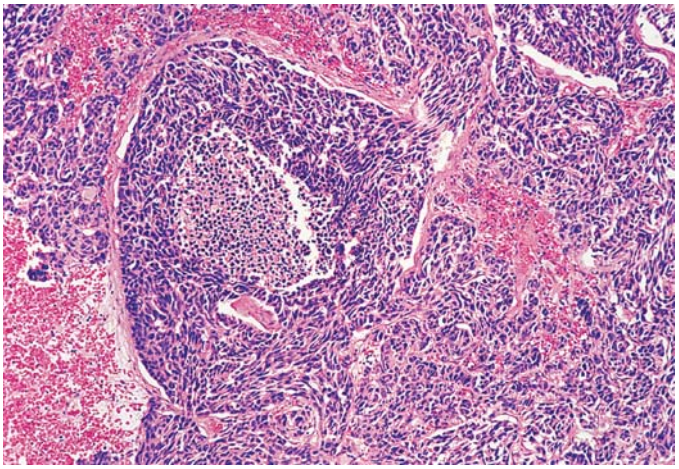

FIGURE 18-93. Atypical carcinoid tumor of the lung. A cellular tumor shows central necrosis and a disorganized architecture.

increased cellularity and architectural disorganization; and (4) nuclear pleomorphism, hyperchromatism and a high nuclear:cytoplasmic ratio.

CLINICAL FEATURES: Carcinoid tumors grow slowly, so half of patients are asymptomatic at presentation. They are often discovered incidentally as a mass in a chest radiograph. If a patient is symptomatic, the most common pulmonary manifestations are hemoptysis, postobstructive pneumonitis and dyspnea. There is a slight female predominance. The mean age at diagnosis is 55, but these tumors can occur at any age. In fact, bronchial carcinoids are the most common lung tumor in childhood. Atypical carcinoid tumors tend to be more aggressive than typical ones. Regional lymph node metastases occur in 15% of patients with typical carcinoids and 50% of those with atypical carcinoids. Patients with typical carcinoids have 90% 5-year survival after surgery, compared with 60% for atypical carcinoids.

Rare Pulmonary Tumors

INFLAMMATORY MYOFIBROBLASTIC TUMOR/INFLAMMATORY PSEUDOTUMOR: Inflammatory myofibroblastic tumor of the lung is an uncommon lesion that consists of variable amounts of inflammatory cells, foamy macrophages and fibroblasts. Most of these masses are within the lung, although the pleura may be involved. In 5% of cases, tumors invade structures outside the lung, such as the esophagus, mediastinum, chest wall, diaphragm or pericardium.

Inflammatory myofibroblastic tumors encompass a spectrum of lesions with a range of histologic findings as described below; as knowledge expands, some of these lesions may be better classified as other entities. Some thought previously to be a nonneoplastic inflammatory process are now known to be inflammatory myofibroblastic tumors, a lesion originally described in soft tissue. Identification of *ALK* gene mutations provides additional evidence that at least some are true neoplasms. Other lesions previously categorized as so-called plasma cell granuloma variants of inflammatory myofibroblastic tumor may be pulmonary manifestations of immune-related processes such as IgG4-related systemic sclerosing disease.

PATHOLOGY: The tumors are solitary circumscribed, with a mean size of 4 cm. Virtually any type of inflammatory cell may be present, including lymphocytes, plasma cells, macrophages, giant cells, mast cells and eosinophils. Inflammatory myofibroblastic tumor causes consolidation of the lung parenchyma and loss of architecture. Two major histologic patterns are fibrohistiocytic (Fig. 18-94) and plasma cell granuloma, depending on the predominant component. In some cases, foamy macrophages impart a xanthomatous picture.

CLINICAL FEATURES: Most patients are under 40, but inflammatory myofibroblastic tumor can occur at any age and is one of the most common lung tumors of childhood. Half of patients are asymptomatic at presentation. A previous history of a pulmonary infection can be elicited in one third of patients. Most inflammatory myofibroblastic tumors are cured by surgical excision, but 5% recur within the chest.

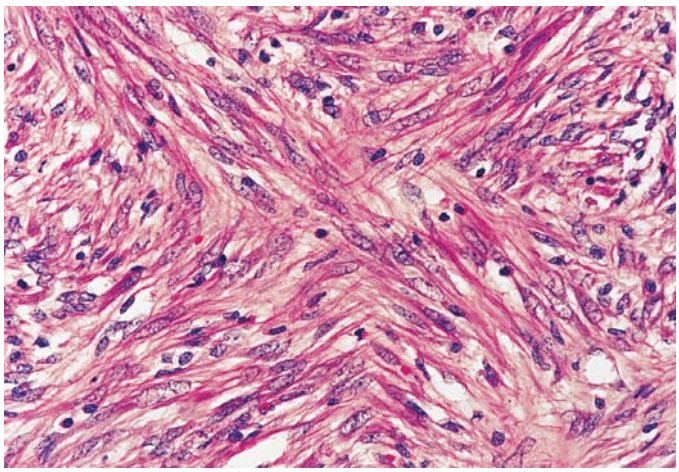

FIGURE 18-94. Inflammatory pseudotumor. A photomicrograph shows intersecting spindle cells and scattered lymphocytes and macrophages.

PULMONARY EPITHELIOID HEMANGIOENDOTHELIOMA: Pulmonary epithelioid hemangioendotheliomas are rare low- to intermediate-grade vascular sarcomas. Most patients are young adults; 80% are women. Half are asymptomatic.

PATHOLOGY: Most patients are first seen with multiple pulmonary nodules. Histologically, the tumor consists of oval-shaped nodules with central, sclerotic, hypocellular zones and cellular peripheral zones. The tumors spread within alveolar spaces (Fig. 18-95). Tumor cells have abundant cytoplasm, with frequent intracytoplasmic vascular lumens, which may contain red blood cells. The tumor matrix is abundant and eosinophilic. The tumors express vascular markers, such as factor VIII, CD34 or CD31. Epithelioid hemangioendotheliomas with a histologic pattern similar to that seen in the lung may occur in the liver, bone and soft tissue. Pulmonary epithelioid hemangioendothelioma has a variable clinical course, with a mean survival of 5 years.

PULMONARY BLASTOMA: This malignant tumor resembles embryonal lung, with a glandular component

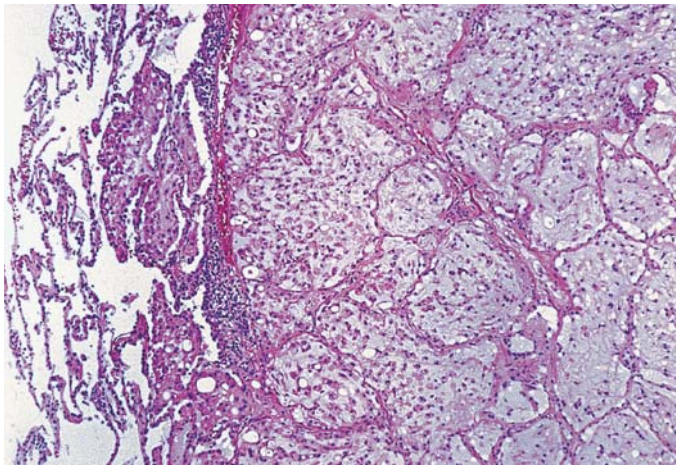

FIGURE 18-95. Epithelioid hemangioendothelioma. A nodule of tumor has spread within alveolar spaces.

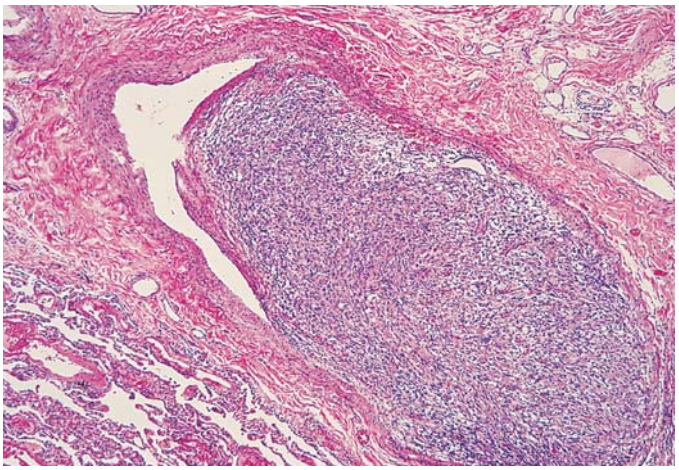

FIGURE 18-96. Pulmonary artery sarcoma. A polypoid mass of malignant spindle cells is spreading within the lumen of this pulmonary artery.

of poorly differentiated columnar cells in tubules, lacking mucus secretion. The intervening tumor contains spindle cells that resemble embryonal mesoderm. There is histologic overlap between pulmonary blastoma and carcinosarcoma, including heterologous elements. The clinical features are also similar.

Despite its embryonal appearance, pulmonary blastomas occur mainly in adults (median age range, 35–43), and most patients are cigarette smokers. The prognosis for patients with biphasic tumors is poor and comparable to that for carcinoma of the lung. Pulmonary blastomas are often associated with β-catenin mutations.

MUCOEPIDERMOID CARCINOMA AND ADENOID CYSTIC CARCINOMA: These neoplasms resemble their namesakes in the salivary glands. They are derived from tracheobronchial mucous glands and are seen in the trachea or proximal bronchus as a luminal mass, often associated with obstructive symptoms. Adenoid cystic carcinomas are difficult to resect locally and often metastasize.

PULMONARY ARTERY SARCOMA: Pulmonary artery sarcoma is a rare tumor of connective tissue (Fig. 18-96), which has a broad histologic spectrum, including fibrosarcoma, leiomyosarcoma, osteosarcoma, rhabdomyosarcoma, angiosarcoma or unclassifiable sarcoma. These tumors are rarely diagnosed during life and may be discovered because of pulmonary hypertension. They often grow in an intraluminal fashion, within proximal arteries, and may extend, worm-like, to peripheral pulmonary artery branches, causing peripheral infarcts.

Pulmonary Lymphomas

All lymphomas, both Hodgkin and non-Hodgkin types, may involve the lung (see also Chapter 26). Most lymphomas involving the lung are metastatic. Primary pulmonary lymphomas are rare, the most common being **extranodal marginal zone B-cell lymphoma.** These tumors are thought to arise from *m*ucosa-*a*ssociated *l*ymphoid *t*issue of the lung and are sometimes designated "MALT" lymphomas. They are low-grade tumors, generally with a favorable prognosis.

Diffuse large B-cell lymphoma may also arise as a primary pulmonary lymphoma (see Chapter 26). **Lymphomatoid granulomatosis,** a subtype of diffuse large B-cell lymphoma, is characterized by nodular pulmonary lymphoid infiltrates with frequent central necrosis and vascular permeation (Fig. 18-97). It affects middle-aged people and is more common in immunosuppressed individuals. The lung is the major location, but the kidney, skin and upper respiratory tract may also be involved. The lymphoid infiltrate is angiocentric and angioinvasive, with polymorphous, small to medium-sized lymphocytes, mainly T cells, admixed with variable numbers of large atypical B cells. The latter typically express EBV, which is thought to drive the proliferation. Lymphomatoid granulomatosis is typically divided into grades depending on the percentage of atypical B cells present. Previously, only the highest grade was considered a "true" lymphoma, the lower grades being considered as less aggressive lesions; however, all grades are now considered to be subtypes of diffuse large B-cell lymphoma for treatment purposes. Despite remissions with chemotherapy, half of all patients eventually develop large cell lymphoma.

Extrapulmonary Tumors Often Metastasize to the Lung

In 1/3 of all fatal cancers, there are lung metastases at autopsy. In fact, metastatic tumors are the most common malignancies in the lung. They are typically multiple and circumscribed. Large metastatic nodules in the lungs seen radiologically are called "cannon ball" metastases (Fig. 18-98). Most metastases resemble their primary tumors. Rarely, metastatic tumors show lepidic growth, particularly mucinous types, in which cases the usual primary site is the pancreas or stomach.

In **lymphangitic carcinoma,** metastatic tumor spreads widely through pulmonary lymphatic channels to form a sheath of tumor around the bronchovascular tree and veins. Clinically, patients suffer from cough and shortness of breath and display a diffuse reticulonodular pattern on the chest radiograph. The common primary sites are the breast, stomach, pancreas and colon.

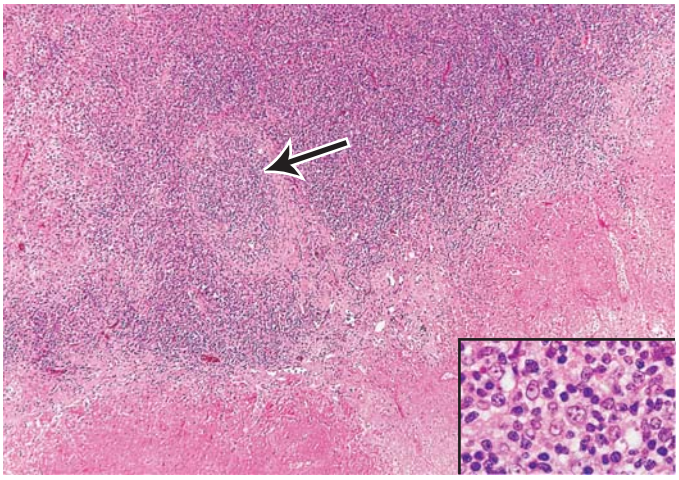

FIGURE 18-97. Lymphomatoid granulomatosis. This extensively necrotic nodular mass consists of a cellular lymphoid infiltrate that penetrates a blood vessel (*arrow*) at the edge of the lesion. *Inset.* The lymphoid infiltrate is composed of a polymorphous population of small, medium-sized and large atypical lymphoid cells.

FIGURE 18-98. Metastatic carcinoma of the lung. A section through the lung shows numerous nodules of metastatic carcinoma corresponding to "cannon ball" metastases seen radiologically.

The Pleura

PNEUMOTHORAX

Pneumothorax is the presence of air in the pleural cavity. It may occur with traumatic perforation of the pleura or may be "spontaneous." Traumatic causes include penetrating wounds of the chest wall (e.g., a stab wound or a rib fracture). Traumatic pneumothorax is most commonly iatrogenic and is seen after therapeutic aspiration of fluid from the pleura (thoracentesis), pleural or lung biopsies, transbronchial biopsies and positive pressure–assisted ventilation.

Spontaneous pneumothorax is typically seen in young adults. For example, a young man may develop acute chest pain and shortness of breath during vigorous exercise. A chest radiograph shows collapse of the lung on the side of the pain and a large collection of air in the pleural space. The cause is rupture, usually of a subpleural emphysematous bleb. In most cases, spontaneous pneumothorax resolves by itself, but some patients require withdrawal of the air.

Tension pneumothorax refers to unilateral pneumothorax extensive enough to shift the mediastinum to the opposite side, with compression of the opposite lung. The condition may be life-threatening and must be relieved by immediate drainage.

Bronchopleural fistula is a serious condition in which there is free communication between an airway and the pleura. It is usually iatrogenic, caused by the interruption of bronchial continuity by biopsy or surgery. It may also be due to extensive infection and necrosis of lung tissue, in which case the infection is more important than the air.

PLEURAL EFFUSION

Pleural effusion is accumulation of excess fluid in the pleural cavity. Normally, only a small amount of fluid in the pleural cavity lubricates the space between the lungs and chest wall. Fluid is secreted into the pleural space by the parietal pleura and absorbed by the visceral pleura. Effusions vary from a few milliliters, detectable only radiologically as blunting of the costophrenic angle, to massive accumulations that shift the mediastinum and the trachea to the opposite side.

HYDROTHORAX: Hydrothorax is an effusion that resembles water and would be regarded as edema elsewhere. It may be due to increased capillary hydrostatic pressure, as occurs in patients with heart failure or in any condition that produces systemic or pulmonary edema. Hydrothorax also occurs in patients with low serum osmotic pressure, as in nephrotic syndrome, cirrhosis of the liver or severe starvation. Other important causes of hydrothorax are collagen vascular diseases (notably systemic lupus erythematosus and rheumatoid arthritis) and asbestos exposure.

PYOTHORAX: A turbid effusion full of polymorphonuclear leukocytes (pyothorax) results from infections of the pleura. It may occasionally be caused by an external penetrating wound that introduces pyogenic organisms into the pleural space but more commonly is a complication of bacterial pneumonia that extends to the pleural surface, the classic example of which is pneumococcal pneumonia. Pyothorax is a rare complication of medical procedures involving the pleural cavity.

EMPYEMA: This disorder is a variant of pyothorax in which thick pus accumulates within the pleural cavity, often with loculation and fibrosis.

HEMOTHORAX: Blood in the pleural cavity as a result of trauma or rupture of a vessel (e.g., dissecting aneurysm of the aorta) is hemothorax. A pleural effusion may be blood stained in tuberculosis, cancers involving the pleura and pulmonary infarction.

CHYLOTHORAX: Chylothorax is accumulation of milky, lipid-rich fluid (chyle) in the pleural cavity due to lymphatic obstruction. It has an ominous portent, because lymphatic obstruction suggests disease of the lymph nodes in the posterior mediastinum. Chylothorax is thus a rare complication of mediastinal tumors, such as lymphoma. In tropical countries, it may result from nematode infestations. It can also be seen in pulmonary lymphangioleiomyomatosis.

PLEURITIS

Pleuritis, or inflammation of the pleura, may result from extension of any pulmonary infection to the visceral pleura, bacterial infections within the pleural cavity, viral infections, collagen vascular disease or pulmonary infarction that involves the lung surface. The most striking symptom is sharp, stabbing chest pain on inspiration. It is often associated with pleural effusions.

TUMORS OF THE PLEURA

Localized (Solitary) Fibrous Tumors of the Pleura Are Usually Benign

Solitary fibrous tumor of the pleura is an uncommon localized neoplasm arising in the pleura. Most are benign, but a

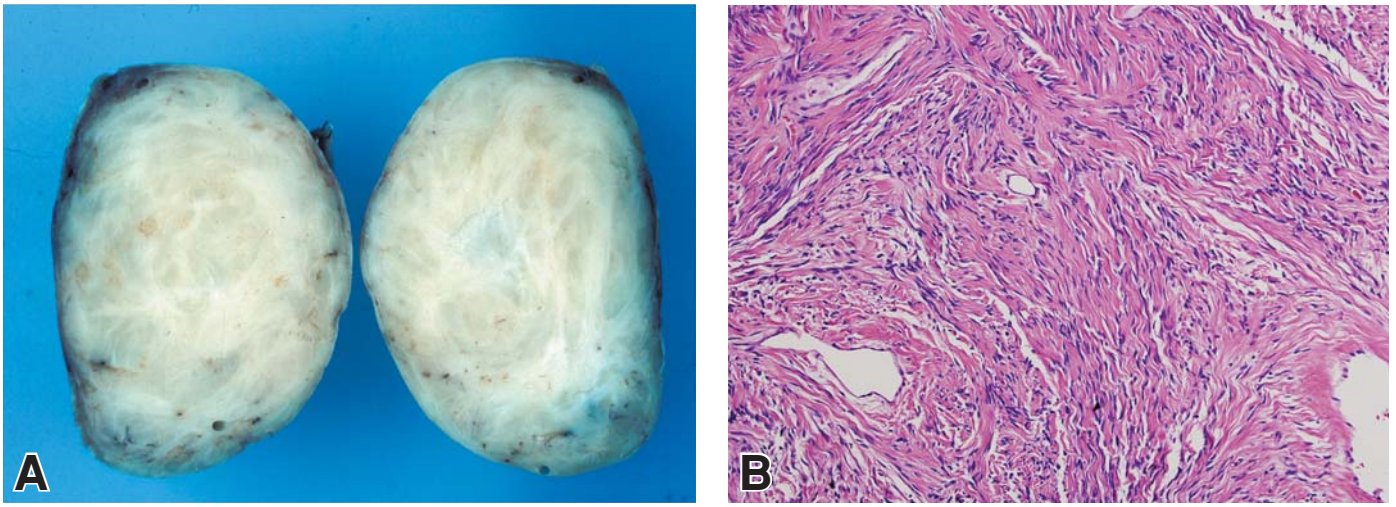

FIGURE 18-99. Pleural localized (solitary) fibrous tumor. A. The tumor is circumscribed with a whorled, tan cut surface. **B.** Tumor cells are round to oval and spindle shaped, with a dense eosinophilic or "ropy" collagen stroma and slit-like blood vessels.

small percentage are malignant. Some 80% arise on the visceral pleura, the remainder being from the parietal pleura. Similar tumors can develop on any mesothelial surface, including the mediastinum, peritoneum, pericardium, liver and tunica vaginalis. They arise from submesothelial connective tissue, not mesothelium, and are unrelated to asbestos.

PATHOLOGY: The tumors are usually pedunculated. More than 60% are over 10 cm in diameter and some reach 40 cm and may weigh up to 3800 g. The cut surface is gray-white, with a nodular, whorled or lobulated appearance (Fig. 18-99A). Cysts are occasionally present, especially at the base near the pleural attachment.

The most common histologic appearance is the "patternless pattern" of disorderly or randomly arranged mixtures of fibroblast-like cells and connective tissue. Other arrangements include hemangiopericytoma-like, storiform (star-like, or spiral), herringbone, leiomyoma-like or neurofibroma-like arrangements (Fig. 18-99B). The tumor cells are spindle to oval shaped, often with a fibroblast-like appearance. The collagen is compressed between the cells in a lacy network or it may form dense, wire-like bands. Histologic features suggesting malignancy include increased cellularity, pleomorphism, necrosis and more than four mitoses per 10 high-power fields. Most tumors are immunopositive for CD34 and *bcl*-2.

CLINICAL FEATURES: The median age of patients diagnosed with localized fibrous tumor of the pleura is 55 years (range, 9–86 years) without any sex predominance. They present most often with chest

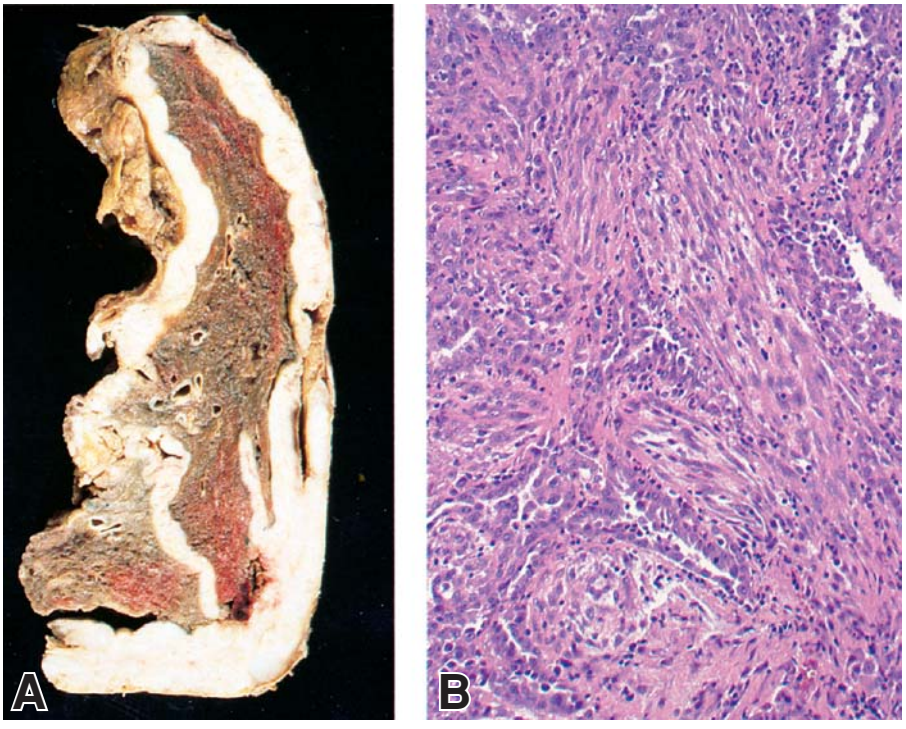

FIGURE 18-100. Pleural malignant mesothelioma. A. The lung is encased by a dense pleural tumor that extends along the interlobar fissures but does not involve the underlying lung parenchyma. **B.** This mesothelioma is composed of a biphasic pattern of epithelial and sarcomatous elements.

pain, followed by shortness of breath, cough, hypoglycemia, weight loss, hemoptysis, fever and night sweats. Patients with benign fibrous tumors of pleura have an excellent prognosis. Half of histologically malignant tumors are cured if resected completely.

Malignant Mesothelioma Usually Reflects Asbestos Exposure

Malignant mesothelioma is a neoplasm of mesothelial cells. It is most common in the pleura but also occurs in the peritoneum, pericardium and tunica vaginalis of the testis.

EPIDEMIOLOGY: Some 2000 new cases of malignant mesothelioma develop yearly in the United States. In the United States, Great Britain and South Africa, 80% of patients report exposure to asbestos. Mesothelioma typically develops after a long latency period, which averages 30–40 years.

PATHOLOGY: Grossly, pleural mesotheliomas often encase and compress the lung, extending into fissures and interlobar septa, a distribution often referred to as a "pleural rind" (Fig. 18-100A). Invasion of pulmonary parenchyma is generally limited to the periphery adjacent to the tumor. Lymph nodes tend to be spared. Microscopically, classic mesotheliomas show both epithelial and sarcomatous patterns (Fig. 18-100B). Glands and tubules that resemble adenocarcinoma are admixed with sheets of spindle cells similar in appearance to a fibrosarcoma. In some instances, only one or the other component is present: if it is epithelial, the tumor may be difficult to distinguish from adenocarcinoma. Less commonly, only a sarcomatous component is present.

Immunohistochemistry is essential for differentiating mesothelioma from adenocarcinoma (see Chapter 5). Both are positive for cytokeratins; however, adenocarcinomas often, but not always, express carcinoembryonic antigen, Leu-M1, B72.3 and BER-EP4, but mesotheliomas are negative for these markers. In contrast, mesotheliomas are typically positive for calretinin, WT-1 and D2-40 (podoplanin), for which adenocarcinomas are typically negative. Other criteria supportive of a diagnosis of mesothelioma include absence of mucin, presence of hyaluronic acid (positive Alcian blue staining) and long, slender microvilli seen by electron microscopy.

CLINICAL FEATURES: The average age of patients with mesothelioma is 60 years. Patients first present with a pleural effusion or a pleural mass, chest pain and nonspecific symptoms, such as weight loss and malaise. Pleural mesotheliomas tend to spread locally within the chest cavity, invading and compressing major structures. Metastases can occur to the lung parenchyma and mediastinal lymph nodes, as well as to extrathoracic sites such as liver, bones, peritoneum and adrenals. Treatment is largely ineffective and prognosis is poor: few patients survive longer than 18 months after diagnosis.

The Esophagus

ANATOMY

The gut and respiratory tract arise embryologically from the foregut, which then divides into two separate tubes, the dorsal esophagus and the ventral trachea. The adult esophagus is a 23–25-cm conduit for food and liquid into the stomach. During upper endoscopy, the esophagus is measured from the incisor teeth with a range of 38 to 43 (average 40) cm from teeth to gastroesophageal junction. The esophagus contains striated and smooth muscle in its upper portion and smooth muscle alone in its lower portion. It is fixed superiorly at the cricopharyngeal and inferior pharyngeal constrictor muscles, which together form the upper esophageal sphincter. It courses inferiorly through the posterior mediastinum behind the trachea and heart and exits the thorax through the diaphragm. Tonic muscular contraction at its lower end creates the **lower esophageal sphincter,** which is a functional sphincter, rather than a true anatomic one.

The esophagus has a mucosa, muscularis mucosae, submucosa, muscularis propria and adventitia. The former is lined by a nonkeratinizing, stratified squamous epithelium. A transition to gastric mucosa at the **gastroesophageal (GE) junction** occurs abruptly at the level of the diaphragm. The esophageal submucosa contains mucous glands, a rich lymphatic plexus and nerve fibers. Lymphatics of the upper third of the esophagus drain to cervical lymph nodes, those of the middle third to mediastinal nodes and those of the lower third to celiac and gastric lymph nodes. These anatomic features are significant in the spread of esophageal cancer.

Venous drainage of the esophagus is important, because the veins can form varices if there is portal hypertension. Varices occur invariably in the lower third of the esophagus, as the veins of the upper third drain into the superior vena cava and those of the middle third drain into the azygous system. Only the veins of the lower third drain into the portal vein via the gastric veins.

CONGENITAL DISORDERS

Tracheoesophageal Fistula Leads to Aspiration Pneumonia

Congenital **atresias** and **stenoses** may occur at any site in the gastrointestinal (GI) tract. Esophageal atresia occurs in 1 in 3500 births and stenosis in 1 in 50,000 births. Atresia may be present alone or, more often, with an associated tracheoesophageal fistula. Stenoses are usually acquired but can be congenital, are usually in the distal esophagus and reflect abnormal wall architecture.

Esophageal atresia with or without tracheoesophageal fistula is the most common esophageal congenital anomaly (Fig. 19-1). Esophageal atresia without a fistula appears in only about 8% of cases. Half of patients have other congenital anomalies, 25% being other gastrointestinal malformations. One fifth have VACTERL syndrome (vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal dysplasia and limb abnormalities). The etiology of esophageal atresias and fistulas is unknown, but genetic and environmental factors are felt to contribute. Prenatal diagnosis is suggested by polyhydramnios, prominent esophageal pouch and small or absent stomach bubble with fluid-filled loops of bowel on ultrasonography. Polyhydramnios develops because amniotic fluid cannot reach the stomach.

PATHOLOGY: In about 85% of tracheoesophageal fistulas, the upper portion of the esophagus ends in a blind pouch and the superior end of the lower segment communicates with the trachea (Fig. 19-1). ***In this type of atresia, the upper blind sac soon fills with mucus, which the infant then aspirates.*** Surgical correction is feasible but difficult.

Another type of fistula is a communication between the proximal esophagus and the trachea; the lower esophageal pouch communicates with the stomach. ***Infants with this condition aspirate shortly after birth.*** In an **H-type fistula,** there is a communication between an intact esophagus and

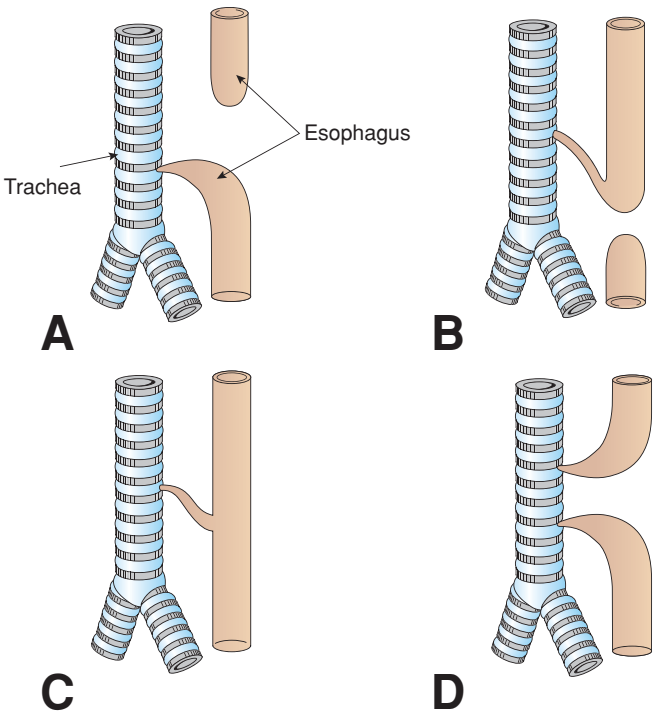

FIGURE 19-1. Congenital tracheoesophageal fistulas. A. The most common type (85% of cases) is a communication between the trachea and the lower portion of the esophagus. The upper segment of the esophagus ends in a blind sac. **B.** In a few cases, the proximal esophagus communicates with the trachea. **C.** H-type fistula without esophageal atresia. **D.** Tracheal fistulas to both a proximal esophageal pouch and distal esophagus.

an intact trachea. In some cases, this lesion is first symptomatic in adulthood, presenting with repeated pulmonary infections.

Duplication Cysts Replicate the Normal Anatomy of the Affected Bowel

Cystic or tubular remnants of a segment of the gut are duplications. These may occur anywhere in the gut but affect the small bowel most often (50%), followed by the esophagus (15%). Duplications are usually continuous with the segment of bowel from which they arise, although ectopic sites may occur. They may form expanding, intramural masses, which may cause partial or complete bowel obstruction.

Rings and Webs Cause Dysphagia

ESOPHAGEAL WEBS: Occasionally, a thin mucosal membrane projects into the esophageal lumen. Webs are usually single and thin (2 mm) and occur anywhere in the esophagus. They have a core of fibrovascular tissue lined by normal mucosa and submucosa. Middle-aged women are most affected and present with difficulty swallowing (dysphagia). They are often successfully treated by dilation with large rubber bougies; if needed, webs can be excised with biopsy forceps via endoscopy.

PLUMMER-VINSON (PATERSON-KELLY) SYNDROME: This exceedingly rare disorder is characterized by (1) a cervical esophageal web, (2) mucosal lesions of the mouth and pharynx and (3) iron-deficiency anemia. Dysphagia, often

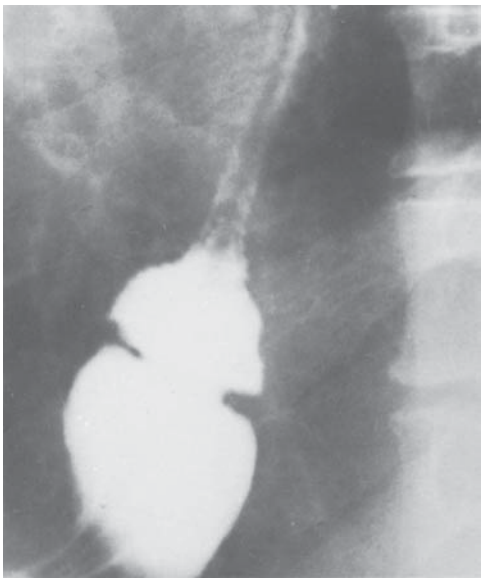

FIGURE 19-2. Schatzki mucosal ring. A contrast radiograph illustrates the lower esophageal narrowing.

associated with aspiration of swallowed food, is the most common clinical manifestation. Ninety percent of cases occur in women. ***Carcinoma of the oropharynx and upper esophagus is a possible complication.***

SCHATZKI RING: This lower esophageal narrowing is usually seen at the GE junction (Fig. 19-2). The upper surface of the mucosal ring has stratified squamous epithelium; the lower, columnar epithelium. Although they are seen in up to 14% of barium examinations, Schatzki rings are usually asymptomatic. Patients with narrow Schatzki rings, however, may complain of intermittent dysphagia. Often dietary and lifestyle changes improve symptoms. If these interventions are ineffective, dilation with bougies can also be done.

Esophageal Diverticula Often Reflect Motor Dysfunction

A **true diverticulum** is an outpouching of the wall that contains all layers of the wall. If a sac has no muscular layer, it is a **false diverticulum** (or pseudodiverticulum). Esophageal diverticula occur in the hypopharyngeal area above the upper esophageal sphincter, in the middle esophagus and just proximal to the lower esophageal sphincter.

ZENKER DIVERTICULUM: Zenker diverticula are uncommon lesions that appear high in the esophagus and affect men more than women. These false diverticula probably reflect disordered function of cricopharyngeal musculature. Most affected people who come to medical attention are older than 60, suggesting that Zenker diverticula are acquired.

These diverticula can enlarge conspicuously and accumulate a large amount of food. The typical symptom is regurgitation of food eaten some time previously (occasionally days), without dysphagia. Patients may develop recurrent aspiration pneumonia. When symptomatic, these lesions are surgically removed or treated endoscopically.

MIDESOPHAGEAL (TRACTION) DIVERTICULA: Diverticula in the middle of the esophagus often reflect a disturbance in esophageal motor function but may also be due to adhesions. They ordinarily have wide stomas and the

pouches are usually higher than their orifices. Thus, these diverticula do not retain food or secretions and remain asymptomatic, with only rare complications.

EPIPHRENIC DIVERTICULA: These diverticula are located in the distalmost 10 cm of the esophagus, usually immediately above the diaphragm. Motor disturbances of the esophagus (e.g., achalasia, diffuse esophageal spasm) are found in two thirds of patients with this true diverticulum. Abnormalities of the lower esophageal sphincter may also lead to an epiphrenic diverticula. When symptomatic, surgery to correct the underlying motor abnormality (e.g., myotomy) is appropriate.

MOTOR DISORDERS

Automatic coordination of muscular movement during swallowing is a **motor function** and results in free passage of food through the esophagus. The hallmark of motor disorders is difficulty in swallowing, or **dysphagia**. Dysphagia is often an awareness that food is not moving downward and in itself is not painful. Pain on swallowing is **odynophagia**. Motor disorders can be caused by:

- **Systemic diseases of skeletal muscle** (in the upper esophagus) such as myasthenia gravis, dermatomyositis, amyloidosis, hypothyroidism and myxedema
- **Neurologic diseases** affecting nerves to skeletal or smooth muscle (e.g., cerebrovascular accidents, amyotrophic lateral sclerosis)
- **Peripheral neuropathy** associated with diabetes or alcoholism

In Achalasia Lower Esophageal Sphincter Function Is Abnormal

Achalasia, once called cardiospasm**,** involves failure of the lower esophageal sphincter to relax with swallowing and poor peristalsis in the body of the esophagus. As a result of these defects in both the outflow tract and esophageal pumping mechanisms, food is retained in the esophagus, and the organ hypertrophies and dilates (Fig. 19-3).

Achalasia is an inflammatory disease that causes loss of inhibitory neurons in the esophageal myenteric plexus. Chronic inflammation (mainly T cells) in the myenteric plexus leads to neuritis and ganglionitis, and eventually to ganglion cell loss and fibrosis. The cause of the inflammation is unknown, but genetic, viral and autoimmune factors have been suggested. Degenerative changes in the dorsal motor nucleus of the vagus and extraesophageal vagus nerves may also contribute. In Latin America, secondary achalasia is a common complication of **Chagas disease** (see Chapter 9), in which ganglion cells are destroyed by the protozoan *Trypanosoma cruzi.* Amyloidosis, sarcoidosis and infiltrative malignancies may also cause achalasia.

Dysphagia (to both solids and liquids), occasionally odynophagia and regurgitation of material retained in the esophagus are common symptoms of achalasia. Squamous cell carcinoma may develop in long-standing cases. Radiography may show a "bird-beak" gastroesophageal junction, but manometry is the standard diagnostic test for confirming achalasia. Treatment may include endoscopic balloon dilation, botulinum toxin injection of the lower esophageal sphincter, endoscopic myotomy or surgical myotomy of the lower esophageal sphincter. Patients may develop GE reflux after treatment.

FIGURE 19-3. Esophagus and upper stomach of a patient with advanced achalasia. The esophagus is markedly dilated above the esophagogastric junction, where the lower esophageal sphincter is located. The esophageal mucosa is redundant and has hyperplastic squamous epithelium.

Systemic Sclerosis Causes Fibrosis of the Esophageal Wall

Systemic sclerosis (scleroderma) causes fibrosis in many organs and involves the GI tract 80% of the time (see Chapter 11). Any segment of the tubal gut may be affected. The esophagus is most frequently impacted, often with severely abnormal esophageal muscle function. The lower esophageal sphincter may be so impaired that the lower esophagus and upper stomach are no longer distinct functional entities and are visualized as a common cavity. Peristalsis may be impaired throughout the esophagus.

PATHOLOGY: Fibrosis is present in the esophageal smooth muscle (especially the inner muscularis propria). Nonspecific inflammation is also evident. Small arteries and arterioles show intimal fibrosis, which may contribute to the fibrosis.

CLINICAL FEATURES: Patients have dysphagia, regurgitation and heartburn caused by peptic esophagitis, owing to reflux of acid from the stomach. Severe reflux changes may occur (see below).

HIATAL HERNIA

Hiatal hernia is a protrusion of the stomach into the chest, through an enlarged diaphragmatic opening. There are two basic types of hiatal hernia (Fig. 19-4).

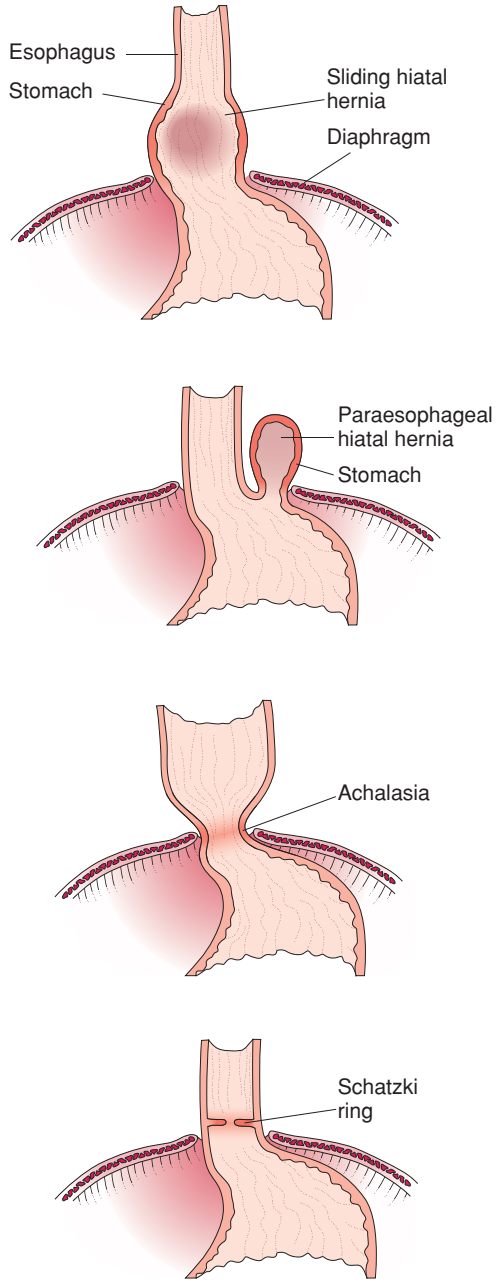

FIGURE 19-4. Disorders of the esophageal outlet.

SLIDING HERNIA: Enlargement of the diaphragmatic hiatus and laxity of the circumferential connective tissue allow a cap of gastric mucosa to move upward, above the diaphragm. This common condition accounts for 85% of hiatal hernias and is usually asymptomatic. The most commonly associated symptom is GE reflux, although it is unclear whether hernias are the causes or results of reflux.

PARAESOPHAGEAL HERNIA: In this uncommon form of hiatal hernia, a portion of gastric fundus herniates through a defect in the diaphragmatic connective tissue that defines the esophageal hiatus and lies beside the esophagus. The hernia progressively enlarges and the hiatus grows increasingly wide, which can compress the esophagus, leading to decrease in reflux of gastric contents. In extreme cases, the entire stomach and other abdominal organs can herniate into the thorax.

CLINICAL FEATURES: Symptoms of sliding hiatal hernia, mostly heartburn and regurgitation, reflect reflux of gastric contents into the esophagus, primarily due to incompetence of the lower esophageal sphincter. Classically, symptoms are worse when subjects recline, as this position facilitates acid reflux. Dysphagia, fullness after meals, shortness of breath, painful swallowing and occasionally bleeding peptic ulcers may be seen in paraesophageal hernias. Large hernias carry a risk of gastric volvulus or intrathoracic gastric dilation.

Sliding hiatal hernias generally do not require surgery and symptoms are treated medically. An enlarging paraesophageal hernia should be corrected surgically, even if it is asymptomatic.

ESOPHAGITIS

Reflux Esophagitis Is Caused by Reflux of Gastric Contents (Gastroesophageal Reflux Disease)

This is by far the most common type of esophagitis. It often occurs together with sliding hiatal hernias but may develop as the result of an incompetent lower esophageal sphincter with no anatomic lesion.

ETIOLOGIC FACTORS: The main barrier to reflux of gastric contents into the esophagus is the lower esophageal sphincter. Episodic reflux is normal, particularly after a meal. The mucosa is partially protected by the alkaline secretions of submucosal glands. Esophagitis results when episodes are frequent and prolonged. Agents that decrease lower esophageal sphincter pressure (e.g., alcohol, chocolate, fatty foods, cigarette smoking) also cause reflux, as may certain central nervous system (CNS) depressants (e.g., morphine, diazepam), abdominal obesity, pregnancy, estrogen therapy and the presence of a nasogastric tube. Acid damages the esophageal mucosa, but the combination of acid plus pepsin is particularly injurious. Moreover, gastric fluid often contains refluxed bile from the duodenum, which magnifies injury to the esophageal mucosa. Alcohol, hot beverages and spicy foods may also injure the mucosa directly.

PATHOLOGY: The first grossly evident effect of GE reflux is hyperemia. Affected areas are susceptible to superficial mucosal erosions and ulcers, which often appear as vertical linear streaks. Mild injury to the squamous epithelium appears as cell swelling (hydropic change; see Chapter 1). With continued injury, hyperplasia develops: the basal epithelium is thickened and the papillae of the lamina propria are elongated and approach the surface (Fig. 19-5). Capillary vessels in the papillae are often dilated. Lymphocytes, neutrophils and eosinophils infiltrate the epithelium. Mucosal ulceration develops in severe cases. Esophageal stricture may occur if the ulcer persists and damages the esophageal wall deep to the lamina propria. In this circumstance, reactive fibrosis can narrow the esophageal lumen.

CLINICAL FEATURES: Gastroesophageal reflux disease (GERD) can occur at any age and can be nonerosive, erosive or involved by Barrett esophagus

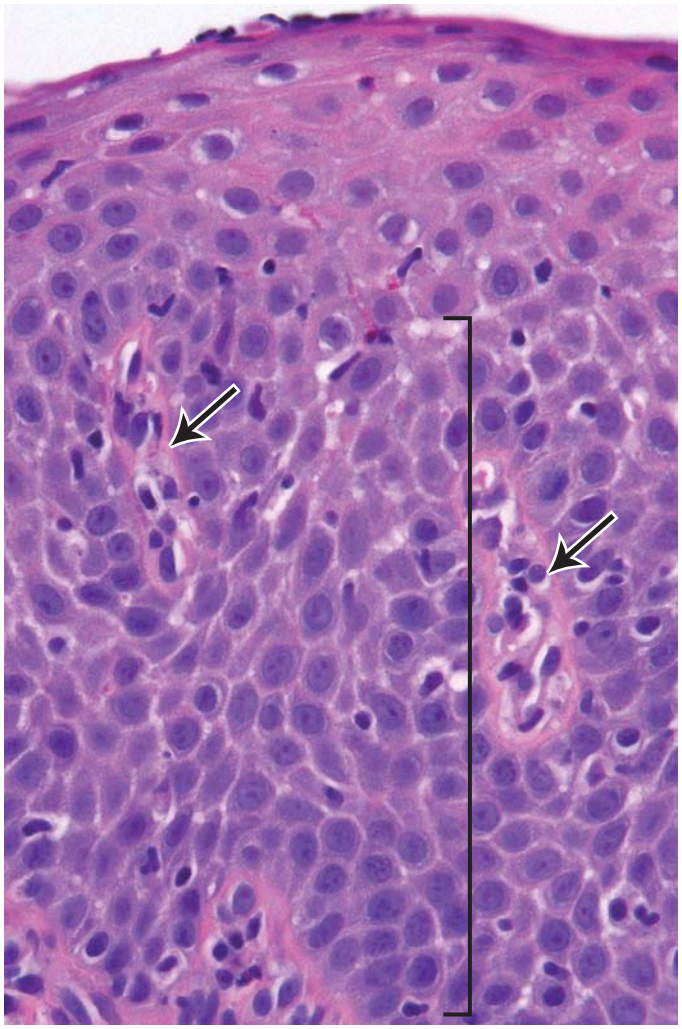

FIGURE 19-5. Reflux esophagitis. Biopsy from a patient with long-standing heartburn. Note the basal hyperplasia (*bracket*) and papillae, squamous hyperplasia and inflammation.

(see below). Heartburn and dysphagia are the usual presenting symptoms and generally respond to agents that reduce gastric acidity, in particular proton pump inhibitors. In cases of erosive GERD, ulceration, hematemesis and stricture may occur.

Barrett Esophagus Is Replacement of Esophageal Squamous Epithelium by Columnar Epithelium (Intestinal Metaplasia)

Barrett esophagus is a result of chronic GERD. For reasons unknown, its incidence has been increasing in recent years, particularly among white men. This disorder occurs in the lower third of the esophagus but may extend higher.

PATHOLOGY: Metaplastic Barrett epithelium may partially involve the circumference of short segments or may line the entire lower esophagus (Fig. 19-6A). The sine qua non of Barrett esophagus is a distinctive "specialized epithelium." By endoscopy, it has a typical salmon-pink color and is an admixture of intestine-like epithelium with well-formed goblet cells, mixed with gastric foveolar cells (Fig. 19-6B). Complete intestinal metaplasia, with Paneth cells and absorptive cells, occurs occasionally. Inflammatory changes are often superimposed on these alterations. Dysplasia develops in this epithelium in a minority of patients (Fig. 19-6C). ***The risk of Barrett esophagus transforming into adenocarcinoma correlates with the length of esophagus involved and the degree of dysplasia.*** Dysplasia in a Barrett esophagus is currently classified as negative, indefinite, low grade or high grade. The cytology and architecture of high-grade dysplasia overlap intramucosal adenocarcinoma, the latter definitively identified by invasion into the lamina propria (Fig. 19-6D).

CLINICAL FEATURES: The diagnosis of Barrett esophagus is established by endoscopy with biopsy, usually after complaints of GERD, although many do not report reflux symptoms. Males predominate (3:1). Prevalence increases with age, and most patients are diagnosed after age 60. Smokers have twice the risk of Barrett esophagus as nonsmokers. Obesity and white race are other risk factors.

Patients with Barrett esophagus are followed closely to detect early microscopic evidence of dysplastic mucosa. Many cases, particularly low-grade dysplasia (or even microscopic foci of high-grade dysplasia), regress after pharmacologic reduction in gastric acidity. However, high-grade dysplasia and intramucosal carcinoma require intervention. Techniques used to ablate these lesions (short of esophagectomy) include endoscopic mucosectomy, laser treatment and photodynamic therapy. Standards of care for high-grade dysplasia/intramucosal adenocarcinoma are evolving.

Eosinophilic Esophagitis Is Increasing in Incidence

A diagnosis of eosinophilic esophagitis requires clinical–pathologic correlation. While the pathogenesis is not completely understood, allergies to ingested food and inhaled allergens likely play a prominent role. Patients often complain of dysphagia or feeling food "sticking" upon swallowing, which they may relate to specific foodstuffs. Affected individuals are often first identified after they fail to improve on standard antireflux therapy. It is important to rule out GERD with several weeks of proton pump inhibitor therapy before biopsy or with pH monitoring. The incidence of eosinophilic esophagitis is increasing, likely from a combination of increasing disease prevalence and increasing awareness of the entity and thus more frequent diagnosis.

PATHOLOGY: On endoscopy, eosinophilic esophagitis shows concentric mucosal rings (called trachealization or felinization because it resembles the trachea or cat esophagus), vertical linear furrows, narrow esophagus, strictures and small white plaques/exudates (Fig. 19-7A). Some patients have a normal-appearing esophagus at endoscopy. Since the disease can be quite patchy, multiple biopsies from various levels of esophagus should be assessed. The epithelium shows hyperplasia (papillary and basal layer hyperplasia), intercellular edema, increased intraepithelial eosinophils (≥15 per high-power field), superficial layering of eosinophils, eosinophilic microabscesses

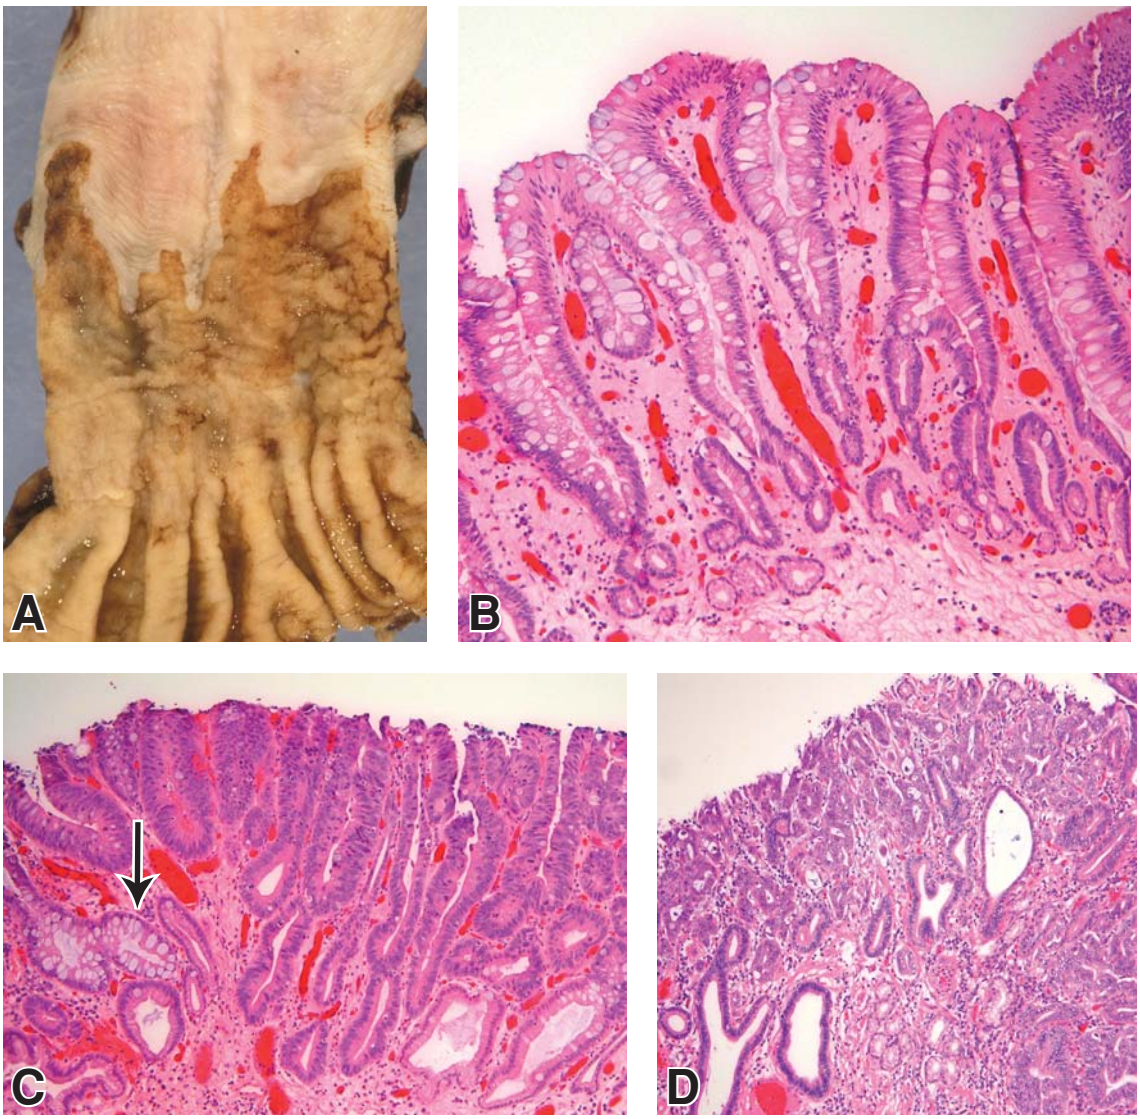

FIGURE 19-6. Barrett esophagus. A. The presence of the tan tongues of epithelium interdigitating with the more proximal squamous epithelium is typical of Barrett esophagus. **B.** The specialized epithelium has a villiform architecture and is lined by cells that are foveolar gastric-type cells and intestinal goblet-type cells. **C. High-grade dysplasia.** Markedly dysplastic glands predominate with hyperchromatic nuclei and early architectural distortion. Intestinalized, nondysplastic glands persist (*arrow*). **D. Intramucosal adenocarcinoma.** Malignant glands are restricted to the mucosa.

and prominent degranulation of eosinophils (Fig. 19-7B). Deeper samples may show subepithelial fibrosis and eosinophils in the lamina propria.

CLINICAL FEATURES: Eosinophilic esophagitis can present at any age and is more common in males. Adults typically complain of dysphagia to solids or food impaction, while young children may show food intolerance, vomiting, feeding difficulties or failure to thrive. Many patients have a personal or family history of atopy (asthma, allergic rhinitis, eczema, atopic dermatitis), and some may have mildly increased blood eosinophils. Eliminating inciting food from the diet can lead to remission in many patients. Swallowed corticosteroids, leukotriene inhibitors and other immunomodulators can also be used to treat eosinophilic esophagitis.

Lymphocytic Esophagitis Is an Emerging Form of Esophagitis

This rare entity is defined by marked esophageal lymphocytosis in peripapillary zones, with rare or absent granulocytes. Intercellular edema is frequent. Patients present with a variety of clinical symptoms, and no specific underlying etiology is known.

Infective Esophagitis Is Associated with Immunosuppression

CANDIDA ESOPHAGITIS: This fungal infection became common as increasing numbers of patients are immunocompromised owing to chemotherapy for malignant disease, immunosuppression after organ transplantation or AIDS.

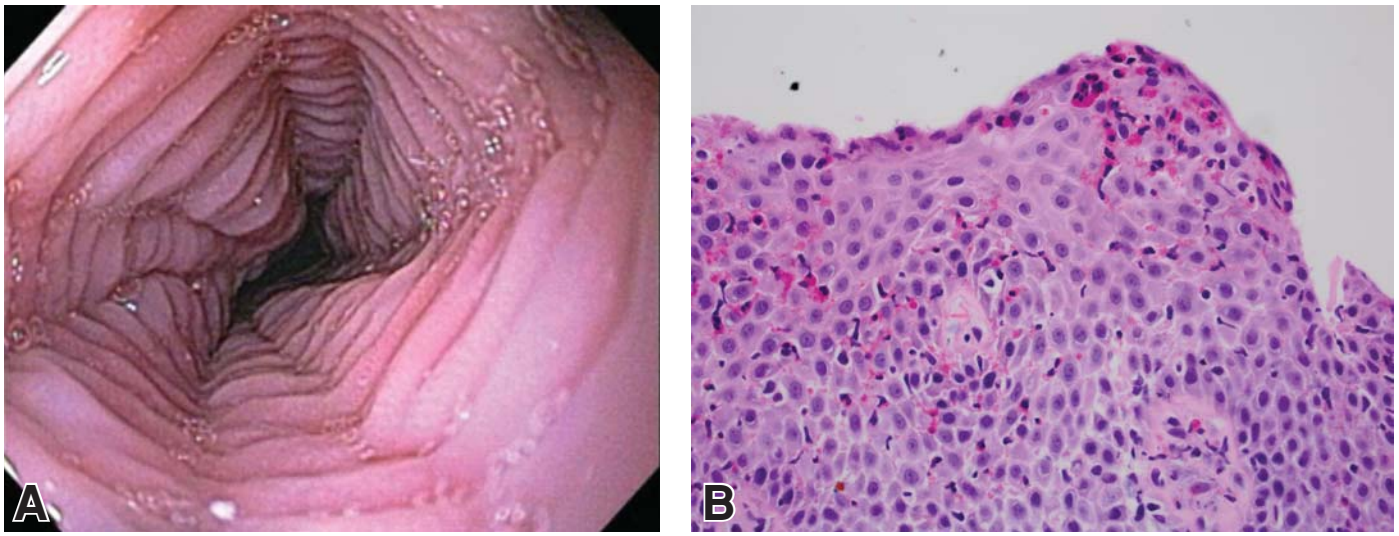

FIGURE 19-7. Eosinophilic esophagitis. A. Endoscopic view of an esophagus from a patient with eosinophilic esophagitis showing concentric mucosal rings (called trachealization or felinization because of its resemblance to the trachea or cat esophagus), vertical linear furrows and small white plaques/exudates. **B.** Microscopic image showing epithelial hyperplasia (papillary and basal layer hyperplasia), intercellular edema, increased intraepithelial eosinophils (≥15 per high-power field), superficial layering of eosinophils, eosinophilic microabscesses and prominent degranulation of eosinophils.

Esophageal candidiasis also occurs in patients with diabetes, in those receiving antibiotic therapy or acid-suppressive therapy or in people using inhaled or swallowed corticosteroids. It is uncommon in the absence of known predisposing factors. Dysphagia and severe pain on swallowing are the usual symptoms.

PATHOLOGY: In mild cases, a few small, elevated white mucosal plaques are surrounded by a hyperemic zone in the middle or lower third of the esophagus. In severe cases, confluent pseudomembranes lie on a hyperemic and edematous mucosa. Candidal pseudomembranes contain fungal forms, necrotic debris and fibrin. *Candida* may involve only the superficial epithelium, but invasion deeper into the esophageal wall can lead to disseminated candidiasis or fibrosis, sometimes severe enough to create a stricture.

HERPETIC ESOPHAGITIS: Esophageal infection with herpesvirus type I most commonly follows solid organ or bone marrow transplantation. Patients complain of odynophagia. Herpetic esophagitis may occur on occasion in otherwise healthy people.

PATHOLOGY: Well-developed lesions of herpetic esophagitis grossly resemble those of candidiasis. Early cases show vesicles, small erosions or plaques; as infection progresses, these coalesce into larger lesions. Epithelial cells show typical nuclear herpetic inclusions and occasional multinucleation. Necrosis of infected cells leads to ulceration. Candidal or bacterial superinfection may cause pseudomembranes.

CYTOMEGALOVIRUS (CMV) ESOPHAGITIS: Involvement of the esophagus, or other segments of the GI tract, with CMV usually reflects systemic viral disease in severely immunosuppressed patients (e.g., those with AIDS, transplant recipients, etc.). Mucosal ulceration, as in herpetic esophagitis, is common. Characteristic CMV inclusion bodies are seen in endothelial cells and granulation tissue fibroblasts.

Chemical Esophagitis Results from Ingestion of Corrosive Agents

Chemical injury to the esophagus usually reflects accidental poisoning in children, attempted suicide in adults or contact with medication ("pill esophagitis"). Strong alkaline agents (e.g., lye) or strong acids (e.g., sulfuric or hydrochloric acid), which are used in various cleaning solutions, can produce chemical esophagitis. The former are particularly insidious, since they are generally odorless and tasteless and so easily swallowed before protective reflexes come into play.

PATHOLOGY: Alkaline agents cause liquefactive necrosis with conspicuous inflammation and saponification of membrane lipids of all layers of the esophagus and stomach. Small vessel thrombosis adds ischemic necrosis to the injury. Severe damage is the rule with liquid alkali, but less than 25% of those who ingest granular preparations have severe complications.

Strong acids produce immediate coagulative necrosis. Resultant protective eschars limit injury and penetration. Still, half of patients who ingest concentrated hydrochloric or sulfuric acid develop severe esophageal injury.

Drug-related esophagitis is most often caused by direct chemical effects on the squamous-lined mucosa, especially with capsules; esophageal dysmotility and cardiac enlargement (which impinges on the esophagus) may be contributing factors.

Esophagitis May Complicate Systemic Illnesses

Esophageal squamous mucosa resembles, and shares some reactions with, the skin.

The **dermolytic (dystrophic) form of epidermolysis bullosa** (see Chapter 28) involves all organs lined by, or derived from, squamous epithelium, including skin, nails, teeth and esophagus. Bullae occur episodically and evolve from fluid-filled vesicles to weeping ulcers. Dysphagia and painful

swallowing are common. Stricture, usually in the upper esophagus, may occur.

Bullous pemphigoid causes subepithelial bullae in the skin and esophagus without scarring. Other dermatologic disorders associated with esophagitis include pemphigus vulgaris, dermatitis herpetiformis, Behçet syndrome and erythema multiforme.

Graft-versus-host disease (GVHD; see Chapter 4) in recipients of bone marrow transplants can cause esophageal lesions and dysphagia, odynophagia and GE reflux.

Esophagitis May Be Iatrogenic

External irradiation for treatment of thoracic cancers may affect parts of the esophagus and lead to esophagitis and stricture. **Nasogastric tubes** may cause pressure ulcers if they are in place for prolonged periods, but acid reflux also plays a role in these cases.

ESOPHAGEAL VARICES

Esophageal varices are dilated veins just beneath the mucosa (Fig. 19-8) ***that are prone to rupture and hemorrhage*** (also see Chapter 20). They arise in the lower third of the esophagus, virtually always in patients with hepatic cirrhosis and portal hypertension. GE anastomoses link lower esophageal veins to the portal system. If portal pressure exceeds a critical level, these anastomoses dilate in the upper stomach and lower esophagus. Without treatment, varices rupture in approximately 1/3 of patients, leading to life-threatening hemorrhage. Reflux injury or infective esophagitis can contribute to variceal bleeding. Esophageal banding and a variety of medications are used to prevent esophageal varices from rupturing.

LACERATIONS AND PERFORATIONS

Lacerations of the esophagus result from external trauma, such as automobile accidents or medical instrumentation, or from severe vomiting, during which intraesophageal pressure may reach 300 mm Hg. Forceful retching may cause mucosal tears, first in the gastric epithelium and then extending into the esophagus.

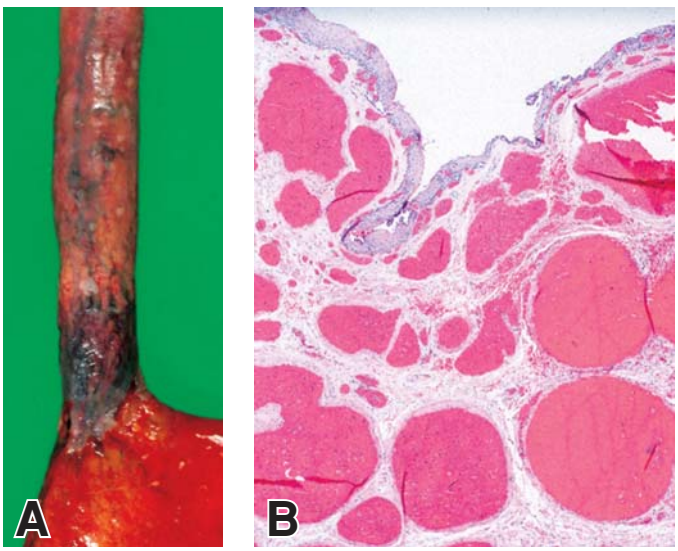

FIGURE 19-8. Esophageal varices. A. Numerous prominent blue venous channels are seen beneath the mucosa of the everted esophagus, particularly above the gastroesophageal junction. **B.** Section of the esophagus reveals numerous dilated submucosal veins.

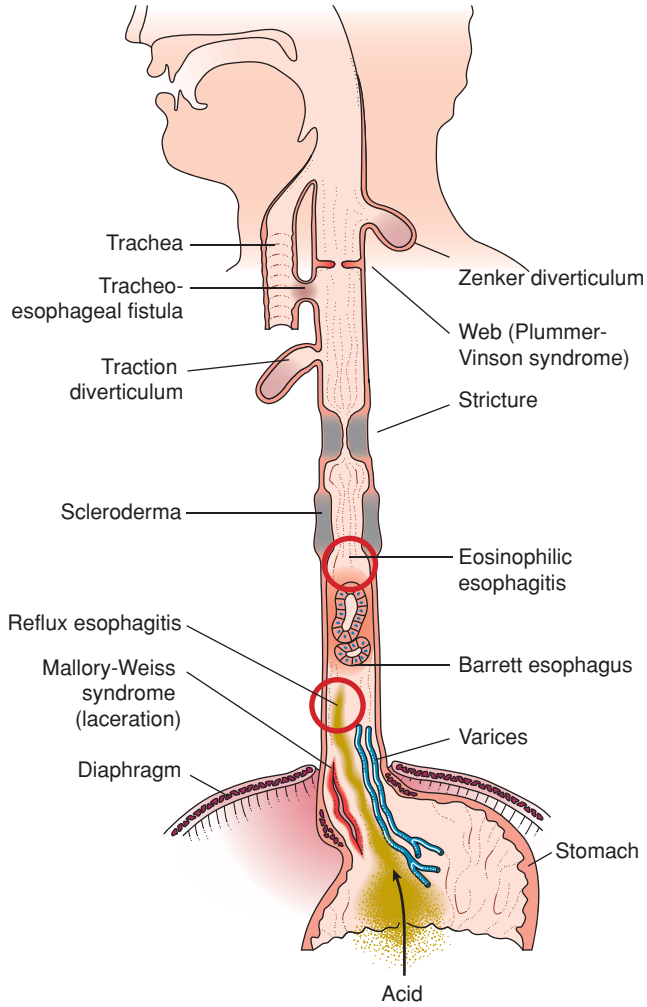

FIGURE 19-9. Nonneoplastic disorders of the esophagus.

Mallory-Weiss syndrome refers to severe retching, often associated with alcoholism. It leads to mucosal lacerations of the upper stomach and lower esophagus. These tears cause patients to vomit bright red blood. Bleeding may be so severe as to require transfusion of many units of blood. Perforation into the mediastinum, called **Boerhaave syndrome,** may result.

Esophageal perforation, whether from trauma, from vomiting or iatrogenic, can be catastrophic. It is a well-known occurrence in newborns, in whom it is caused occasionally by suctioning or feeding with a nasogastric tube. However, it may also occur spontaneously.

The major nonneoplastic esophageal disorders are summarized in Fig. 19-9.

NEOPLASMS OF THE ESOPHAGUS

Benign Tumors of the Esophagus Are Uncommon

Unlike other parts of the gastrointestinal tract, most spindle cell submucosal tumors of the esophagus derive from

smooth muscle **(leiomyoma)** rather than from interstitial cells of Cajal (gastrointestinal stromal tumors [GISTs]; see below). They are almost always benign. **Squamous papillomas** of the esophagus are uncommon and may be related to human papillomavirus (HPV) infection.

Esophageal Squamous Carcinomas Vary Geographically and Histologically

EPIDEMIOLOGY: Worldwide, most esophageal cancers are squamous cell carcinomas. Esophageal cancer is the eighth most common cancer. In the United States, adenocarcinoma is now more common (see below).

Global geographic variations in the incidence of esophageal squamous carcinomas are striking: areas of high incidence often abut areas of low incidence. The greatest frequency is in China, Iran, South America and South Africa. In the United States, black men have a much higher incidence than whites, and American urban dwellers are at greater risk than those in rural areas. Esophageal squamous cell carcinoma is more common in older males.

ETIOLOGIC FACTORS: The variable distribution of esophageal squamous carcinomas, even among relatively homogeneous populations, suggests that environmental factors strongly affect its development. The most common factors are smoking and alcohol, which have a synergistic rather than additive effect. Other contributors include diet, consuming large amounts of hot beverages, HPV, radiation exposure, dietary nitrates and nitrosamines, vitamin deficiencies, genetic factors, Plummer-Vinson syndrome, achalasia and prior caustic injury.

PATHOLOGY: About half of cases of esophageal squamous cell carcinoma involve the middle and upper thirds of the esophagus. Tumors may be endophytic or exophytic (Fig. 19-10). They can also be infiltrating, growing mainly in the wall. Bulky polypoid tumors tend to obstruct early, but ulcerated ones are more likely to bleed. Infiltrating tumors gradually narrow the lumen by circumferential compression. Extension of tumor into mediastinal structures is often a major problem.

Neoplastic squamous cells range from well differentiated, with squamous "pearls," to poorly differentiated, without evident squamous differentiation. Some tumors have a predominant spindle cell population of tumor cells.

The rich lymphatic drainage of the esophagus provides a route for most metastases. Tumors of the upper third spread to cervical, internal jugular and supraclavicular nodes. Those of the middle third metastasize to paratracheal and hilar lymph nodes and to nodes in the aortic, cardiac and paraesophageal regions. Since the lower third of the esophagus is supplied by the left gastric artery, lower esophageal tumors spread via accompanying lymphatics to retroperitoneal, celiac and left gastric nodes. Metastases to liver and lung are common, but almost any organ may be affected.

CLINICAL FEATURES: Dysphagia is the most common presenting complaint, but by the time this occurs, most tumors are inoperable. Patients may become cachectic from anorexia, difficulty in swallowing and the remote effects of a cancer. Odynophagia occurs in half of patients. Persistent pain suggests extension to the mediastinum or to spinal nerves. Compression of the recurrent laryngeal nerve causes hoarseness, and tracheoesophageal fistula presents clinically as a chronic cough. Treatment is similar to esophageal adenocarcinoma (see below).

FIGURE 19-10. Esophageal squamous cell carcinoma. There is a large ulcerated mass present in the squamous mucosa with normal squamous mucosa intervening between the carcinoma and the stomach.

Adenocarcinoma of the Esophagus Often Arises in a Background of Barrett Esophagus

EPIDEMIOLOGY: In North America, Western Europe and Australia, esophageal adenocarcinoma is far more common than squamous cancer. Incidence of esophageal adenocarcinoma is increasing faster than any solid tumor: it has increased sevenfold in the United States in the last 30 years. Men are affected more often than women.

ETIOLOGIC FACTORS: Most esophageal adenocarcinomas arise from Barrett esophagus and so have similar underlying risk factors. These include white race, male gender, obesity, GERD, diet, tobacco use and genetic factors. Other risk factors that lead to increased gastric acid production or reflux include lower esophageal sphincter dilation or myotomy, scleroderma, Zollinger-Ellison syndrome or use of medications that relax the lower esophageal sphincter.

PATHOLOGY: The majority of esophageal adenocarcinomas involve the distal esophagus or GE junction, and can extend into the proximal stomach. Tumors may be flat, ulcerated, polypoid or fungating. Often there is surrounding nonneoplastic Barrett mucosa that can be seen grossly or microscopically (Fig. 19-11).

FIGURE 19-11. Esophageal adenocarcinoma. There is a large exophytic ulcerated mass lesion just proximal to the gastroesophageal junction. This well-differentiated adenocarcinoma was separated from the most proximal squamous epithelium by a tan area representing Barrett esophagus.

These tumors may be well differentiated, with well-developed glands, ranging to poorly differentiated tumors with essentially no glandular differentiation. Some poorly differentiated adenocarcinomas have signet ring cellular morphology.

CLINICAL FEATURES: The symptoms and clinical course of esophageal adenocarcinoma are like those of squamous carcinoma. Symptoms generally appear in white, obese men with histories of GERD. Diagnosis and staging are typically done using endoscopy with ultrasound. Early invasive cancers (T1) can be treated with endoscopic mucosal resection. Patients with T2 cancers (invading into the submucosa) usually undergo primary esophagectomy. More advanced disease requires neoadjuvant chemotherapy and radiation treatment, which can then be followed by surgical resection in patients who have a good clinical response.

It is controversial as to whether there is an improvement in survival for esophageal adenocarcinoma, but endoscopic surveillance is commonly done in the United States for people with Barrett esophagus. Patients with dysplasia undergo more frequent screening endoscopies. The goal is to identify and treat precursor lesions and early cancers.

The Stomach

ANATOMY

The stomach arises as a dilatation of the embryonic foregut. In adult life, it assumes a J configuration with its convexity (the greater curvature) extending leftward from the GE junction. The concave aspect (lesser curvature) extends from the GE junction to the right. The whole stomach is covered by peritoneum; the omentum extends downward from the greater curvature.

The stomach is commonly divided into four regions: the cardia, fundus, body (corpus) and antrum (Fig. 19-12A,B). The **cardia** separates the esophagus from the rest of the stomach; in many ways it mirrors more the problems of the distal esophagus than of the rest of the stomach. Its exact proximal and distal limits are controversial. Most would consider its distal margin to be where gastric rugal folds begin. The proximal margin is more difficult to define as columnar metaplasia in the distal esophagus may blur the border between esophagus and stomach. The cardia is said

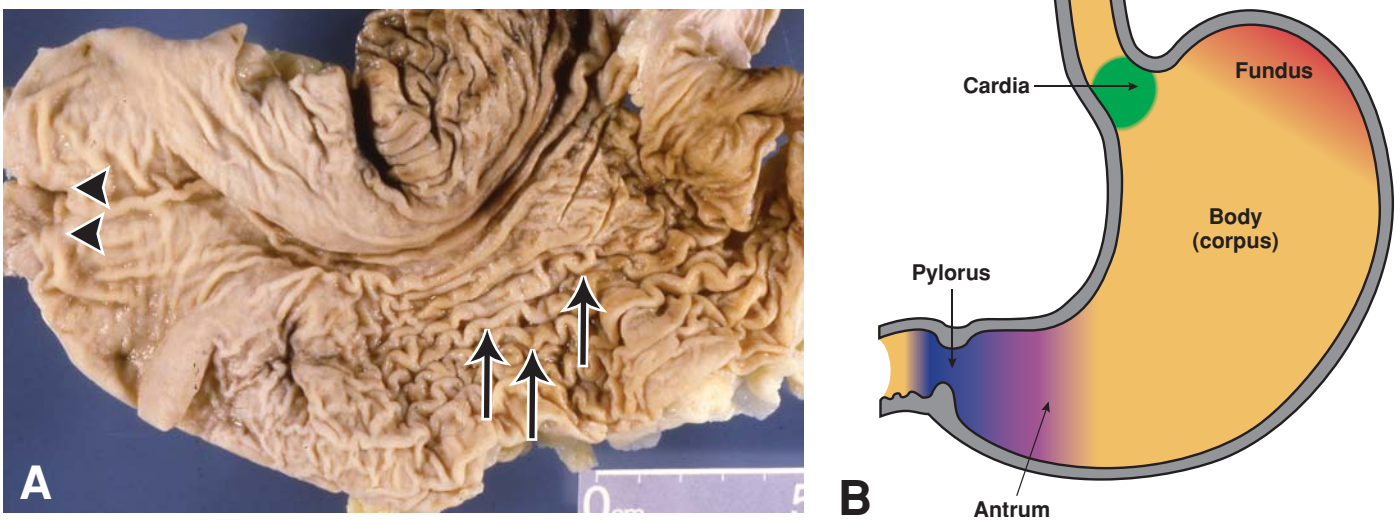

FIGURE 19-12. A. A normal stomach from an autopsy. The rugal folds are readily seen in the body (*arrows*). The sweep of the lesser curvature leads into the V-shaped antrum (*arrowheads*). **B.** Anatomic regions of the stomach.

to range between 0.5 and 3 cm in length, although some concern has been raised that the longer cardias (over 2 cm) may represent metaplasia responding to reflux.

The **fundus** and **body** are basically identical except that the fundus is that part of the stomach which bulges above the GE junction. Acid and intrinsic factor are produced in these regions. The boundary between the body and antrum is usually taken to be the incisura angularis, a notch in the lesser curvature.

The **antrum** is the distal stomach, ending in the duodenum, from which it is separated by the pyloric sphincter. The hormone gastrin is made here, eliciting acid production in the gastric body.

In addition to the inner circular and outer longitudinal layers of the muscularis propria seen elsewhere in the gut, there is an oblique layer that aids in the mixing necessary in early phases of digestion.

The histology of the stomach is quite distinct in the cardia, fundus/body and antrum. However, the top mucosal layer of the entire stomach is a characteristic foveolar epithelium (Fig. 19-13A); the term "foveolar" refers to the shallow pits covering the entire gastric surface. The neutral pink mucin in these epithelial cells is periodic acid–Schiff (PAS) positive and Alcian blue negative; it provides a safe haven for *Helicobacter pylori.* The foveolae are separated from underlying glands by a small neck region. This is important since it is the proliferative region and differs from the rest of the gastrointestinal tract where cell division occurs in the base of the glands.

In the glands underlying the foveolae, the main regions of the stomach take on their characteristic features.

The glands of the cardia (Fig. 19-13B) are loosely packed and lined by cells containing neutral mucous. They somewhat resemble the antral glands but do not produce gastrin cells. They often show a slight degree of cystic dilatation.

The gastric fundus and body glands (Fig. 19-13C) are where the acid-producing parietal cells (Fig. 19-13D) are located. These cells also produce intrinsic factor. They are large and polygonal, with slightly granular pink cytoplasm. Deeply in these glands, chief cells predominate; they have a granular blue cytoplasm marking production of pepsinogen. The deepest aspect of the glands is also home to neuroendocrine cells: the enterochromaffin-like (ECL) cells.

The antral (or pyloric) mucosa (Fig. 19-13E) also contains loosely packed glands lined by cells that make neutral mucous. However, it is by the neuroendocrine cells that the antrum differs from the cardia. Gastrin-producing G cells (Fig. 19-13F) are numerous here. There are also enterochromaffin cells (ECs) that produce serotonin and some somatostatin-producing D cells.

The cardia, body and antrum are distinct in their anatomy and function. Thus, it is important to keep track of landmarks during endoscopic examination and biopsy of

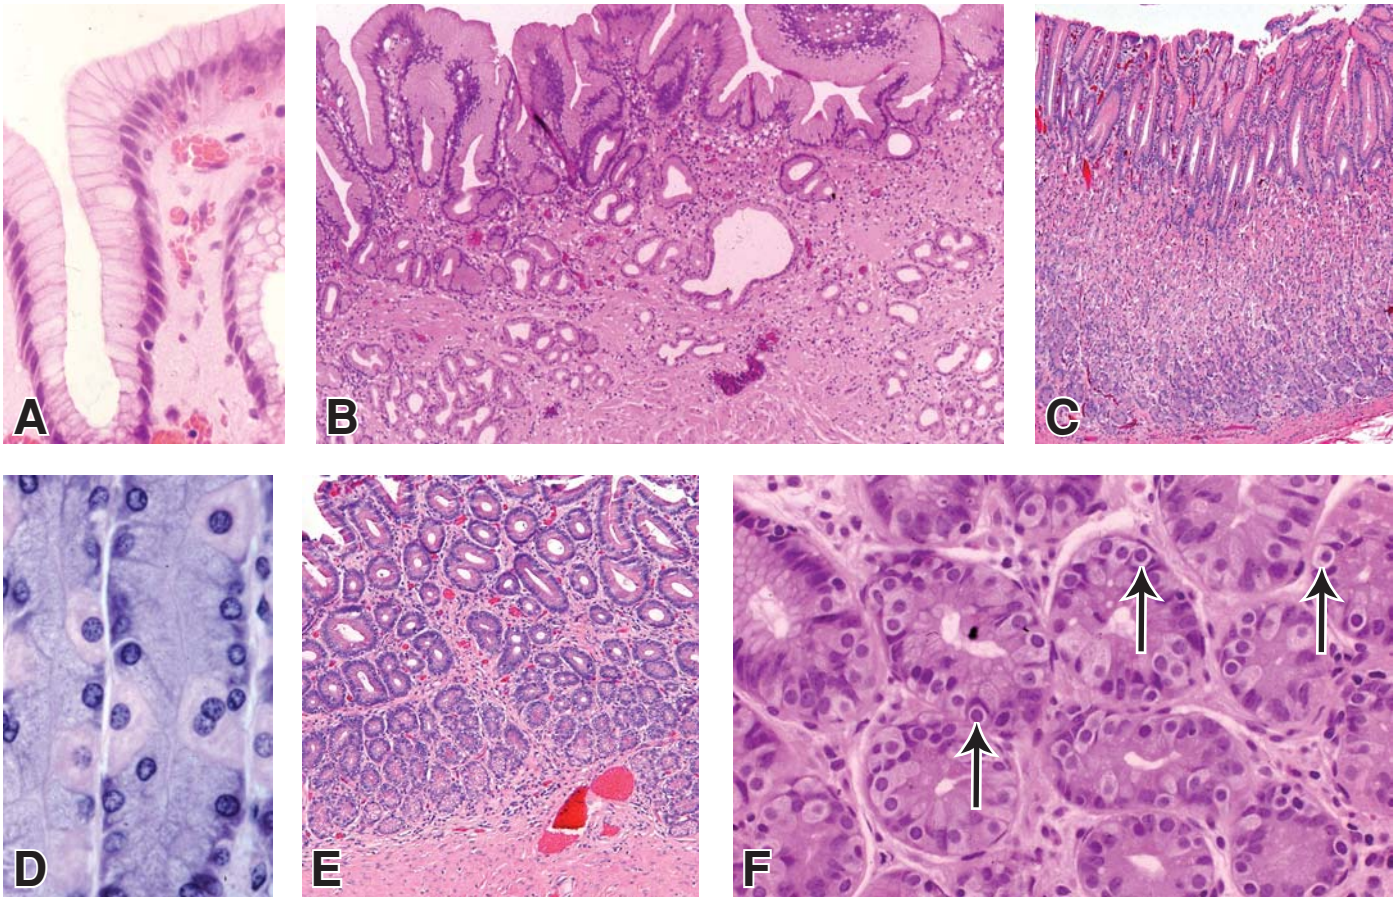

FIGURE 19-13. Histology of the stomach. A. The **foveolar epithelium. B.** The gastric **cardia**. **C.** The gastric **body**. **D. Parietal** cells (pink) and **chief cells** (granular blue). **E.** The gastric **antrum. F. Gastrin**-producing cells in antrum; they resemble fried eggs (*arrows*). See text for further description.

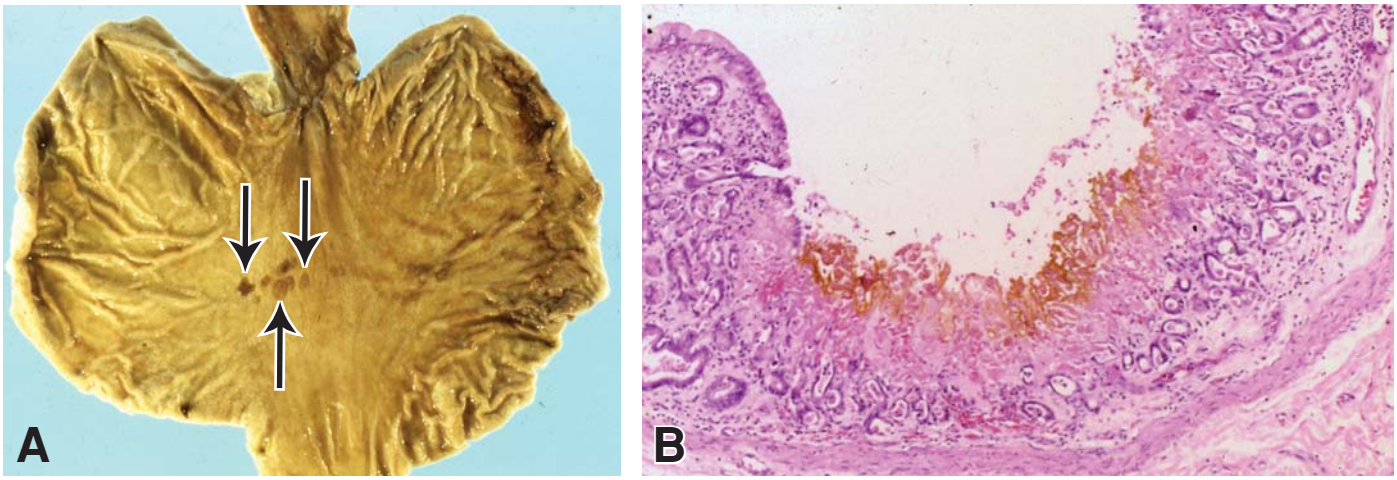

FIGURE 19-14. **A.** Several shallow erosions/ulcers are scattered in the gastric body (*arrows*). **B.** There is an area of erosion with hemorrhage.

the stomach. It should also be noted that the transition from each of these areas to the other is not very sharp and they may intermingle somewhat in areas of transition.

CONGENITAL DISORDERS

Congenital disorders of the stomach are uncommon. Of these, the most common is **congenital pyloric stenosis**. This condition presents with projectile vomiting during the first 6 months of life. It is more common in boys than girls and may have a genetic basis.

ACUTE GASTRITIS

Acute Gastritis/Acute Gastric Ulceration

These conditions usually occur in specific clinical situations: severe physiologic stress such as trauma, severe burns, increased intracranial pressure or sepsis. At times, acute gastritis may be related to back-diffusion of hydrogen ions related to ingestion of alcohol or aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs). Superficial ulcers related to burns are called Curling ulcers; if such ulcers are related to increased intracranial pressure, they are Cushing ulcers. Unlike chronic peptic ulcers, which are usually in the antrum or the junction of the body and antrum, these ulcers are usually shallow and multiple and found in the acid-producing mucosa of the body (Fig. 19-14A,B). The gastritis itself (Fig. 19-15) is usually hemorrhagic (acute hemorrhagic gastritis) but can show a significant fibroinflammatory reaction (acute erosive gastritis). These processes can be life-threatening and patients with predisposing conditions may be treated prophylactically.

CHRONIC GASTRITIS

Chronic gastritis is an increase in lamina propria inflammatory cells and is very common worldwide. It may be asymptomatic, or it may present with vague dyspeptic symptoms. Endoscopic examination is less accurate in assessing gastritis than similar examinations are for esophagitis and colitis. In part for this reason, and partly because of the heterogeneity of this disorder, there has been a profusion of classifications of gastritis and subsequent variable nomenclature.

Helicobacter pylori Infection Is the Major Cause of Gastritis Worldwide

Helicobacter are short rod-shaped bacteria with a unique habitat: the surface of foveolar cells. The presence and significance of these bacteria went unnoticed for many years, until the astute observations of Warren and Marshall in 1984, for which they were awarded the Nobel Prize, explained the mystery of chronic gastritis. In some countries, over 80% of

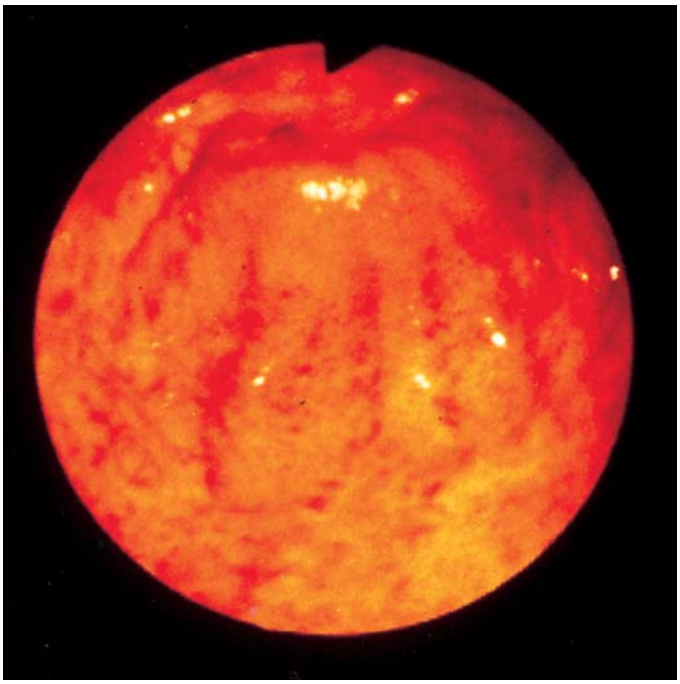

FIGURE 19-15. Endoscopic view of erosive gastritis from a patient who had ingested aspirin. Note the hemorrhagic lesions.

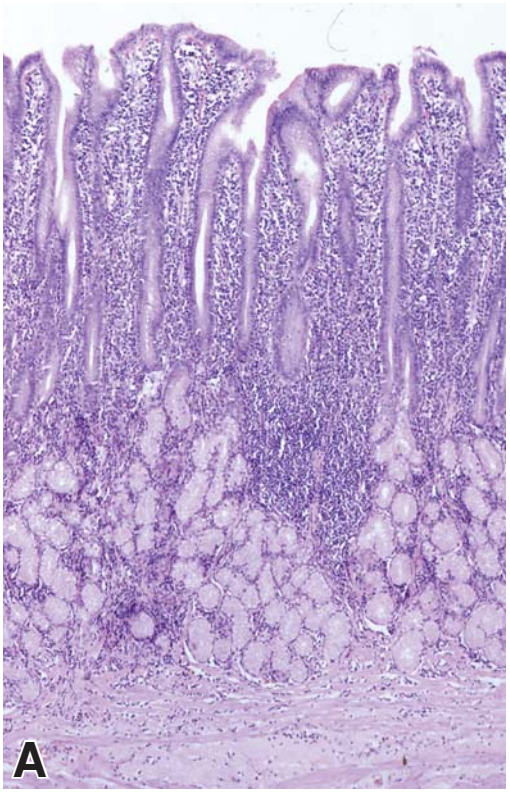
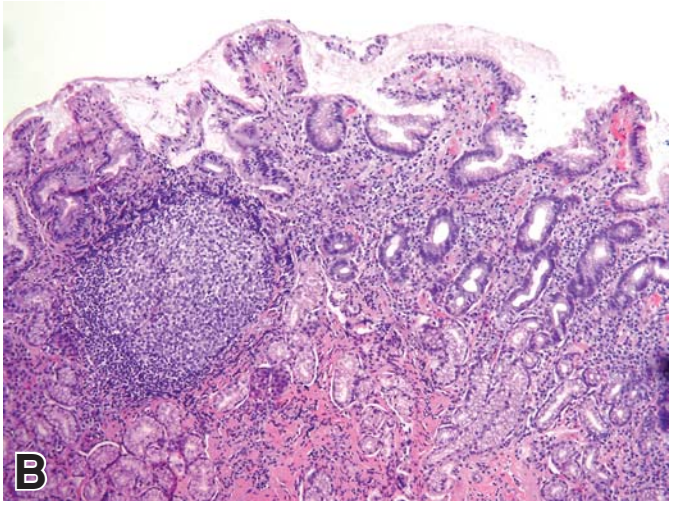
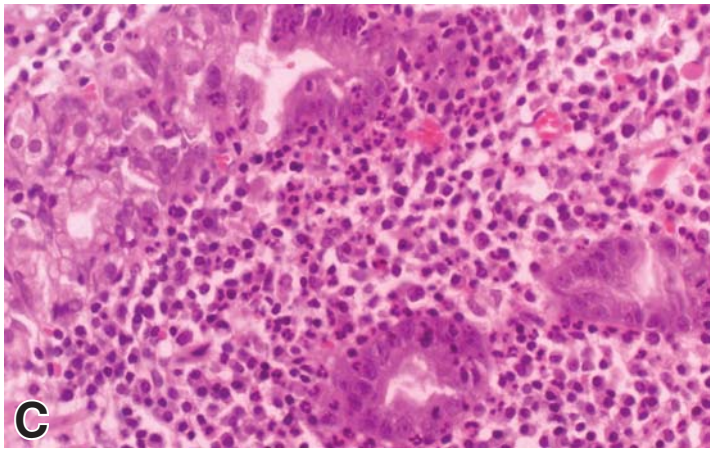
people are affected. In the United States, such percentages vary from 4% to 30%. It should be noted that over the past 30 years, recognition and subsequent treatment of *Helicobacter pylori* gastritis has led to a continuing reduction of these percentages.

PATHOLOGY: *Helicobacter* gastritis tends to be localized. In most cases, the antrum is mostly affected. But with advancing time, or with therapy with proton pump inhibitors (PPIs), the more proximal stomach may become involved. Inflammation in involved areas starts in the superficial lamina propria (Fig. 19-16A), since the organisms are in a thin layer of mucus adherent to the surface foveolar cells. *Helicobacter* do not invade. The bacteria are not found in the absence of foveolar cells or in association with intestinal-type epithelium. Thus, areas of intestinal metaplasia are devoid of organisms. Lymphoid aggregates are often present in *Helicobacter* gastritis (Fig. 19-16B). The inflammatory infiltrate is largely a mixture of lymphocytes and plasma cells, although neutrophils are often present. They can accumulate in foveolae to form "pit abscesses" (Fig. 19-16C). The presence of such neutrophils does not denote acute gastritis, which is an entirely different process (see above). Rather, neutrophils indicate an active chronic gastritis, with ongoing flares of inflammation in an underlying chronic gastritis.

Helicobacter (Fig. 19-16D) are small curvilinear bacilli found in the mucin-covered surface of foveolar cells. With a trained







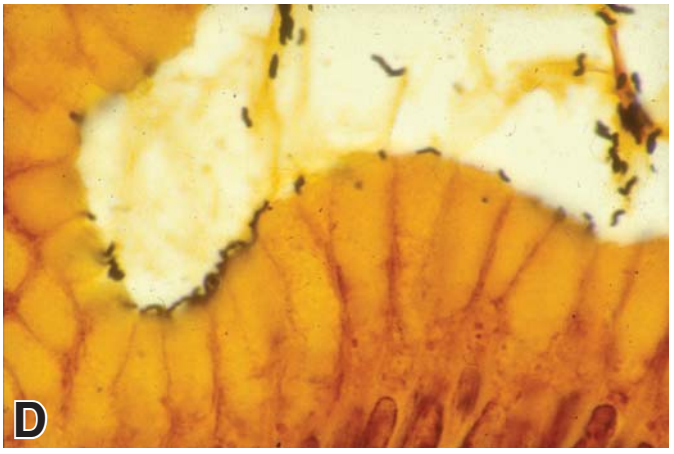


FIGURE 19-16. **A.** There is a superficial dense lymphoplasmacytic infiltrate in the lamina propria. **B.** A lymphoid aggregate; when present, these are highly suggestive of *Helicobacter.* **C.** Neutrophils are scattered in the lamina propria infiltrate and can penetrate the glandular epithelium. **D.** The Warthin-Starry stain highlights the small curvilinear organisms at the foveolar surface.

eye (and mind), they are usually visible with hematoxylin and eosin stains, but several special stains enhance their recognition: silver impregnation, as in the Warthin-Starry stain, is most often used; immunostaining is also effective.

Gastritis Caused by Non–*Helicobacter pylori Helicobacter* Species

Several other species of *Helicobacter,* often collectively called *Helicobacter heilmannii,* can cause human disease. These species are commonly found in the stomachs of domestic animals such as cats, dogs and pigs. They are longer and thicker than *H. pylori* and have several tight spirals. Gastritis caused by these organisms is quite similar to that seen with *H. pylori.* Like *H. pylori,* they produce urease and respond to the same treatment regimens.

Significance of *Helicobacter* Infections

The most common serious problem related to chronic *Helicobacter* gastritis is peptic ulcer disease. Duodenal ulcers occur in 10%–20% of patients with antral-predominant gastritis. This is the main pattern in Western countries, where for years duodenal ulcer disease had been epidemic. Such ulcer disease was often refractory to medical therapy, resulting in a large number of gastrectomies. Recognition of the role of *Helicobacter* has greatly lessened the incidence of duodenal ulcers and their complications. The disease is now largely treated medically and surgical intervention is rarely necessary.

H. pylori infection involving the gastric body increases the risk for gastric cancer. The magnitude of this risk is difficult to ascertain as the involved stomach often shows intestinal metaplasia and *H. pylori* may no longer be readily identifiable. Still, it is widely held that *H. pylori* infection is the most common known cause of gastric cancer. Countries with a high incidence of *H. pylori* carriage have a high gastric cancer risk.

Active Chronic Gastritis without Identified *Helicobacter*

In many cases, this likely represents prior therapy with antibiotics and PPIs, which partly or totally eradicated the organisms. Other infections (e.g., CMV), or adverse drug effects, may also be responsible. Similar gastric inflammation occurs with some frequency in patients with idiopathic inflammatory bowel disease, particularly Crohn disease.

Causes of Chronic Gastritis with Atrophy and Metaplasia Are Controversial

Save for that associated with pernicious anemia (see below), the etiology of chronic gastritis (Fig. 19-17) with atrophy (loss of glands) and metaplasia is uncertain. Still, this condition is felt to predispose to gastric carcinoma. It occurs in multiple scattered foci, though the antrum is usually most affected. At least some cases probably result from long-standing *Helicobacter* infection, and the possibility of other as yet unidentified exposures has led to the use of the noncommittal term "environmental."

Identification of atrophy is difficult in less severe cases. Intestinal metaplasia may be complete (faithfully replicating all aspects of small intestine epithelium) or incomplete. The latter is felt to be the major type predisposing to carcinoma. Pyloric (pseudopyloric) metaplasia is more difficult to recognize; it mimics the glands of the antrum but lacks G cells. It is recognized by its presence outside the antral area.

FIGURE 19-17. The inflammatory infiltrate fills the lamin propria (*arrows*). There is loss of gland volume, and a patch of intestinal metaplasia (*arrows*) has replaced the gastric epithelium.

Autoimmune Gastritis Is Limited to the Gastric Antrum

Autoimmune gastritis is often unrecognized, and its overall significance is often not appreciated. The target of the autoimmune reaction is gastric parietal cells, hence its limitation to the gastric antrum. Without parietal cells, the stomach does not produce acid, and clinical achlorhydria results. Also lost is the other product of the parietal cells, intrinsic factor, which mediates absorption of vitamin B_{12} in the distal small intestine.

Immunologically mediated destruction of parietal cells leads to production of antiparietal cell and anti-intrinsic factor antibodies. These antibodies are the basis of diagnostically useful serum tests. With careful sampling from the proximal (body) and distal (antrum) stomach, the diagnosis can be established long before loss of B_{12} results in clinical anemia, known as pernicious anemia (see Chapter 26). Unlike other forms of chronic gastritis, the antrum is spared from inflammation and metaplasia. Hyperplasia of antral G cells occurs because there is no feedback inhibition, as there is no acid production. These G cells consequently produce large amounts of gastrin, which exerts a trophic effect on neuroendocrine ECL cells of the proximal stomach. Hyperplasia of these ECL cells predisposes to development of neoplasms (neuroendocrine tumors or gastric carcinoids; see below).

These conditions lead to a characteristic histology of autoimmune gastritis (Fig. 19-18A,B). Parietal cells are gone and there is significant mononuclear inflammation and intestinal and pseudopyloric metaplasia. In time, neuroendocrine hyperplasia may become prominent. Autoimmune gastritis indicates a significant predisposition to other autoimmune diseases (see Chapter 11) in both the patient and family members. These diseases include type I diabetes, hypothyroidism and Addison disease.

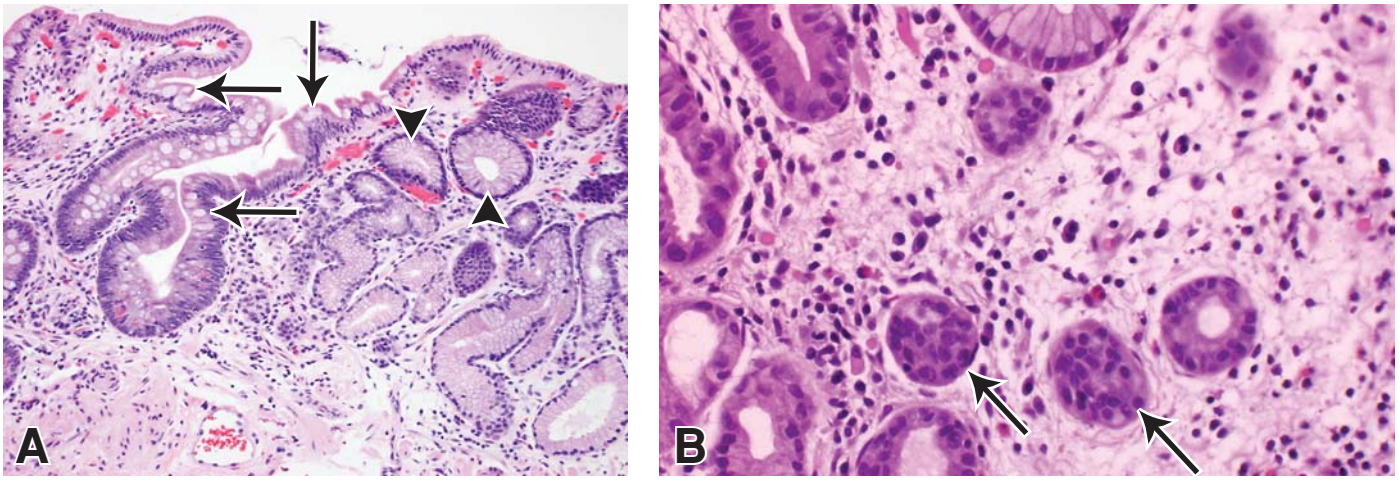

FIGURE 19-18. **A.** The gastric body is atrophic and devoid of parietal cells. There is intestinal metaplasia (goblet cells, *arrows*) and pseudopyloric metaplasia (*arrowhead*). **B.** Elsewhere in the body there are micronodules composed of enterochromaffin-like (ECL) cells (*arrows*). Note: these biopsies were from the stomach of one of the authors (FAM).

Lymphocytic Gastritis

As the name suggests, this process is characterized by increased numbers of lymphocytes. These occur both in the lamina propria and, importantly, in the surface epithelium (Fig. 19-19). A characteristic "varioliform" endoscopic appearance describes the mucosal lesion's resemblance to poxvirus infection. Several clinical associations account for the importance of this entity. The most important of these is its relationship to celiac disease. Some 10% of patients with celiac disease have lymphocytic gastritis. Diagnostic confusion with *Helicobacter* gastritis may occur as occasional patients with *Helicobacter* have increased lymphocytes at the gastric surface; organisms are usually sparse in these cases, and serology may be needed to confirm this relationship. Lymphocytic gastritis may also be seen together with Menetrier disease (see below).

Focal Enhanced Gastritis

In this process, there are foci of inflammation centered on small portions or groups of glands, which are surrounded by normal mucosa. The inflammation consists of a mixture of lymphocytes and histiocytes, often admixed with neutrophils. Some reports suggest a close relationship to Crohn disease or ulcerative colitis, but this pattern can occur in patients without idiopathic inflammatory bowel disease. Still, its presence, particularly in children, should raise awareness of the possibility of Crohn disease.

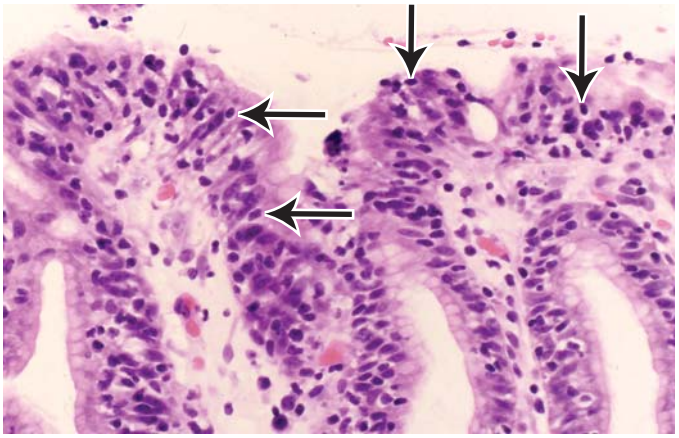

FIGURE 19-19. There is a dense infiltrate of T lymphocytes (*arrows*) in the surface, and here extending into the rest of the gland.

Portal Hypertensive Gastropathy

This lesion is seen in patients with portal hypertension, typically from cirrhosis. A typical endoscopic appearance ("mosaic" or "snakeskin") is due to abnormal dilatation of submucosal vasculature. As these vessels are not usually included in endoscopic biopsies, mucosal biopsies often are bland, belying the endoscopic appearance.

Granulomas in Gastric Mucosa

There are multiple causes of gastric granulomas. Finding granulomas in the gastric mucosa should prompt a search for responsible processes (e.g., sarcoidosis or Crohn disease). Typical findings elsewhere (lung, ileum, etc.) are necessary to establish such diagnoses. Infections (fungal and mycobacterial) must also be excluded.

Reactive (Chemical) Gastropathy Is Most Often Due to NSAIDs

While it is clear that exposure to NSAIDs or bile can alter the gastric mucosa, it is not clear when these changes represent a clinically significant condition. These agents lead to hyperplasia of foveolar cells, resulting in loss of the normal nearly flat surface. Resulting short abortive villus-like structures impart a villiform appearance. These structures may become irregular, resulting in a "corkscrew" appearance (Fig. 19-20A). Additional changes may include reactive hyperplasia of foveolar cells and proliferation of lamina propria smooth muscle (Fig. 19-20B). Inflammation is infrequent unless there has been an ulcer or erosion with a subsequent localized inflammatory response.

Much confusion and controversy continue to surround this entity. This is not surprising, given the facts that the

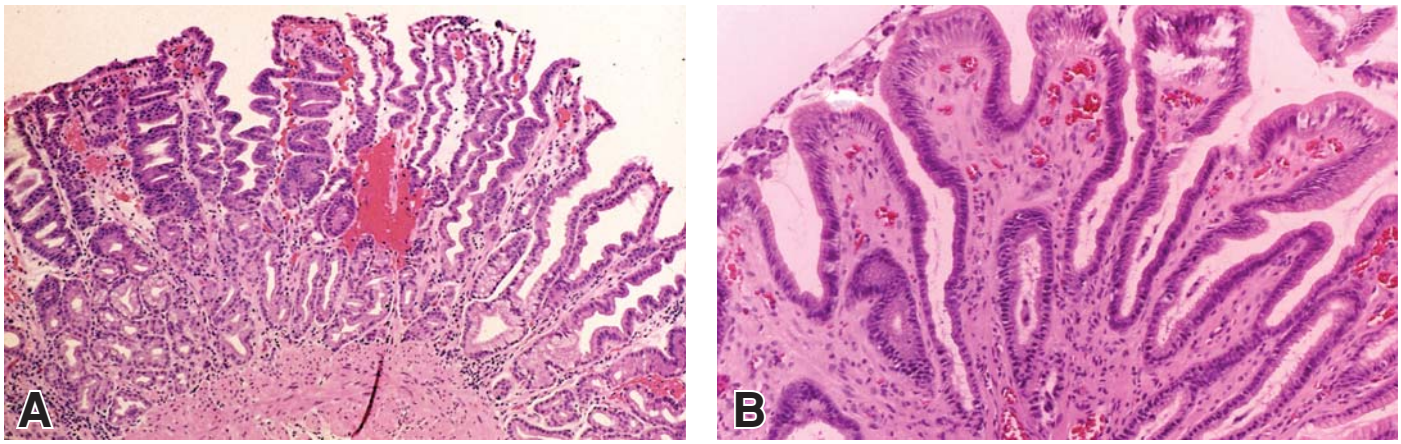

FIGURE 19-20. A. The corkscrew contour of the antral glands deviates from normal architecture in this patient with bile reflux. **B.** There is increased smooth muscle in the villiform structures in the antrum of a patient with chronic use of nonsteroidal anti-inflammatory drugs (NSAIDs).

symptoms of gastric mucosal disease are usually vague and that endoscopic appearances are neither specific nor particularly sensitive. A practical approach is helpful. A patient with dyspepsia or ulcer who shows these changes instead of the previously described changes of *Helicobacter* likely has a clinically significant condition, and any NSAID ingestion should be curtailed.

Drug Effects

The most common drug effect is caused by PPIs, which is not surprising given their widespread use. In the gastric body, glands lined by parietal cells show luminal dilatation and some protrusion into these lumens by parietal cells' cytoplasm. Many patients develop fundic gland polyps (see below). Since acid production is blocked, antral G cells visibly multiply in compensation and produce excess gastrin. This causes ECL cell proliferation in the gastric body, though less so than in autoimmune gastritis.

Reactions to NSAIDs are also very common and may result in the reactive or chemical gastropathy described above. Ulceration may occur.

Iron sulfate tablets may cause surface encrustation by the mineral and its congeners. Colchicine and mycophenolate may produce changes mimicking gastritis.

PEPTIC ULCER DISEASE

"Peptic ulcer disease" is focal destruction of the mucosa of the stomach and small intestine, mainly the proximal duodenum. It is caused by gastric secretions. Duodenal ulcers have declined greatly in frequency over the past 30 years.

Peptic ulceration may occur as far proximally as the esophagus and as far distally as the Meckel diverticulum with gastric heterotopia, but the disease mostly affects the distal stomach and proximal duodenum. Many clinical and epidemiologic features distinguish gastric from duodenal ulcers; the common factors that unite them are gastric hydrochloric acid secretion and *H. pylori* infection.

EPIDEMIOLOGY: Peptic ulcers may occur at any age (including infancy), but the peak incidence has progressively changed, so that it is now between age 30 and 60. Gastric ulcers usually afflict the middle-aged and elderly and affect both sexes equally. Duodenal ulcers are more common in males.

Racial differences have been postulated, but most data suggest that all ethnic groups are susceptible in an urban Western setting. Surveys in the United States and Great Britain show a trend toward an inverse relation between duodenal ulcers and socioeconomic status and education.

ETIOLOGIC FACTORS: No single agent seems to be responsible, although many etiologies have been proffered.

H. PYLORI: *H. pylori* is isolated from the gastric antrum of virtually all patients with duodenal ulcers. The converse is not true; that is, only a small minority of those carrying the bacterium have duodenal ulcer disease. Thus, *H. pylori* infection may be necessary, but is not sufficient, for peptic duodenal ulcers to develop. Such ulcers heal more quickly after treatment for *H. pylori* infection, and recur less.

Just how *H. pylori* infection predisposes to duodenal ulcers is not completely clear, but several mechanisms have been proposed. Cytokines produced by inflammatory cells in response to the infection stimulate gastrin release and suppress somatostatin secretion. Interleukin-1β (IL-1β), an acid inhibitor, is a key mediator of inflammation in *H. pylori*–infected gastric mucosa. These effects, plus release of histamine metabolites from the organism itself, may stimulate basal gastric acid secretion. In addition, luminal cytokines from the stomach may enter and injure duodenal epithelium.

H. pylori infection may also block inhibitory signals from the antrum to G cells and the parietal cell region, thus increasing gastrin release and impairing inhibition of gastric acid secretion. Such an effect might increase acid load in the duodenum, contributing to duodenal ulceration. Acidification of the duodenal bulb leads to islands of metaplastic gastric mucosa in the duodenum in many patients with peptic ulcers. Such gastric epithelium in the duodenum is sometimes colonized with *H. pylori,* like the gastric mucosa, and infection of the metaplastic epithelium by *H. pylori* may render the mucosa more susceptible to peptic injury (Fig. 19-21).

H. pylori infection is probably also important in the pathogenesis of gastric ulcers, because the organism causes most of the chronic gastritis that underlies this disease. About 75% of patients with gastric ulcers harbor *H. pylori.* The other 25%

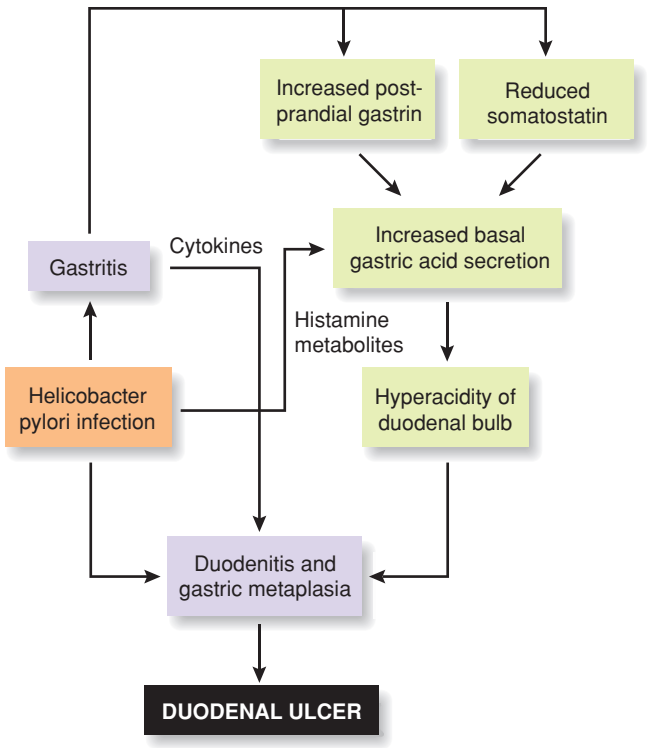

FIGURE 19-21. Possible mechanisms in the pathogenesis of duodenal ulcer disease associated with *Helicobacter pylori* infection.

of cases may reflect the influences of other types of chronic gastritis. The gastric and duodenal factors that have been implicated as possible mechanisms in the pathogenesis of duodenal ulcers are summarized in Fig. 19-22.

HCl SECRETION: Hyperacidity due to increased hydrochloric acid secretion is necessary for peptic ulcers to form and persist in the stomach and duodenum. This is evidenced principally by the following: (1) all patients with duodenal ulcers and almost all with gastric ulcers are gastric acid secretors; (2) experimental ulcer production in animals requires acid; (3) hypersecretion of acid is present in many, but not all, patients with duodenal ulcers (there is no evidence that acid overproduction alone explains duodenal ulceration); and (4) surgical and medical treatment that reduces acid production results in the healing of peptic ulcers. Gastric secretion of pepsin, which may also play a role in peptic ulceration, parallels that of hydrochloric acid.

DIET: Despite the folk wisdom that spicy food and caffeine are ulcerogenic, there is little evidence that any food or beverage, including coffee and alcohol, leads to the development or persistence of peptic ulcers.

DRUGS: Aspirin is an important contributor to duodenal, and especially gastric, ulcers. Other nonsteroidal anti-inflammatory agents and analgesics have been incriminated in peptic ulcerogenesis. Prolonged treatment with high doses of corticosteroids may also increase the risk of peptic ulceration slightly.

CIGARETTE SMOKING: Smoking is a definite risk factor for duodenal and gastric ulcers, particularly gastric ulcers.

GENETIC FACTORS: First-degree relatives of people with duodenal or gastric ulcers have a 3-fold higher risk of developing an ulcer—but only at the same site. Monozygotic twins show much higher (50%) concordance for these ulcers than do dizygotic twins, but this figure also indicates that environmental factors must also be involved.

The role of genetic factors is further supported by the fact that blood-group antigens correlate with peptic ulcer disease. Duodenal ulcers occur 30% more often in people with type O blood than in those with other types. This does not hold for gastric ulcers. People who do not secrete blood-group antigens in saliva or gastric juice have 50% higher risk of duodenal ulcers. Those who are both type O and nonsecretors (10% of white people) have a 2.5-fold increase in duodenal ulcers.

Pepsinogen I is secreted by gastric chief and mucous neck cells and appears in gastric juice, blood and urine. Serum levels of this proenzyme correlate with the capacity for gastric acid secretion and reflect parietal cell mass. Someone with high blood pepsinogen I levels has 5 times the normal risk of developing a duodenal ulcer. Hyperpepsinogenemia has been attributed to autosomal dominant inheritance and may reflect an inherited tendency to increased parietal cell mass. Half of children of ulcer patients with hyperpepsinogenemia have hyperpepsinogenemia themselves.

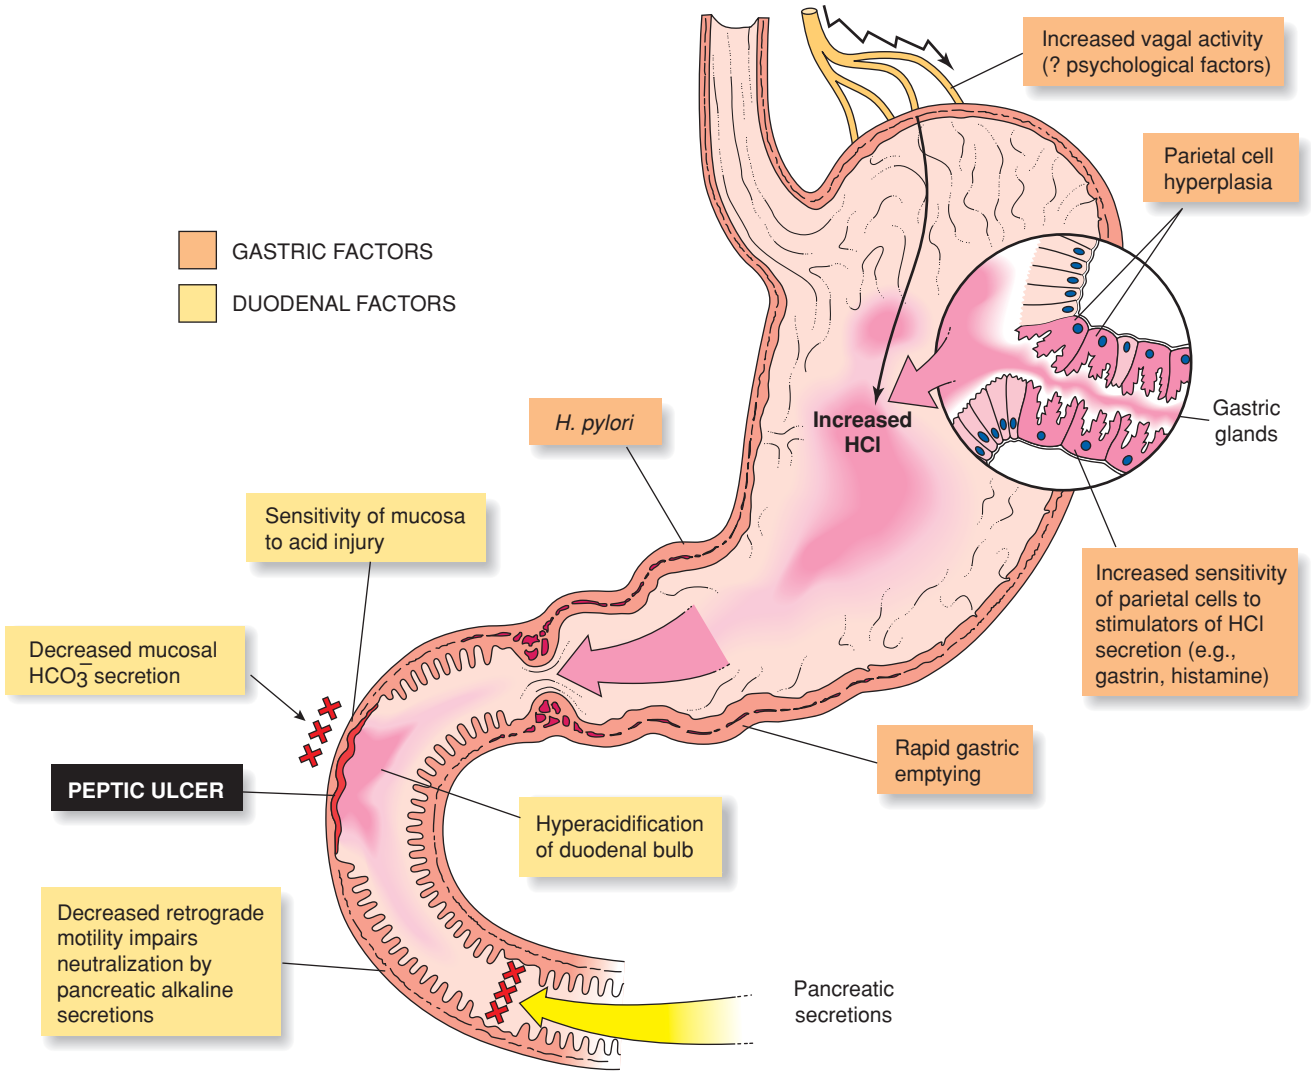
Familial tendencies for other features are reported in ulcer patients. Many such patients have normal pepsinogen I levels and still show familial aggregation. Family clustering of duodenal ulcers and rapid gastric emptying have been noted, as has familial hyperfunction of antral G cells. Patients with a childhood duodenal ulcer are much more likely to have a family history of ulcers than people in whom the disease begins when they are adults.

PATHOPHYSIOLOGY:

DUODENAL ULCERS: Maximal capacity for gastric acid production is a function of total parietal cell mass. Patients with duodenal ulcers may have up to double the normal parietal cell mass and maximal acid secretion. However, there is a large overlap with normal values, and only one third of ulcer patients secrete excess acid. Increased chief cell mass often accompanies increased parietal cells, reflecting the prevalence of hyperpepsinogenemia in patients with ulcers.

Food-stimulated gastric acid secretion is increased in magnitude and duration in people with duodenal ulcers, but here, too, there is significant overlap with normal values. This may involve, at least in part, altered G-cell responses to meals. Such patients show postprandial hypergastrinemia and increased antral G cells. Most people with duodenal ulcers, however, show no G-cell hyperfunction. Acid secretion in people with duodenal ulcers may also be more sensitive than normal to gastric secretagogues such as gastrin, possibly owing to increased vagal tone or increased affinity of parietal cells for gastrin. Brisk secretion of acid after a meal may reflect increased vagal tone.

Patients with duodenal ulcers show accelerated gastric emptying. This might lead to excessive duodenal acidification. However, as with other factors, there is overlap with normal rates. Duodenal bulb acidification normally inhibits further gastric emptying, but not in most people with duodenal ulcers. In them, duodenal acidification leads to continued, rather than delayed, gastric emptying. Rapid gastric emptying may in some cases be an inherited trait.



GASTRIC FACTORS
DUODENAL FACTORS
Increased vagal activity (? psychological factors)
Parietal cell hyperplasia
Gastric glands
Increased HCl
H. pylori
Sensitivity of mucosa to acid injury
Decreased mucosal HCO_3^- secretion
PEPTIC ULCER
Increased sensitivity of parietal cells to stimulators of HCl secretion (e.g., gastrin, histamine)
Rapid gastric emptying
Hyperacidification of duodenal bulb
Decreased retrograde motility impairs neutralization by pancreatic alkaline secretions
Pancreatic secretions

FIGURE 19-22. Gastric and duodenal factors in the pathogenesis of duodenal peptic ulcers.

The pH of the duodenal bulb reflects a balance between delivery of gastric juice and its neutralization by biliary, pancreatic and duodenal secretions. Duodenal ulceration requires an acidic pH in the bulb. In ulcer patients, duodenal pH after a meal decreases to a lower level and remains depressed longer than in normal people. Such duodenal hyperacidity certainly reflects the gastric factors discussed above. The role of neutralizing factors, particularly bicarbonate secretion by the duodenal mucosa or by the pancreas in response to secretin, is uncertain.

Impaired mucosal defenses may also contribute to peptic ulceration. Factors such as prostaglandins may or may not protect the duodenum as they do the gastric mucosa (see above).

GASTRIC ULCERS: Gastric ulcers almost invariably arise in the setting of epithelial injury by *H. pylori* or chemical gastritis. Just how chronic gastritis predisposes to gastric ulceration is obscure. Most patients with gastric ulcers secrete less acid than do those with duodenal ulcers and even less than normal people. Factors implicated include (1) back-diffusion of acid into the mucosa, (2) decreased parietal cell mass and (3) abnormalities of parietal cells themselves. A few gastric ulcer patients produce excess acid. Their ulcers are usually near the pylorus and are considered variants of duodenal ulcers. Interestingly, intense gastric hypersecretion such as occurs in the Zollinger-Ellison syndrome (see below) is associated with severe ulceration of the duodenum and even the jejunum, but rarely of the stomach.

The concurrence of gastric ulcers and gastric hyposecretion implies that (1) the gastric mucosa may in some way be particularly sensitive to low concentrations of acid; (2) something other than acid may damage the mucosa (e.g., NSAIDs); or (3) the gastric mucosa may be exposed to potentially injurious agents for unusually long periods. As discussed above, the mucosal barrier to the action of acid and perhaps to other contents of the stomach may be impaired in some patients with gastric ulcers, although evidence is not conclusive. Bile reflux (particularly deoxycholic acid and lysolecithin) and pancreatic secretions may contribute to the development of gastric ulcers.

Diseases Associated with Peptic Ulcers

Duodenal ulcers occur 10 times more often in patients with cirrhosis than in others. End-stage renal disease with hemodialysis increases the risk of peptic ulceration. Patients with kidney transplants have a much higher incidence of peptic ulceration and its complications, such as bleeding and perforation. There is an increased frequency of peptic ulcers in people with multiple endocrine neoplasia type 1 (see Chapter 27).

Zollinger-Ellison syndrome causes severe peptic ulceration. It is characterized by gastric hypersecretion, caused by a gastric-producing islet cell adenoma of the pancreas. Almost one third of patients with this disease have peptic ulcers, and the incidence is even higher if they also have lung disease.

Peptic ulcers are also increased in people heterozygous for mutant α_1-antitrypsin. Long-standing pulmonary dysfunction significantly raises the risk of ulcers. One fourth of those with such disorders have peptic ulcer disease. Conversely, chronic lung disease is increased 2–3-fold in people with peptic ulcers.

PATHOLOGY: Most peptic ulcers arise in the lesser gastric curvature, in the antral and prepyloric regions and in the first part of the duodenum.

Gastric ulcers are usually single and smaller than 2 cm. Ulcers on the lesser curvature are often associated with chronic gastritis; those on the greater curvature are commonly related to NSAIDs. Edges tend to be sharply punched out, with overhanging margins. Deeply penetrating ulcers produce a serosal exudate that may cause the stomach to adhere to nearby structures. Scarring of ulcers in the prepyloric region may be severe enough to cause pyloric stenosis. Grossly, chronic peptic ulcers may resemble ulcerated gastric carcinomas. They differ from the latter by their tendency to produce radiating folds in the surrounding mucosa, their lack of a raised border and a "clean" (fibrin-covered)-appearing base (Fig. 19-23). Endoscopists must biopsy the edges and bed of gastric ulcers multiply, as ulcer centers tend to show only necrotic tissue.

Duodenal ulcers (Fig. 19-24) are ordinarily on the anterior or posterior wall of the first part of the duodenum, near the pylorus. They are usually solitary, but it is not uncommon to find paired ulcers on both walls, so-called "kissing ulcers."

FIGURE 19-23. Gastric ulcer. There is a characteristic sharp demarcation from the surrounding mucosa, which has prominent radiating folds. The base of the ulcer is covered with fibrin, giving it a gray color.

FIGURE 19-24. Duodenal ulcers. There are two sharply demarcated duodenal ulcers surrounded by inflamed duodenal mucosa. The gastroduodenal junction can be seen in the midportion of the photograph.

Gastric and duodenal ulcers are histologically similar (Fig. 19-25A,B). From the lumen inward, there are several layers: (1) a superficial zone of fibrinopurulent exudate, (2) necrotic tissue, (3) granulation tissue and (4) fibrotic tissue with variable degrees of chronic inflammation at the depth of the ulcer's base. Ulceration may penetrate muscle layers, interrupting them with scar tissue after healing. Blood vessels at the margins of the ulcer are often thrombosed. Mucosal margins tend to be slightly hyperplastic. With healing, mucosa grows over ulcerated areas as a single epithelial layer. Duodenal ulcers are usually accompanied by peptic duodenitis, with Brunner gland hyperplasia and gastric mucin cell metaplasia.

CLINICAL FEATURES: The symptoms of gastric and duodenal ulcers are generally not distinguishable by history or physical examination. Classic duodenal ulcers are characterized by epigastric pain 1–3 hours after a meal or that awakens a patient at night. Alkali and food relieve these symptoms. Dyspeptic symptoms often associated with gallbladder disease, such as fatty food intolerance, distention and belching, occur in half of patients with peptic ulcers.

The major complications of peptic ulcer disease are hemorrhage, obstruction and perforation with peritonitis. Of these, the most common is bleeding, which occurs in up to 20% of patients. It is often occult. If there are no other symptoms, it may manifest as iron-deficiency anemia or occult blood in stools. Massive life-threatening bleeding is a well-known complication of active peptic ulcers.

Perforation is a serious complication that occurs in 5% of patients. In 1/3 of these, there are no antecedent symptoms of a peptic ulcer. Duodenal ulcers perforate more often than do gastric ulcers, mostly on the anterior wall of the duodenum. As the anterior gastric and duodenal walls are undefended by contiguous tissue, perforations there are more likely to lead to generalized peritonitis and to air in the abdominal cavity, called **pneumoperitoneum**. Posterior gastric ulcers perforate into the lesser peritoneal sac, where inflammation may be contained. An ulcer that penetrates the

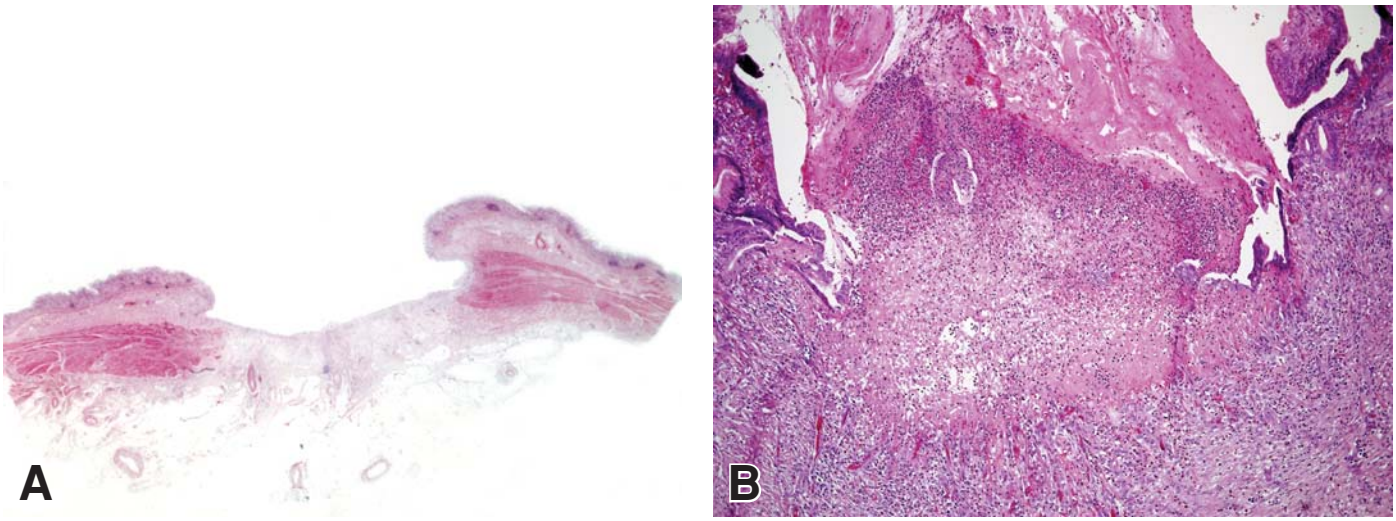


FIGURE 19-25. **A.** Gastric ulcer: The destructive nature of this lesion is shown by the loss of the underlying muscle in the muscularis propria with replacement by fibrous tissue. **B.** Classic appearance of peptic ulcer with superficial fibrin exudate over necrosis, followed by granulation tissue and fibrosis in the deep aspect.

pancreas, liver or greater omentum can cause severe intractable pain. Ulcers may also penetrate the biliary tract and fill it with air, a condition known as **pneumobilia**.

Perforation carries a high mortality rate, which is 10%–40% for gastric ulcers, 2–4 times more than for duodenal ulcers (10%). Perforations may be complicated by hemorrhage. Shock, abdominal distension and pain are common symptoms, but perforations are occasionally diagnosed for the first time at autopsy, particularly in institutionalized, elderly patients.

Pyloric obstruction occurs in up to 10% of ulcer patients, and peptic ulcer disease is its most common cause in adults. Narrowing with eventual obstruction of the pyloric lumen by an adjacent peptic ulcer may be caused by muscular spasm, edema, muscular hypertrophy or contraction of scar tissue, or, most commonly, a combination of these.

Gastric and duodenal ulcers may occur together in the same patient far more often than can be accounted for by chance alone. Patients with either one have a much greater risk of developing the other later.

ENLARGED RUGAL FOLDS USUALLY REFLECT MÉNÉTRIER OR ZOLLINGER-ELLISON DISEASES

In Ménétrier disease (Fig. 19-26), there is massive foveolar hyperplasia with no increase in underlying glands. This is due to overexpression of transforming growth factor-α (TGF-α) and may cause intramucosal cysts lined by foveolar epithelium. There is often adherent surface mucin or proteinaceous material. Lymphocytic gastritis may be present and may cause a varioliform appearance (see above). The process is more common in men. There is postprandial pain. Protein loss from the mucosa results in hypoalbuminemia and subsequent peripheral edema. Patients with Ménétrier disease have a predisposition to develop gastric carcinoma.

The other prominent condition causing enlarged rugal folds is due to a proliferation of parietal cells rather than foveolar cells (Zollinger-Ellison [Z-E] syndrome). The cause is gastrin production by a neuroendocrine tumor (gastrinoma). Most cases are sporadic, in which case the gastrinomas are more commonly duodenal than pancreatic. A minority of cases are related to multiple endocrine neoplasia syndrome type 1 (MEN1). Gastrinomas in Z-E patients may occur in the duodenum, pancreas or gastric antrum, and they may be multiple and exceedingly small. Rugal folds are enlarged owing to increased numbers of hypertrophied parietal cells; the rugae consequently have a characteristic bumpy appearance (Fig. 19-27). These patients have intractable peptic ulcer disease, with the ulcers often being multiple and in unusual locations.

BENIGN NEOPLASMS

Polyps are endoscopically or grossly identifiable elevations of the mucosa. In the stomach, unlike the colon, the vast majority are not true neoplasms.

FIGURE 19-26. **Menetrier disease.** The rugal folds are diffusely enlarged. They appear to be hemorrhagic because of the accompanying lymphocytic gastritis.

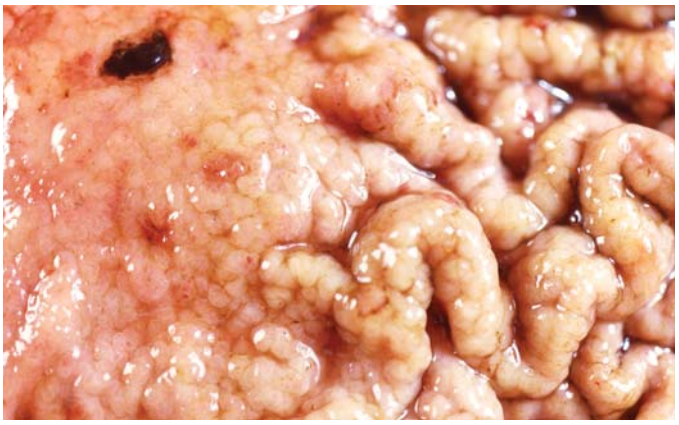

FIGURE 19-27. Zollinger Ellison syndrome. The rugal folds are convoluted and thickened. They appear bumpy owing to hyperplasia of the parietal cells occurring in groups.

Fundic Gland Polyps Occur Only in the Body and Fundus

They are mucosal elevations composed of cystically dilated glands lined by a mixture of parietal cells, chief cells and neutral mucous cells (Fig. 19-28A,B). They were first described in patients with familial adenomatous polyposis (FAP; see below); in affected patients, a myriad of such polyps carpet the proximal gastric mucosa. Rarely, fundic gland polyps in these patients show focal dysplasia. Far more common are isolated or small numbers of fundic polyps in patients taking PPIs.

The mechanism for their formation is unknown. Polyps related to PPI use appear to be innocuous. Because of the ever-increasing use of PPIs in recent years, fundic gland polyps are now the most common form of polyp seen in the stomach.

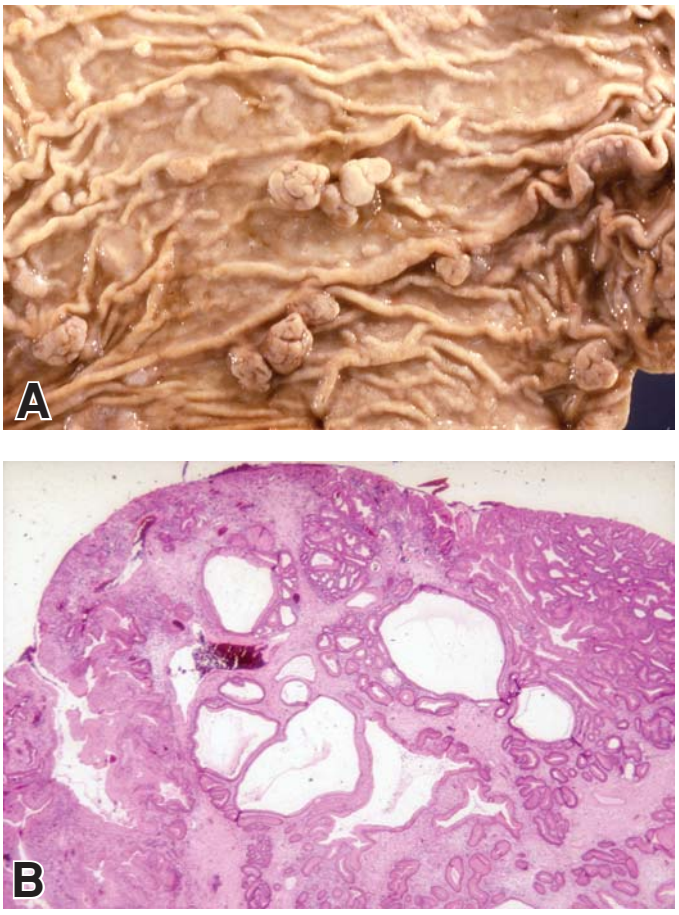

FIGURE 19-29. Hyperplastic polyp. A. Multiple mucosal elevations are seen in this resected stomach. **B.** The polyp is a mound of inflamed lamina propria. The cystically dilated glands are lined by foveolar epithelium.

Hyperplastic Polyps

This term is something of a misnomer, and these polyps have nothing but the name in common with polyps of the colon that bear the same name (see below). They occur in the setting of chronic gastritis or reactive gastropathy, may be single or multiple and are exaggerated focal responses to mucosal injury. Gastric hyperplastic polyps consist of hyperplastic foveolar cells sometimes forming small cysts, and an inflamed lamina propria (Fig. 19-29A,B). Reactive atypia may be present, particularly if there are surface erosions. They are sometimes called "hyperplastic/inflammatory" polyps, reflecting the manner in which they arose. Their malignant potential is that of the background mucosa from which they arose.

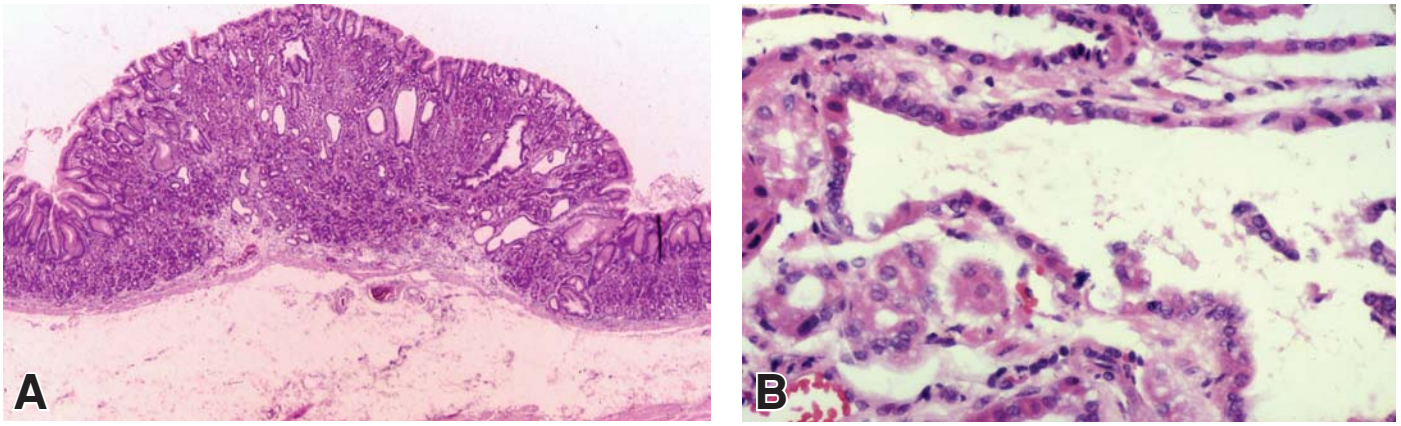

FIGURE 19-28. Fundic gland polyp. A. Low-power view shows the polyp as a slight elevation above the surrounding body-type mucosa. **B.** The cystically dilated glands contain parietal and chief cells.

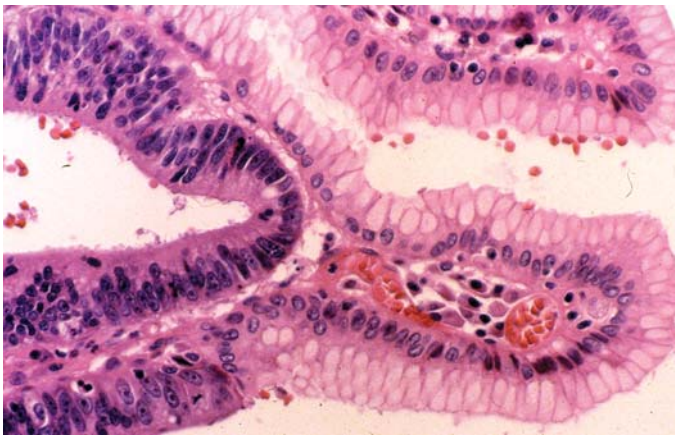

FIGURE 19-30. Gastric adenoma. There is sharp demarcation between the glandular epithelium with enlarged, hyperchromatic pencil-shaped nuclei (*left*) and adjacent normal foveolar epithelium (*right*).

Gastric Adenomas Are Relatively Uncommon

True adenomas of the stomach occur far less often than adenomas of the colon. They are usually single except in FAP, and can be of foveolar- or intestinal-type mucosa. By definition, dysplastic changes are present (Fig. 19-30). Intestinal-type adenomas are far more common and usually arise in stomachs with intestinal metaplasia. Nuclei tend to be enlarged, elongated and hyperchromatic, like their intestinal counterparts. In contrast, foveolar-type adenomas have no relationship to intestinal metaplasia; there does appear to be a relationship to FAP.

Although gastric adenomas can be related to gastric carcinoma, the very close relationship of adenoma to carcinoma seen in the colon is not present.

Gastric Polyposis Syndromes

Multiple gastric polyps can be seen in FAP and in several distinct syndromes. These include generalized familial juvenile polyposis (Fig. 19-31A–C) and Peutz-Jeghers, Cronkhite-Canada and Cowden syndromes. The polyps in these syndromes are usually bland in appearance, often somewhat resembling large hyperplastic polyps. Their true nature is established by identifying other features of the respective syndrome.

MALIGNANT NEOPLASMS

Adenocarcinoma Is the Most Common Gastric Malignancy

EPIDEMIOLOGY: There are striking geographical differences in its incidence. Gastric adenocarcinoma has declined markedly in incidence in Western countries over the past century. Many Eastern countries have a far higher incidence. There are a number of factors involved, but the most important appears to

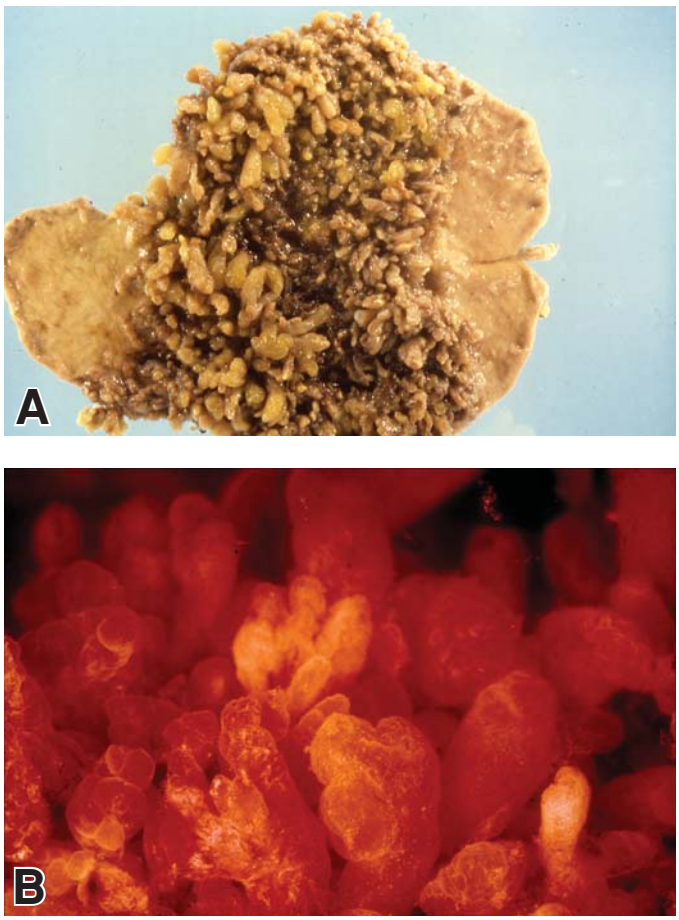

FIGURE 19-31. Familial juvenile polyposis. A, B. While the colon is the main target organ in this syndrome, the stomach can be involved and carpeted by polyps. **C.** Histologically, they are innocuous and somewhat resemble hyperplastic polyps.

reflect differences in the prevalence of *Helicobacter* and chronic gastritis. With improved recognition and treatment of *Helicobacter* infections, gaps between the West and East are narrowing. Other environmental factors also contribute, especially food. Diets high in smoked or pickled foods are associated with a higher cancer rate, while consumption of fresh vegetables and leafy greens has the opposite effect. Genetic factors also play a significant role, particularly with some types of gastric cancer.

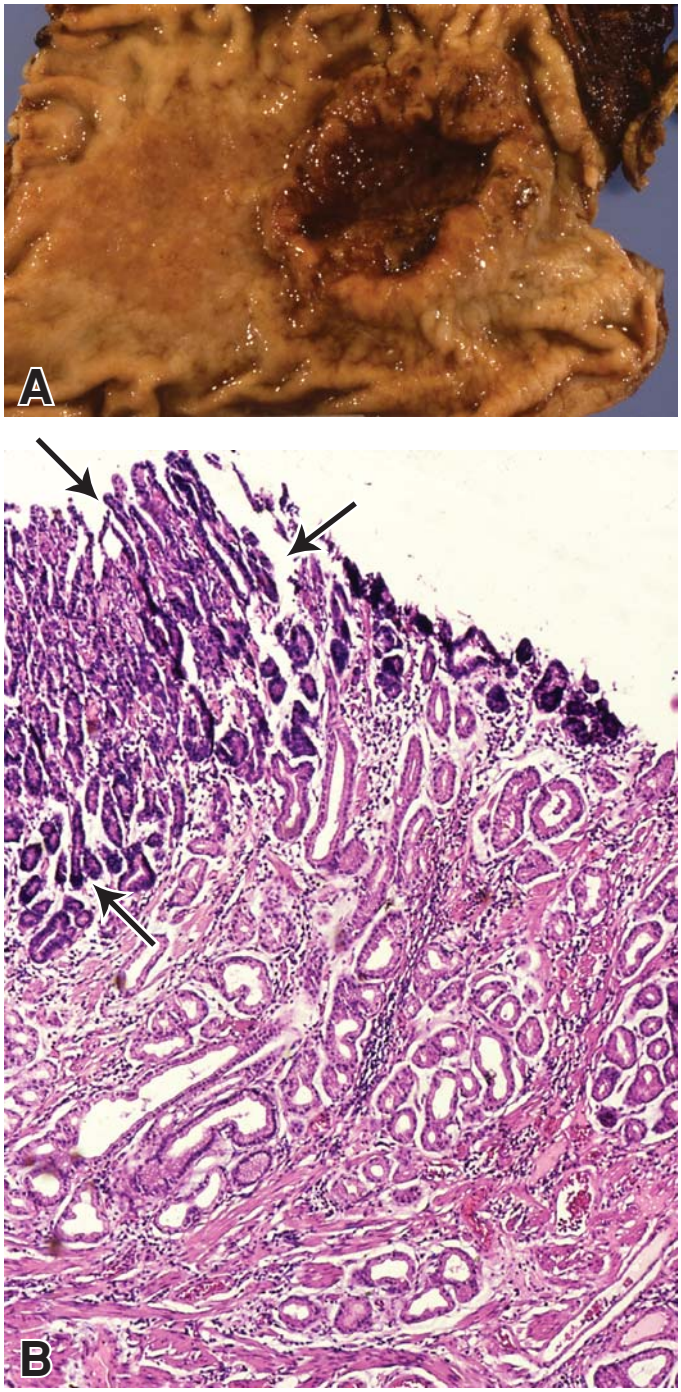

FIGURE 19-32. Gastric carcinoma. A. This large antral lesion is clearly distinguished from a benign ulcer by its raised firm edges and necrotic base. **B.** Microscopically, there are innumerable poorly formed glands (*arrows*) replacing mucosa in this intestinal-type carcinoma.

PATHOLOGY: Gross appearance is variable. Most carcinomas form large polypoid masses or growths with significant ulceration (Fig. 19-32A,B). The latter differ from benign peptic ulcers by their large size, raised firm irregular borders and ragged ulcer surfaces. A minority of cancers infiltrate the gastric wall deeply, beneath a surface that may seem deceptively intact. The infiltrating cells elicit a prominent desmoplastic response. This results in a rigid thick-walled stomach, an appearance that has been classically described as **linitis plastica** (Fig. 19-33A–C).

Gastric carcinoma has traditionally been separated into two categories, intestinal and diffuse, with some cases showing overlap; this is the Lauren classification. The term "intestinal" in this context mainly describes the architecture, rather than the cell type. These tumors form glands or papillae, as well as some solid areas; mucin production may occur. This is the more common pattern and is the one associated with chronic gastritis. It is declining in incidence because of its relationship to *Helicobacter.*

Diffuse-type carcinoma contains poorly cohesive cells, widely infiltrating the gastric wall, often with striking desmoplasia. Although the diffusely infiltrating cells may have a signet ring appearance, other cells may more mimic histiocytes or even lymphocytes. The incidence of this tumor has been more stable in all countries. It has a clearer genetic component. In fact, a hereditary diffuse gastric cancer exists as an uncommon autosomal dominant condition due to germline mutations in *CDH1,* the gene that encodes E-cadherin. These patients may develop cancer at an early age and often have multiple small foci of signet ring carcinoma in situ detectable only by thorough microscopic examination. Prophylactic gastrectomy is considered. E-cadherin inactivation also occurs in many sporadic diffuse gastric carcinomas.

Early versus Late Gastric Carcinoma

There are complex systems describing the character and depth of gastric carcinomas, but there is one simple fact of paramount importance: *patients with early gastric cancer (i.e., tumors confined to the mucosa and submucosa) are very likely to survive. Patients with late cancers (i.e., lesions that extend beyond the submucosa into the muscularis propria or beyond) are likely doomed.* The significance of this fact is that most carcinomas in the lower-incidence Western countries are diagnosed only at later stages.

The Stomach Is a Common Site of Extranodal Lymphomas

The gastrointestinal tract is the most common location for extranodal lymphomas, and the stomach is the most common portion of the GI tract affected. Most gastric lymphomas are either extranodal marginal zone lymphomas of mucosa-associated lymphoid tissue (MALT lymphoma; see Chapter 26) or diffuse large B-cell lymphomas. Both are associated with *Helicobacter* infection; eradication of the organisms leads to remission in the striking majority of cases. MALT lymphoma is difficult to distinguish from chronic gastritis with lymphoid hyperplasia. The presence of gastric glands infiltrated by lymphocytes (lymphoepithelial lesions) and a uniform monocytoid morphology of the cells infiltrating the lamina propria are distinguishing features (Fig. 19-34). Diffuse large

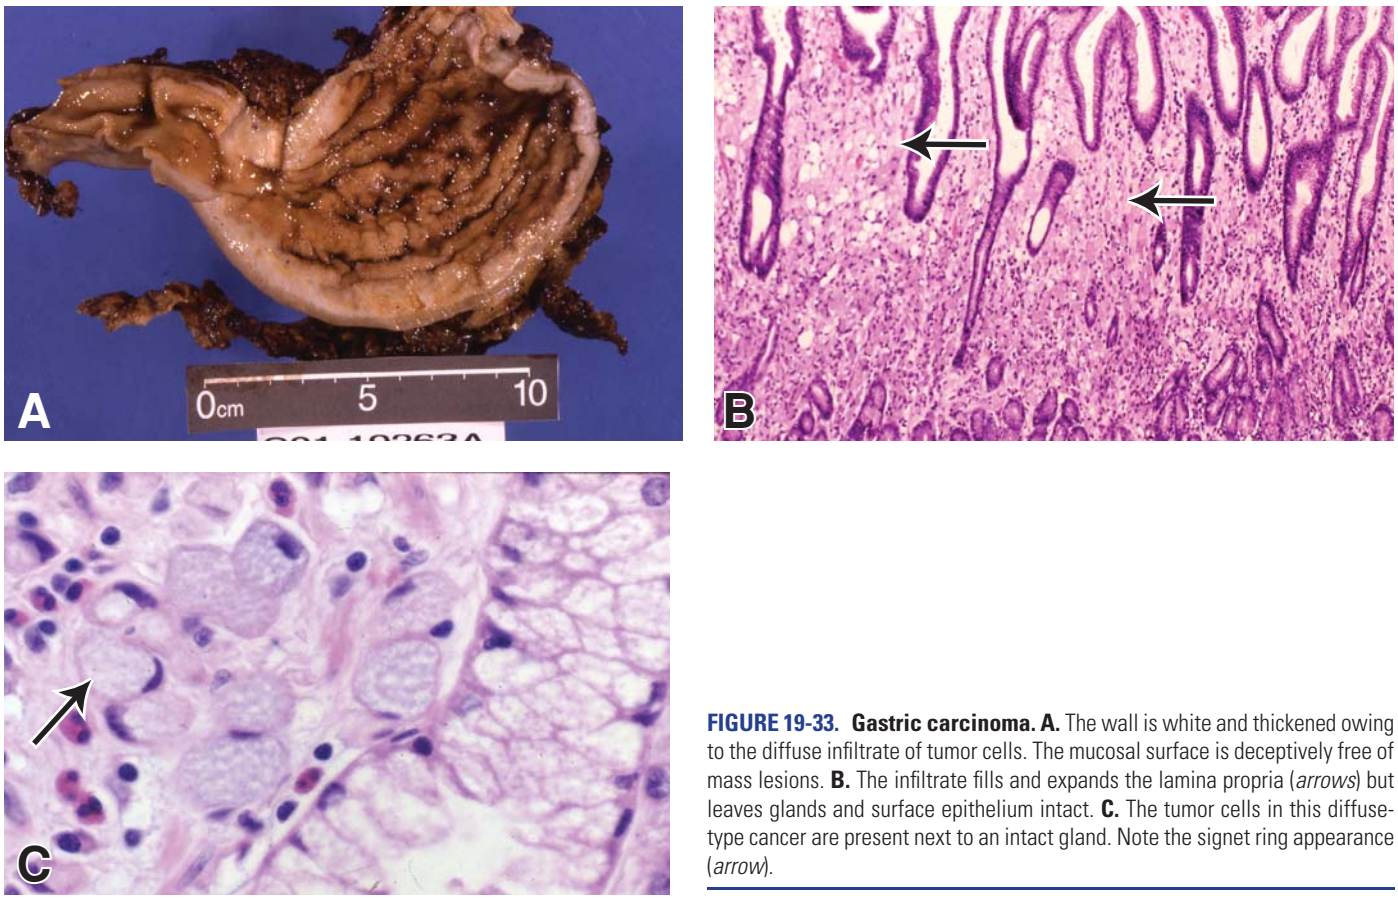

FIGURE 19-33. Gastric carcinoma. A. The wall is white and thickened owing to the diffuse infiltrate of tumor cells. The mucosal surface is deceptively free of mass lesions. **B.** The infiltrate fills and expands the lamina propria (*arrows*) but leaves glands and surface epithelium intact. **C.** The tumor cells in this diffuse-type cancer are present next to an intact gland. Note the signet ring appearance (*arrow*).

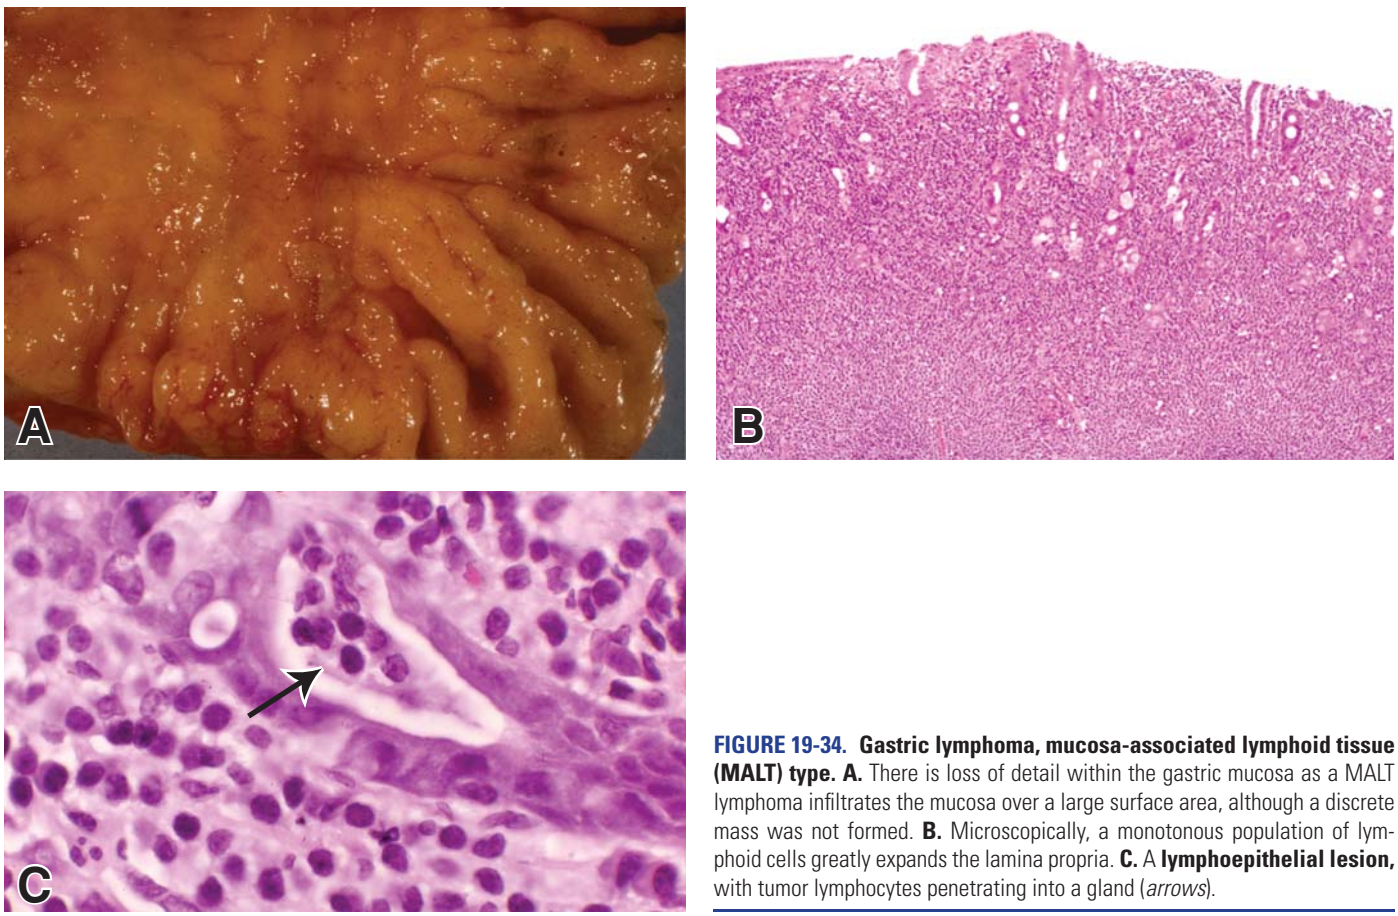

FIGURE 19-34. Gastric lymphoma, mucosa-associated lymphoid tissue (MALT) type. A. There is loss of detail within the gastric mucosa as a MALT lymphoma infiltrates the mucosa over a large surface area, although a discrete mass was not formed. **B.** Microscopically, a monotonous population of lymphoid cells greatly expands the lamina propria. **C.** A **lymphoepithelial lesion,** with tumor lymphocytes penetrating into a gland (*arrows*).

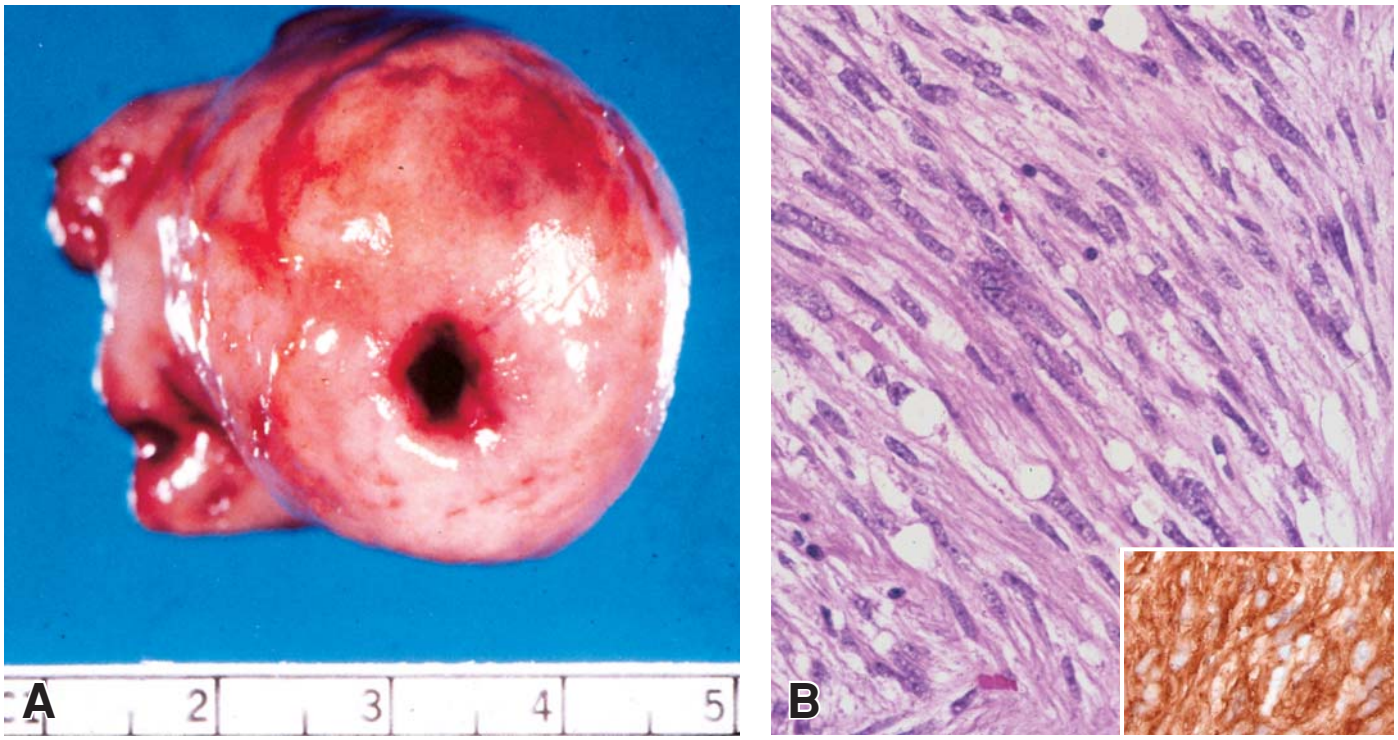

FIGURE 19-35. Gastrointestinal stromal tumor (GIST). A. The resected tumor is submucosal and covered by mucosa with a deep central ulcer. **B.** Microscopic appearance of tumor cells that are spindled and have cytoplasmic vacuoles. **Inset:** Immunohistochemical stain positive for c-kit.

B-cell lymphomas are more easily recognized because of their more pleomorphic appearance.

GI Stromal Tumors Derive from the Interstitial Cells of Cajal

For years these tumors, which contain elongate spindly cells, were felt to be of smooth muscle origin and were called leiomyomas and leiomyosarcomas. In fact, true smooth muscle gastric tumors are very uncommon. The interstitial cells of Cajal, from which these tumors derive, normally reside in the muscularis propria and are pacemakers.

The tumors are usually large and bulky, arising in the muscularis propria (Fig. 19-35A,B). They may show central ulceration in the overlying mucosa, and so present with bleeding. Most stain positively for CD117, although not all. CD117-negative GISTS are often immunopositive with another antibody, DOG1.

GISTs occur throughout the GI tract but are particularly common in the stomach. It is not possible to distinguish clearly between benign and malignant GISTs. Rather, criteria predicting progressively more aggressive behavior are being established for each site in the gut, since behavior varies in this regard. More distal lesions show a greater tendency toward malignant behavior. In addition to site, tumor size and mitotic rate are reliable discriminators. Fortunately, most gastric GISTs are less likely to show aggressive behavior.

Neuroendocrine Tumors

These tumors were once called "carcinoids," but that term is being replaced by "neuroendocrine tumor" (NET). As for GISTs, the site of origin is the major determinant of likely behavior. The best predictive features within a given site are the size and mitotic rate (proliferative activity may be assessed immunohistochemically by Ki67).

Interestingly, within a segment of the GI tract, tumor behavior depends on the conditions under which the neoplasms arise. This is especially so for gastric NETs. There are three major clinical scenarios in which such tumors are found. The first of these is autoimmune gastritis. As described previously, the profound activity of antral G cells results in a proliferation of ECL cells in the body and fundus. An identifiable sequence of proliferation has been identified. At first there are merely increased numbers of these cells. Then, strings of such cells form linear arrays, which later coalesce to form micronodules, which separate from the bases of gastric glands. As time progresses, propelled by prominent hypergastrinemia, these micronodules coalesce into larger and larger structures until a clinically evident neoplasm is formed. Patients with NETs arising in autoimmune gastritis often have multiple visible tumors (Fig. 19-36).

Gastric neuroendocrine tumors also arise in the hypergastrinemic state associated with Z-E syndrome (see above). Finally, gastric NETs can occur sporadically; these are more frequently antral. Of interest, tumors arising in autoimmune gastritis are rarely aggressive, while sporadic NETs often are. Those arising in association with Zollinger-Ellison syndrome are intermediate with regards to their aggressiveness.

The Small Intestine

ANATOMY

The intestinal tract develops as a tube from the stomach to the cloaca. This tube progressively elongates, and its

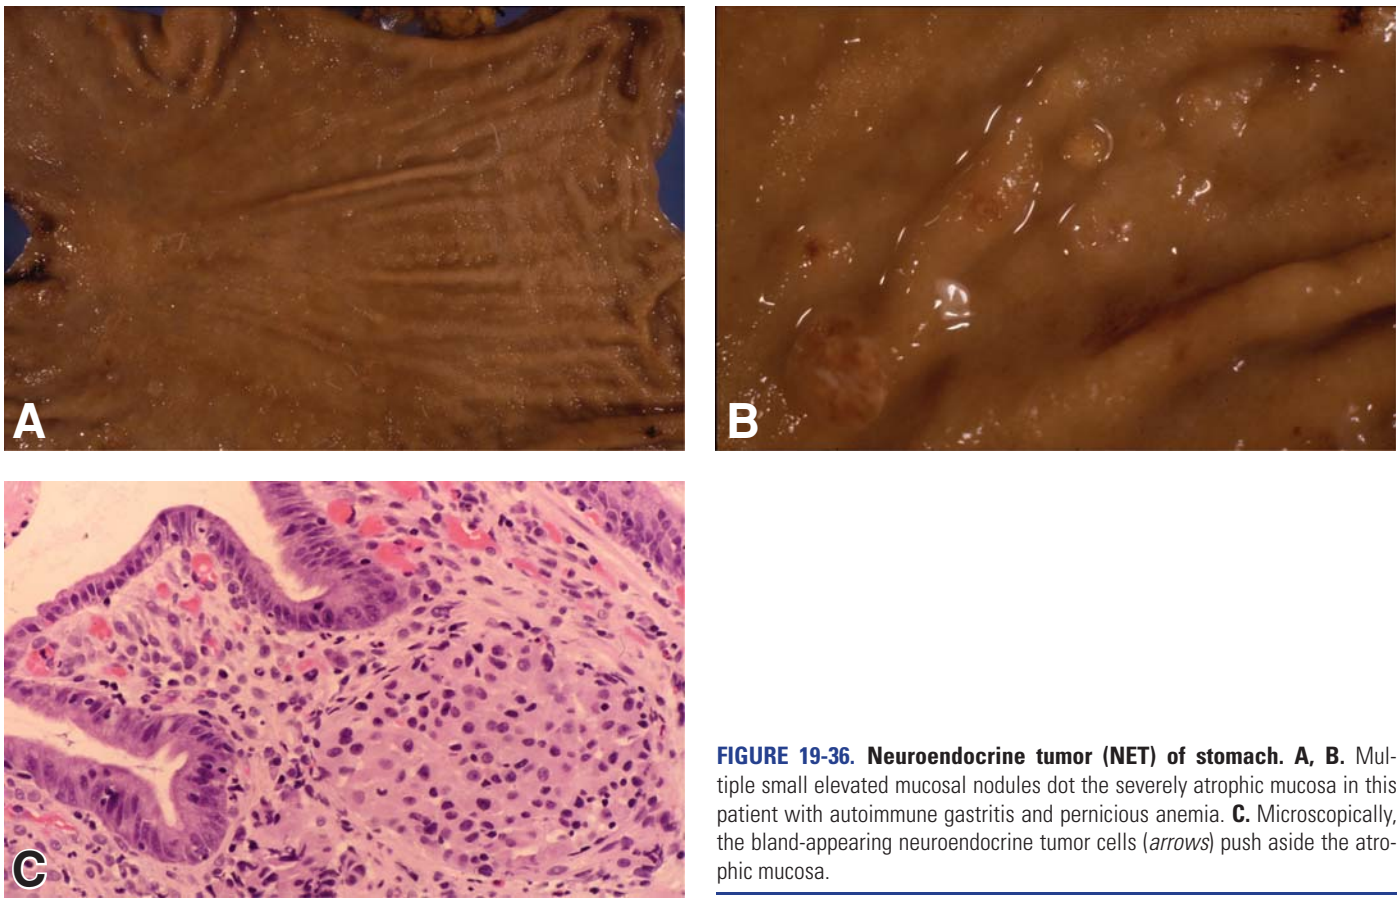

FIGURE 19-36. Neuroendocrine tumor (NET) of stomach. A, B. Multiple small elevated mucosal nodules dot the severely atrophic mucosa in this patient with autoimmune gastritis and pernicious anemia. **C.** Microscopically, the bland-appearing neuroendocrine tumor cells (*arrows*) push aside the atrophic mucosa.

cephalic part becomes the segment that extends from the distal duodenum to the proximal ileum. The more caudal portion develops into distal ileum and the proximal 2/3 of transverse colon. The vitelline duct, which connects the primitive duct to the yolk sac, may persist as a Meckel diverticulum (see below). To reach its final position, the fetal gut undergoes a complex series of rotations.

The small intestine extends from the pylorus to the ileocecal valve and, depending on its muscle tone, is from 3.5 to 6.5 m long. It is divided into three regions:

1. **The duodenum** extends to the ligament of Treitz.
2. **The jejunum** is the proximal 40% of the remainder of the small intestine.
3. **The ileum** is the distal 60%.

The duodenum is almost entirely retroperitoneal and thus fixed. The remainder of small intestine, which is disposed in redundant loops, is movable.

The C-shaped duodenum surrounds the head of the pancreas. It receives biliary drainage of the liver and pancreatic secretions through the common bile duct at the ampulla of Vater. The distal duodenum becomes invested by mesentery and merges with the jejunum at the ligament of Treitz. There is no demarcation between jejunum and ileum, which merge gradually. The wall of the jejunum is thicker and its lumen wider than those of the ileum.

The plicae circularis, spiral folds of mucosa and submucosa, are most prominent in the distal duodenum and proximal jejunum, usually disappearing in the terminal ileum. Peyer patches are submucosal lymphoid aggregates up to 3 cm in diameter, in the antimesenteric aspect of the distal half of the ileum. The ileocecal valve is a muscular sphincter that regulates flow of intestinal contents into the cecum.

The duodenum is served by the pancreaticoduodenal branch of the hepatic artery, which arises from the celiac artery. The jejunum and ileum are supplied by the superior mesenteric artery (a branch of the aorta), which is arranged in arcades in the mesentery, thus providing abundant collateral circulation in its distal reaches. Venous flow from the small intestine empties into the portal venous system. The small intestinal wall has four layers: mucosa, submucosa, muscularis and serosa. In the retroperitoneal duodenum, however, only the anterior wall is covered by a serosa.

The serosa contains loose connective tissue bounded by a single layer of mesothelium. The muscularis propria has an outer longitudinal layer and an inner circular layer, which act together to propel intestinal contents by peristalsis.

The submucosa consists of vascularized connective tissue and scattered lymphocytes, plasma cells and macrophages, occasional mast cells and eosinophils. In the proximal duodenum, the submucosa is occupied by Brunner glands, branched structures with mucous and serous cells. These secrete mucus and bicarbonate, which protect the duodenal mucosa from peptic ulceration. Mucosal lymphatics and venous capillaries drain into a highly developed system of lymphatic and venous plexuses in the submucosa.

The distinctive feature of intestinal mucosa is its unique villi (Fig. 19-37), 0.5–1-mm-long finger-like projections that expand the absorptive area enormously. Villi in the proximal duodenum tend to be broad and blunted, but in the distal duodenum and proximal jejunum they are more slender. Shorter, finger-shaped villi are the rule in the distal jejunum and ileum.

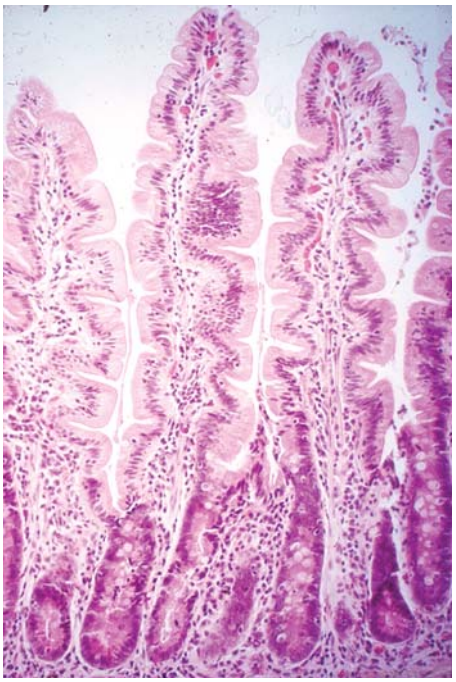

FIGURE 19-37. Intestinal villi from the proximal jejunum. The villi are several times longer than the crypts that gave rise to them. The lamina propria normally contains a mixture of lymphocytes and plasma cells with some scattered eosinophils.

In villi, the columnar epithelium sits on a basement membrane. A lamina propria and muscularis mucosae separate the mucosa from the submucosa. The connective tissue of the lamina propria forms the core of the villus and surrounds the crypts of Lieberkühn at the base of the villi. The normal lamina propria contains lymphocytes, plasma cells and macrophages. Plasma cells here mainly secrete immunoglobulin A (IgA) into the intestinal lumen or the lamina propria itself. Scattered eosinophils and mast cells and a few smooth muscle cells and fibroblasts are present. This cellular composition reflects the roles of the lamina propria: preventing bacteria from penetrating the mucosa and segregating foreign material that breaches the mucosa.

Some IgA made by lamina propria plasma cells is dimeric. It diffuses through the basement membrane of the crypt, then reaches the basal or lateral surfaces of epithelial cells, where it combines with a secretory component produced by that cell. Resulting secretory IgA is taken up by epithelial cells and secreted into the lumen. Secretory IgA is more resistant to proteolysis than is serum IgA. It binds food antigens and prevents bacterial adherence to intestinal epithelium. Moreover, it can neutralize bacterial toxins and inhibit viral replication and mucosal penetration.

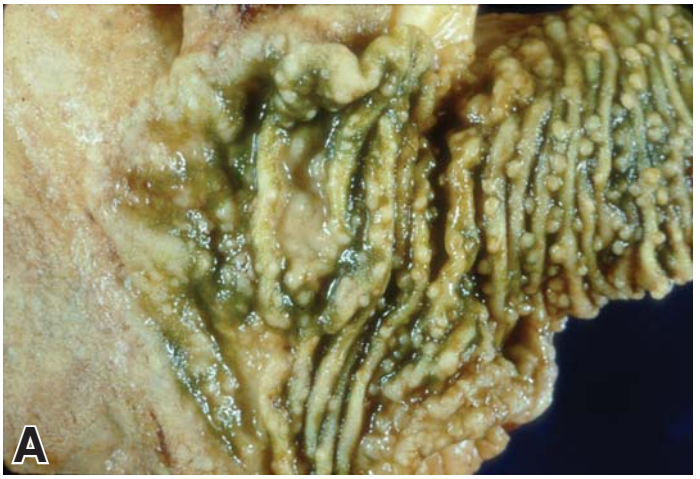
Lymphoid nodules are scattered throughout the mucosa and aggregate into visible Peyer patches (Fig. 19-38A,B). The villous columnar epithelial cells are mainly absorptive, while those lining the crypts are the source of cell renewal and secretion. There are normally a moderate number of intraepithelial T lymphocytes.

Absorptive cells, or enterocytes (Fig. 19-39), are the main lining cells of intestinal villi, which also contain a few goblet and endocrine cells. Enterocytes are tall, with basal nuclei and microvilli extending from their surfaces into the lumen, thus hugely increasing the absorptive area. The plasma membrane of the microvilli is covered by a glycocalyx (fuzzy coat), wherein reside disaccharidases and peptidases. In the ileum, the glycocalyx also contains receptors for the intrinsic factor–vitamin B_{12} complex.

The cytosol just under the microvilli has a network of actin microfilaments, the terminal web. These also associate with myosin and other contractile proteins, insert into the core of the microvilli and likely serve as a contractile apparatus. The plasma membranes of adjacent cells form tight junctions that permit passive paracellular transport of small molecules but are impermeable to macromolecules. Absorbed material moves from epithelial cells to intercellular spaces between absorptive cells, via lateral or basal plasma membranes. It then penetrates the basement membrane, traverses the lamina propria and enters capillaries or lymphatic channels.

There are four cell types in the crypts:

- **Paneth cells** at crypt bases resemble pancreatic or salivary zymogen cells and are active in exocrine secretion. Their eosinophilic secretory granules fill a basophilic cytoplasm. Paneth cells function in mucosal defense, as evidenced by the presence of lysozyme; antimicrobial products,



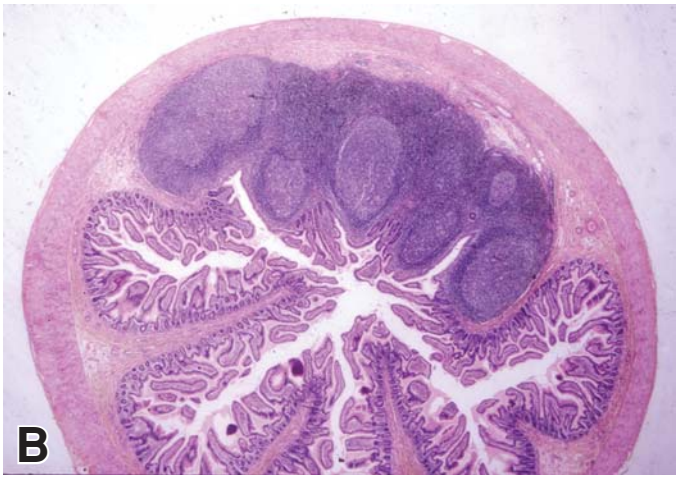


FIGURE 19-38. A. Peyer patches are particularly prominent in the terminal ileum; they are small dome-shaped mucosal mounds. **B.** The Peyer patch is composed of lymphoid tissue, often with prominent germinal centers, displacing the epithelial structures.

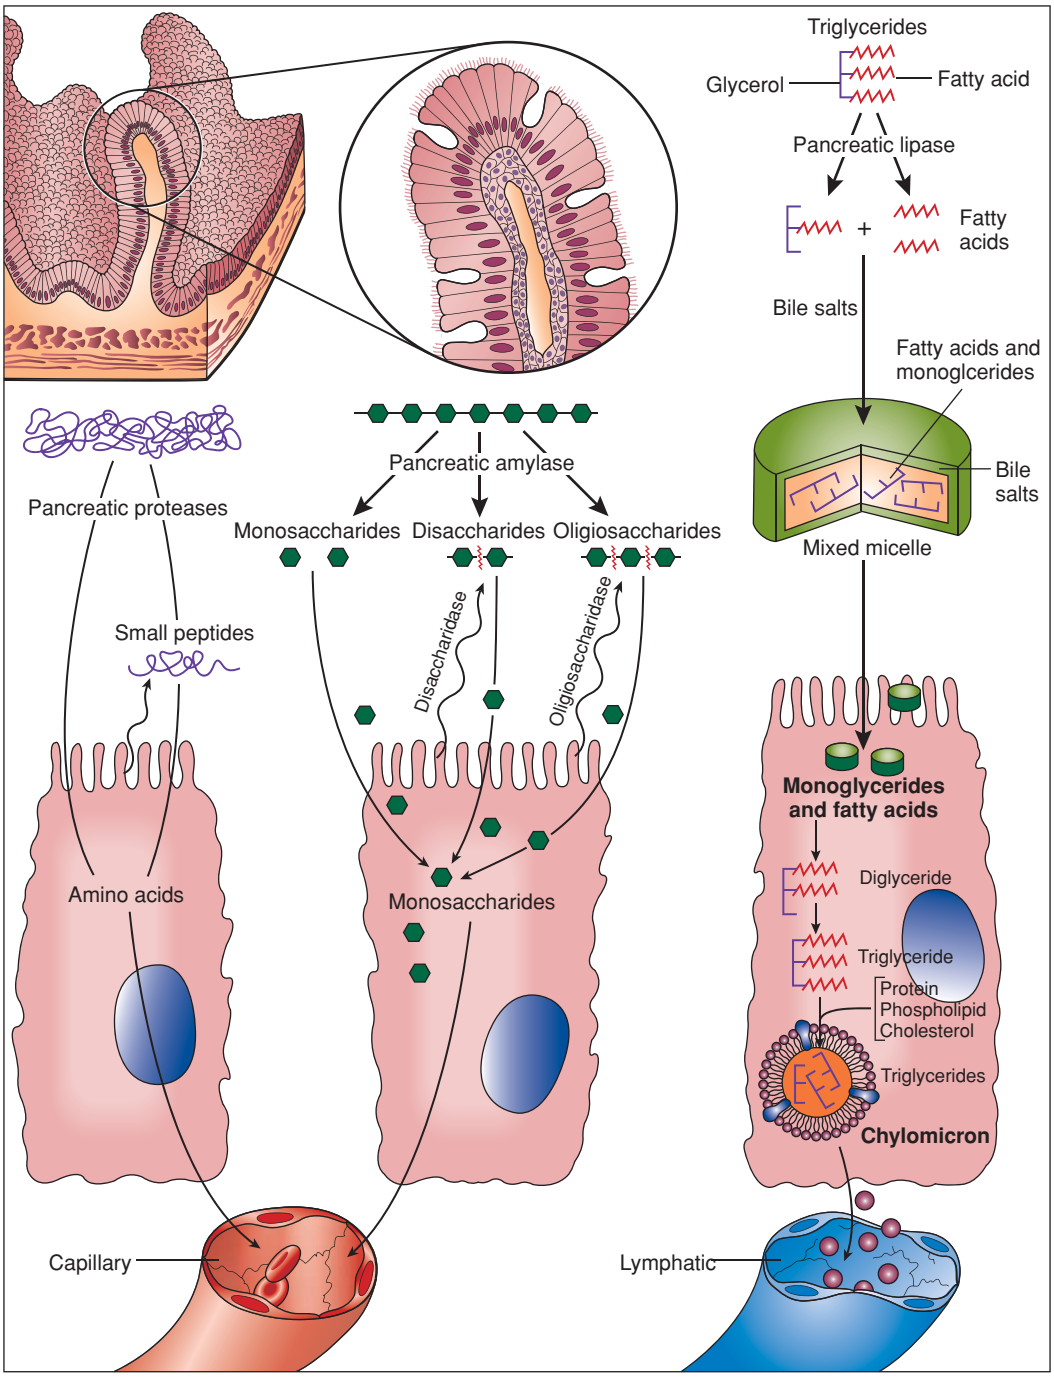

FIGURE 19-39. Mechanisms of nutrient absorption in the small intestine.

including peptides called crypt defensins (cryptdins); and CD95 ligand, a member of the tumor necrosis factor (TNF) family of cytokines.

- **Goblet cells** of the lateral walls of the crypts are flask shaped and filled with mucous granules. They resemble goblet cells elsewhere both structurally and functionally, with neutral and acid mucins.
- **Endocrine cells** have apical nuclei and basal eosinophilic granules. These cells make several gastrointestinal hormones and peptides, including gastrin, secretin, cholecystokinin, glucagon, vasoactive intestinal peptide (VIP) and serotonin. These hormones regulate many gastrointestinal functions, and tumors derived from these cells often exhibit striking hormone secretion.
- **Undifferentiated cells** in the lateral crypt walls and interspersed between Paneth cells at their bases are the most abundant cells in the crypts. Small glycoprotein secretory granules may be grouped in their apical cytoplasm. These cells act as reserve cells, from which all other mucosal cell populations are renewed, and thus they show abundant mitotic activity.

Cell renewal in the small intestine is limited to the crypts, where undifferentiated cells divide. Resulting cells migrate

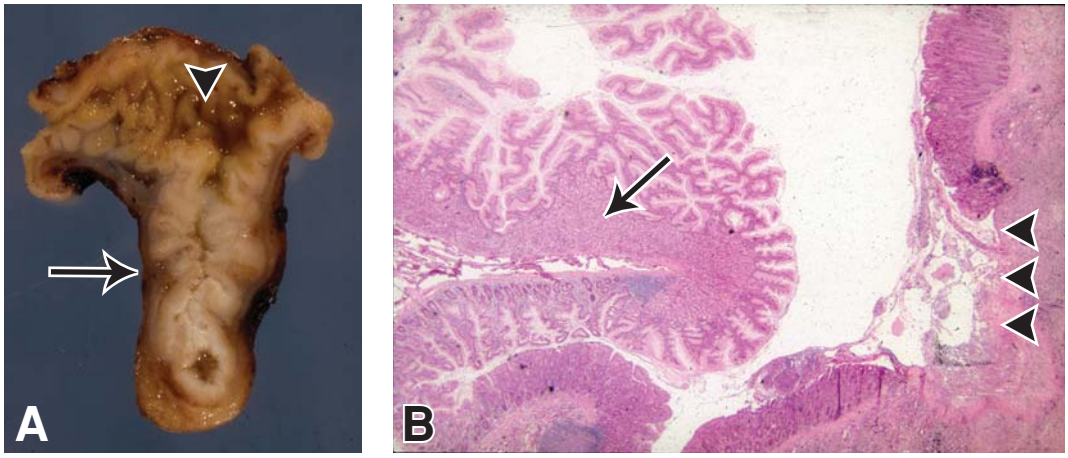

FIGURE 19-40. **A.** The **Meckel diverticulum** (*arrow*) here is seen extending downward from the lumen of the ileum (*arrowhead*). **B.** Heterotopic gastric mucosa with parietal cells (*arrow*) sits opposite the peptic ulcer (*arrowheads*) in the intestinal mucosa.

up the villus, where they differentiate into goblet cells and absorptive cells, and eventually slough into the lumen at the tip of the villus. Their absorptive capacity is maximal in the upper 1/3 of villi. The mucosal epithelium of the small intestine is replaced every 4–7 days. Intestinal epithelium is therefore very sensitive to radiation and chemotherapeutic agents.

CONGENITAL AND NEONATAL DISORDERS

Meckel Diverticulum Is Present in about 2% of the Population

This is the most commonly encountered clinically significant congenital disorder affecting the small intestine. It is solitary and is a true diverticulum, containing all layers of the intestinal wall (Fig. 19-40A,B). It is a remnant of the vitelline duct, and so extends from the antimesenteric side of the distal ileum. Males are more affected than females. Most Meckel diverticula are asymptomatic, but bleeding, perforation or obstruction due to intussusception may occur. The bleeding and perforation result from peptic ulceration, due to the presence of heterotopic gastric tissue with parietal cells. Heterotopic pancreatic tissue may also be present. Rarely, neoplasms develop, usually neuroendocrine tumors.

Meconium Ileus May Be an Early Complication of Cystic Fibrosis

In the neonatal period, infants with cystic fibrosis may develop intestinal obstruction owing to the thick viscid mucus characteristic of that condition plugging the lumen of the distal ileum. Perforation and peritonitis due to the meconium may occur.

Other Congenital Conditions

Atresia and stenosis are uncommon but can cause obstruction in the newborn. Duplications or enteric cysts are spherical or tubular structures adjacent to the long axis of the intestine; they too are rare.

Necrotizing Enterocolitis Is the Most Serious Acquired Neonatal GI Disorder

Neonatal necrotizing enterocolitis, commonly known as NEC, is, unfortunately, not uncommon. It is more common and more severe in premature and low–birth-weight infants. Signs of obstruction occur and perforation may occur. The ileocecal region is most commonly affected; in fatal cases, the area of involvement may be much more extensive. Onset usually follows the start of enteral feeding. Its pathogenesis is poorly understood; it appears to be multifactorial, involving such factors as solute loading and bacterial proliferation, as well as diversion of blood flow away from abdominal organs. The bowel resembles that seen in ischemic damage (Fig. 19-41). Pneumatosis cystoides intestinales (see below) is frequent. Healing may result in stenosis.

In Intussusception, a Segment of Bowel Is Drawn into a Distal Segment

In this setting, peristalsis pushes a part of bowel distally, causing it to telescope (Fig. 19-42A,B). The mesentery and blood vessels accompany the bowel and can become compressed, leading to edema, ischemic damage and entrapment. Intussusception can reverse spontaneously, or sometimes a barium enema may reduce it. Surgical

FIGURE 19-41. A segment of necrotic ileum with hemorrhage and pneumatosis from a premature infarct with **Neonatal necrotizing enterocolitis (NEC).**

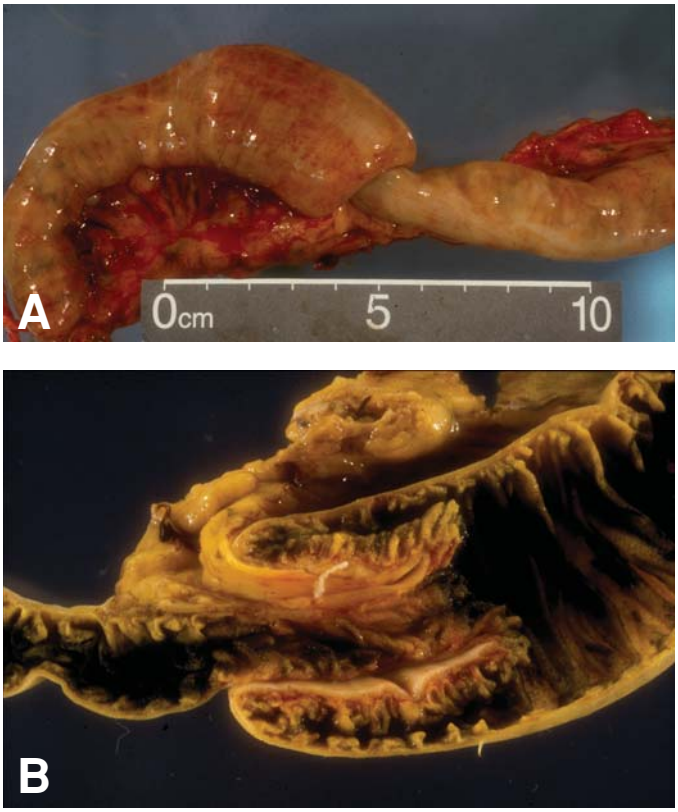

FIGURE 19-42. **A, B.** The proximal ileum has telescoped into the distal ileum in this case of **intussusception;** the anatomy is well seen in the cut section.

removal may be necessary. In children, there is usually no causative anatomic defect, other than lymphoid hyperplasia. This may be physiologic for age, but in some, rotavirus or adenovirus may be implicated in causing the hyperplasia. In adults, there is often a neoplastic luminal process, with the mass serving as a point of traction.

Pneumatosis Cystoides Intestinales Is Gas Bubbles in the Bowel Wall

The small intestine and colon are most commonly affected (Fig. 19-43). Pneumatosis almost always complicates another condition, such as NEC. In adults, it may be seen in pulmonary disease such as emphysema or complicating such processes as endoscopic polypectomy, ischemia, *Clostridium difficile* colitis or AIDS. Entrapped gas may cause a mass effect that can be mistaken for a neoplastic process.

Gas may enter the bowel by several routes. In pulmonary disease, air from ruptured blebs may track through the retroperitoneum and follow vascular adventitia into the bowel wall. Increased intra-abdominal pressure may force gas through minute mucosal defects. Finally, some cases result from gas formed by luminal anaerobic organisms. Prognosis is related to the underlying condition.

MALABSORPTION

Malabsorption is a general term that covers diverse clinical conditions in which important nutrients are inadequately absorbed by the gut. Some nutrient absorption occurs in the

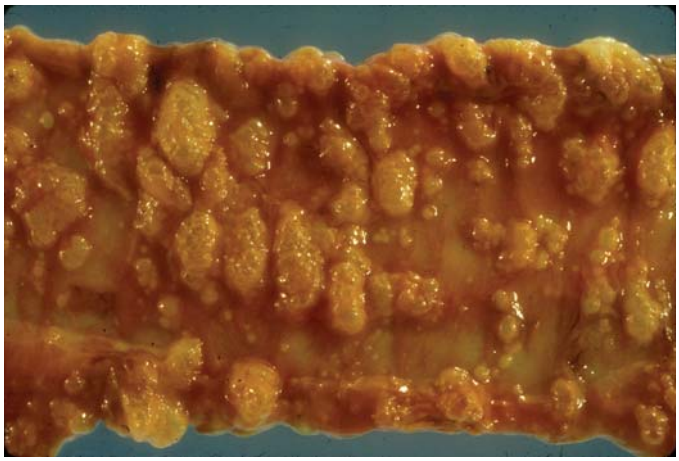

FIGURE 19-43. Multiple gas-filled blebs protrude into the lumen in this case of **pneumatosis cystoides intestinales.**

stomach and colon, but only absorption from the small intestine, mainly in the proximal portion, is clinically important. Two substances are preferentially absorbed by the distal small intestine: bile salts and vitamin B_{12}.

In normal intestinal absorption, there is a luminal phase and an intestinal phase. In the luminal phase (i.e., those processes that occur within the small intestine lumen), the physicochemical state of nutrients is altered so they can be taken up by absorptive cells. **The intestinal phase** includes processes occurring in cells and transport channels of the intestinal wall. Each phase has several critical components; derangement of any one or more of these components can impair absorption.

In the luminal phase**,** adequate amounts of pancreatic enzymes and bile acids are secreted into the duodenum in normal physicochemical conditions. Also, normal, regulated flow of gastric contents into the duodenum and a sufficiently high duodenal pH are needed. Normal pancreatic enzyme excretion into the duodenum requires adequate pancreatic exocrine function and unobstructed flow of pancreatic juice.

Supplying bile in normal quantity and quality to the duodenum requires (1) adequate liver function, (2) unobstructed bile flow and (3) intact enterohepatic bile salt circulation. Enterohepatic circulation of bile begins with absorption of most intestinal bile salts from the distal ileum and ends with their excretion into the duodenum through the bile ducts. Normally, 95% of intestinal bile salts are recycled via this circuit; 5% are excreted in the stool. Normal functioning of the enterohepatic circulation requires (1) normal intestinal microflora, (2) normal ileal absorptive function and (3) an unobstructed biliary system.

Intestinal-Phase Malabsorption Frequently Reflects Specific Enzyme Defects or Impaired Transport

Abnormalities in any of the four parts of the intestinal phase may cause malabsorption, but some diseases affect more than one of these components.

ETIOLOGIC FACTORS:

MICROVILLI: Intestinal disaccharidases and oligopeptidases are integrally bound to microvillous membranes. Disaccharidases are essential for sugar

absorption, since only monosaccharides can be absorbed by intestinal epithelial cells. Oligopeptides and dipeptides may be absorbed by alternate routes that do not require peptidases. Abnormal microvillous function may be primary—as in primary disaccharidase deficiencies—or secondary, if there is damage to villi, as in celiac disease (see below). Enzyme deficiencies (e.g., of lactase) entail intolerance to the respective disaccharides.

ABSORPTIVE AREA: The considerable length of the small bowel and the amplification of its surface by the intestinal folds (valves of Kerckring) provide a large absorptive surface. Severe diminution in this area may cause malabsorption. Surface area may be decreased by (1) small bowel resection (short bowel syndrome), (2) gastrocolic fistula (bypassing the small intestine) or (3) mucosal damage due to various small intestinal diseases (celiac disease, tropical sprue, Whipple disease).

METABOLIC FUNCTION OF ABSORPTIVE CELLS: For their subsequent transport to the circulation, nutrients in absorptive cells must be metabolized within these cells. Monoglycerides and free fatty acids are reassembled into triglycerides and coated with proteins (apoproteins) to make chylomicrons and lipoprotein particles. Specific metabolic dysfunction occurs in abetalipoproteinemia (associated with erythrocyte acanthocytosis; see Chapter 26), in which absorptive cells cannot synthesize the apoprotein required for assembling lipoproteins and chylomicrons. Nonspecific damage to small intestinal epithelial cells occurs in celiac disease, tropical sprue, Whipple disease and hyperacidity due to gastrinoma.

TRANSPORT: Nutrients are moved from the intestinal epithelium through the intestinal wall via blood capillaries and lymphatic vessels. Impaired transport of nutrients through these conduits is probably important in malabsorption due to Whipple disease, intestinal lymphoma and congenital lymphangiectasia.

CLINICAL FEATURES: Malabsorption may be specific or generalized:

- **Specific or isolated malabsorption** reflects an identifiable molecular defect that leads to malabsorption of one nutrient. Examples are disaccharidase deficiencies (e.g., lactase deficiency) and vitamin B_{12} insufficiency (pernicious anemia) from lack of intrinsic factor. Anemias may be caused by deficiencies of iron, folic acid, vitamin B_{12} or a combination of these. A bleeding diathesis may be due to vitamin K deficiency; malabsorption of vitamin D and calcium may lead to tetany, osteomalacia (in adults) or rickets (in children) (also see Chapter 8).
- **Generalized malabsorption** occurs when absorption of several or all major nutrient classes is impaired. It leads to generalized malnutrition. In adults, this appears as weight loss and sometimes cachexia; in children, it is "failure to thrive" with poor growth and weight gain.

Diverse Laboratory Studies May Detect Specific Forms of Malabsorption

Thus, disaccharidase deficiency is diagnosed by measuring blood sugar after ingestion of a standard amount of disaccharide, as in a lactose tolerance test, or by measuring enzyme activity in small bowel biopsies.

In generalized malabsorption, absorption of dietary fat is almost always impaired. Quantitative fecal fat analysis is the most reliable and sensitive test of overall digestive and absorptive function and is a standard for all other tests for malabsorption. **Steatorrhea** (fat in the stools) is a hallmark of generalized malabsorption.

Several key tests are often used to assess causes of malabsorption.

- **D-xylose absorption:** Xylose is a 5-carbon sugar whose absorption does not require any component of the luminal phase. Blood levels and urinary excretion after eating a defined amount of it thus are tested in the intestinal phase of absorption.
- **$^{14}CO_2$-cholyl-glycine breath test:** Measuring $^{14}CO_2$ in exhaled air after oral administration of $^{14}CO_2$-cholylglycine tests bile salt absorption by the ileum. It is used to diagnose blind- or stagnant-loop syndrome (due to bacterial overgrowth) and to assess ileal absorptive function. A ^{14}C-xylose breath test detects bacterial overgrowth.

Lactase Deficiency Causes Intolerance to Milk Products

The intestinal brush border contains disaccharidases that are important for absorption of carbohydrates. Lactose is present in milk and other dairy products and is one of the most common disaccharides in the diet. Before domestication of milk-producing animals about 9000 years ago, human milk was probably the only milk consumed by babies and young children. Dairy products were nonexistent. The availability of nonhuman milk favored lactase production, perhaps leading cattle-herding societies (e.g., Europeans) to be lactose tolerant, while non–cattle herders (e.g., Native Americans, Asians) are lactose intolerant.

Acquired lactase deficiency is widespread. Symptoms typically begin in adolescence, with abdominal distention, flatulence and diarrhea after consuming dairy products. Removing milk and dairy products from the diet provides relief. Diseases that injure the intestinal mucosa (e.g., celiac disease) may also cause acquired lactase deficiency. Congenital lactase deficiency is rare but may be lethal if not recognized.

Celiac Disease Is Due to Sensitivity to Gluten

PATHOPHYSIOLOGY: Gluten is found in wheat, rye and barley; the main culprit appears to be a peptide fraction of gluten, namely, **gliadin**. Other environmental factors may also be operative. Many patients have evidence of previous infection with adenovirus 12; a protein component of this virus shows homology with α-gliadin. Gluten-sensitive enteropathy (GSE) is an immunologic disorder that occurs in genetically susceptible individuals. The genetic nature was first established by family studies; the fact that a significant percentage of people with type 1 diabetes, another immunologic disorder (see Chapter 13), have GSE is further confirmation. It appears that two separate genes involved in the major histocompatibility complex, namely, class I human leukocyte antigen (HLA)-B8 and class II HLA-DR3 and DQW2, are present in almost all patients (Fig. 19-44).

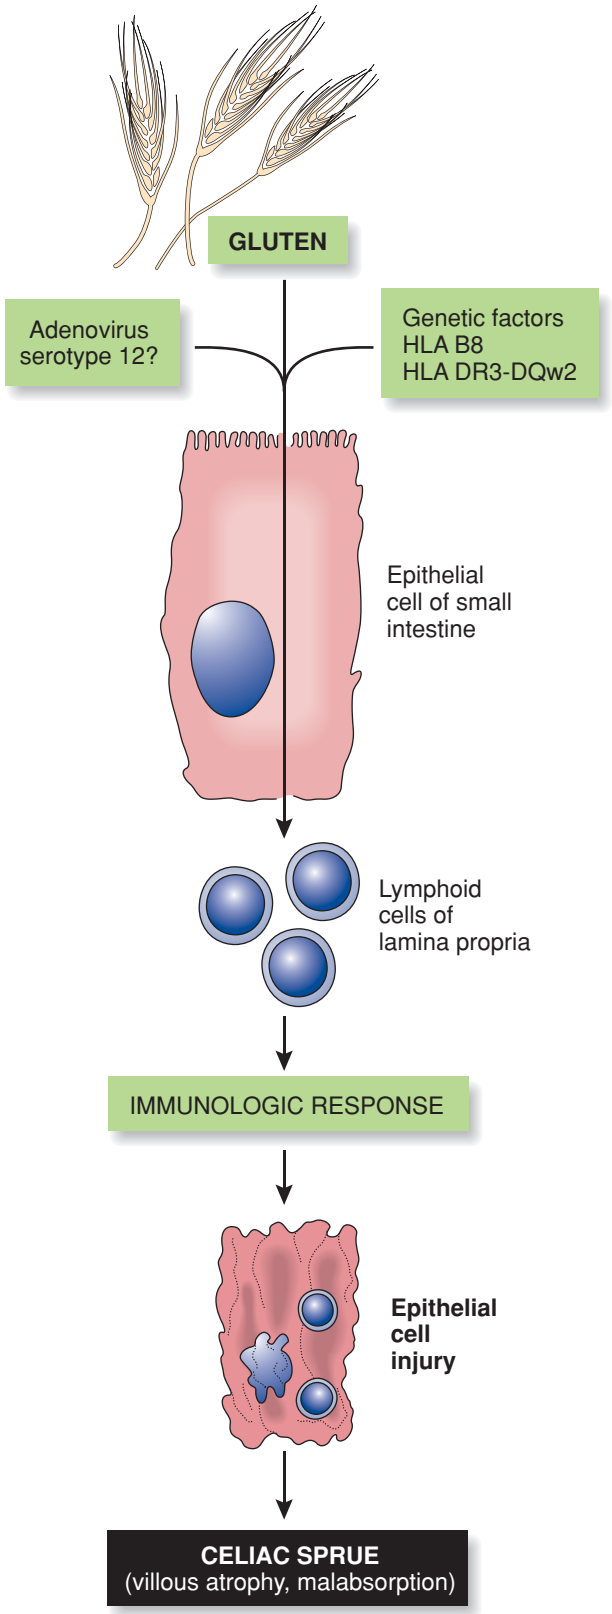

FIGURE 19-44. Proposed mechanism of the pathogenesis of celiac disease. HLA = human leukocyte antigen.

Although many patients with these genes do not have celiac disease, it is thought that absence of these genes virtually excludes the diagnosis.

Both cellular immunity and antibodies are involved. Activated mucosal T lymphocytes cause mucosal injury via release of cytokines; antigen–antibody complex deposition with complement activation may also lead to injury. Because of this, a number of serologic tests are useful in diagnosing GSE. The most important of these are **tissue transglutaminase (tTG)** and **antiendomysial antibody;** the former is now the test of choice. Testing for antigliadin antibody has a much lower sensitivity than these two tests.

CLINICAL FEATURES: The classic symptoms are abdominal discomfort and diarrhea. With more advanced disease and consequent increased difficulty in absorbing fat, steatorrhea develops. Because of its high fat content, the stool tends to float and develops a particularly offensive odor owing to the action of intestinal bacteria on lipid. Eventually there can be severe malnutrition with weight loss, muscle wasting and hypoalbuminemia with edema. Other findings reported are osteoporosis and short stature compared to siblings.

These "classic" findings in GSE are becoming increasingly rare with better means of diagnosis and subsequent treatment. However, improved understanding of the pathogenesis of GSE and better means of recognizing the process serologically and morphologically has led to the concept of a much broader spectrum of the disease. Patients may even be asymptomatic, only to be discovered after a proband in their family has been identified. More importantly, it is now recognized that patients with GSE commonly present with iron-deficiency anemia resistant to oral therapy.

The last several decades have seen a particularly wide swing of the pendulum. Early on GSE was very much underdiagnosed, since the process was not considered unless the patient had several classic findings. With the current realization that GSE can manifest much more subtly than previously believed, many symptoms or conditions are attributed to GSE without unequivocal evidence. Care must be taken, as the diagnosis requires strong clinical, serologic or histologic evidence.

Treatment is exclusion of gluten from the diet and is usually quite effective. However, gluten is ubiquitous and adhering to the diet can be difficult. As well, diet change has been known to lead to a placebo effect, underscoring the need for concrete evidence before diagnosing GSE.

PATHOLOGY: The histologic hallmark of GSE is both increased inflammation and architectural derangement in the small intestinal villi. The previously accepted classic histology of the disease included total or near-total loss of villi, resulting in a flat mucosa, plus an increase in lamina propria inflammation, including lymphocytes, plasma cells and some eosinophils.

In recent years there has been an increased emphasis on the character of the inflammation, in particular, the increase in intraepithelial lymphocytes (IELs). T lymphocytes are normally present in the surface epithelium (Fig. 19-45A,B), but in the GSE these T cells may increase to the point where

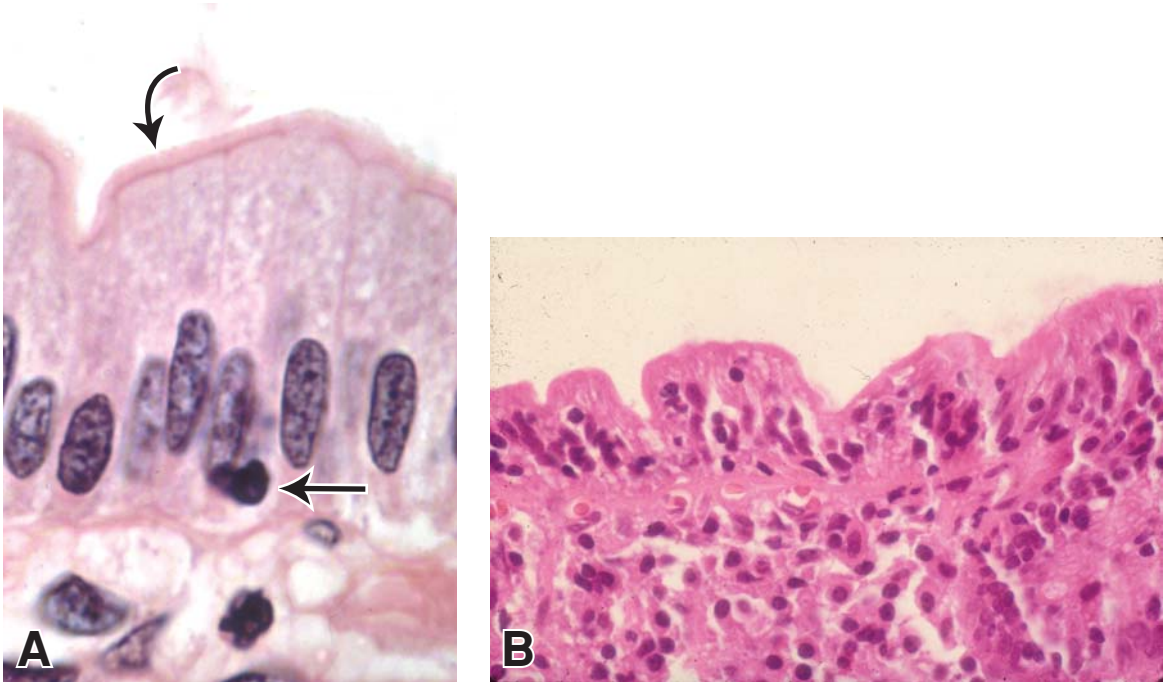

FIGURE 19-45. **A.** High-power view of small intestine surface epithelium; note the **brush border** (*arrow*) and intraepithelial lymphocyte (*curved arrow*). **B.** The surface epithelium in **celiac disease:** the epithelial height is reduced, the brush border is destroyed and intraepithelial lymphocytes are numerous.

they outnumber the surface epithelial cells. The exact number necessary to diagnose GSE is controversial, as is the best method for enumerating them. Increased T cells are not specific for GSE (they may be seen in, e.g., NSAID exposure and *H. pylori* gastritis), but IELs are essentially always increased in patients with GSE, as would be expected from the pathophysiology of that process.

Surface epithelial cells are damaged and lose their brush border. This damage shortens their life span, so that mitotic activity in the crypts increases to compensate for the increased cell loss. As a result, there is hyperplasia of the crypts. This leads to deeper crypts, even as villi decrease in height (Fig. 19-46). Eventually a flat mucosa may result, but there are a series of gradations between total loss of villi and villi of relatively normal height notable only for an increase in IELs, particularly at their tips. These changes are most prominent in the proximal small intestine where the most intense gluten exposure occurs; the distal ileum is only rarely involved. In severe cases, the surface area of small intestine available for absorbing nutrients is greatly reduced.

There is evidence that patients with chronic GSE have increased risk for primary intestinal T-cell lymphoma and small intestinal adenocarcinoma, but the magnitude of this risk is unclear.

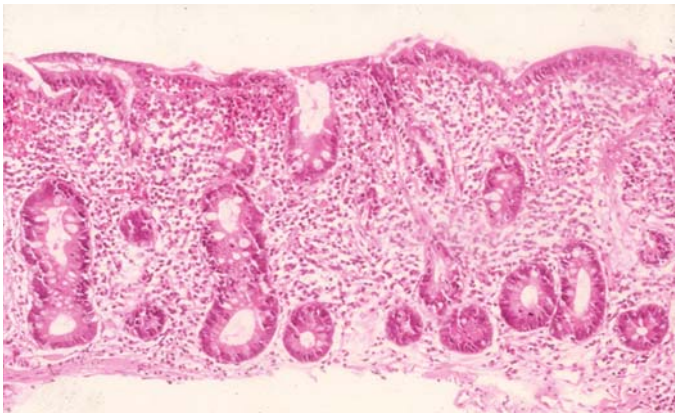

FIGURE 19-46. Classic advanced **celiac disease:** villi are no longer visible, crypts are taller than normal and a lymphoplasmacytic infiltrate expands the lamina propria. Even at low power, damage to the surface epithelium is evident.

Tropical Sprue Is Chronic Malabsorption That Is Restricted Geographically

Affected locations are the Indian subcontinent, portions of Southeast Asia, Central America and the Caribbean. Tropical sprue can develop both in residents and in visitors to the area. The term "sprue" is from a Dutch term meaning diarrhea and has also been applied to GSE at times ("nontropical sprue"). Evidence supports a complex bacterial etiology in that broad-spectrum antibiotics are effective in alleviating the condition. The exact nature of the causative agent(s) is uncertain.

The entire small intestine including ileum is involved. The histologic appearance is very similar to that of GSE; however, IELs are more prominent in the crypts than in the villus tips. Completely flat mucosa is less common than in GSE.

Severe folate and B_{12} deficiency may occur, the latter reflecting ileal involvement; this may lead to megaloblastic change.

Autoimmune Enteritis Is a Rare Disease but Is Increasing in Frequency

It is characterized by severe diarrhea. Small intestinal biopsies are similar in appearance to those in GSE. Antibodies are present, but these are directed against the intestinal epithelial cells themselves. Severe villous atrophy may be present, but IELs are not as prominent as in GSE. Also, there is usually loss of goblet and Paneth cells. Importantly, the stomach and colon are often involved in addition to the small intestine. Likewise, extraintestinal involvement, such as the pancreas and lung, may also be present. Treatment differs radically from that for GSE; potent immunosuppressives are needed and gluten restriction has no effect.

Whipple Disease Is Caused by *Tropheryma whippelii*

While this disease is uncommon, it is important to recognize this process, which also presents as malabsorption. The causative bacterium is an actinobacterium and was identified only many years after the disease was first described. Villi are enlarged and bulbous owing to massive numbers of bacteria within macrophages, which are unable to degrade the organisms; these macrophages take on a foamy appearance (Fig. 19-47A–D). Defective T-cell function may also be present. Because of their polysaccharide content, the bacteria impact striking positivity to the foamy macrophages when the PAS stain is employed. This time-honored method of establishing the diagnosis of the disease is being replaced by specific polymerase chain reaction (PCR) testing for the causative organism. Extraintestinal manifestations are very common and affect the heart, joints, lymph nodes and brain. Because of the CNS involvement, these patients may first present with neuropsychiatric symptoms. This disease responds dramatically to antibiotic therapy.

Giardiasis Is the Leading Gastrointestinal Protozoal Infection in the United States

The causative agent is *Giardia lamblia*. Symptoms may include severe watery diarrhea as well as abdominal discomfort with nausea and vomiting. Malabsorption can occur. Infection usually occurs after drinking from unprotected water sources. *Giardia* spores are extremely hardy; person-to-person transmission can occur, particularly among children in day care centers. The trophozoites can be identified in duodenal fluid or stool, but they are often

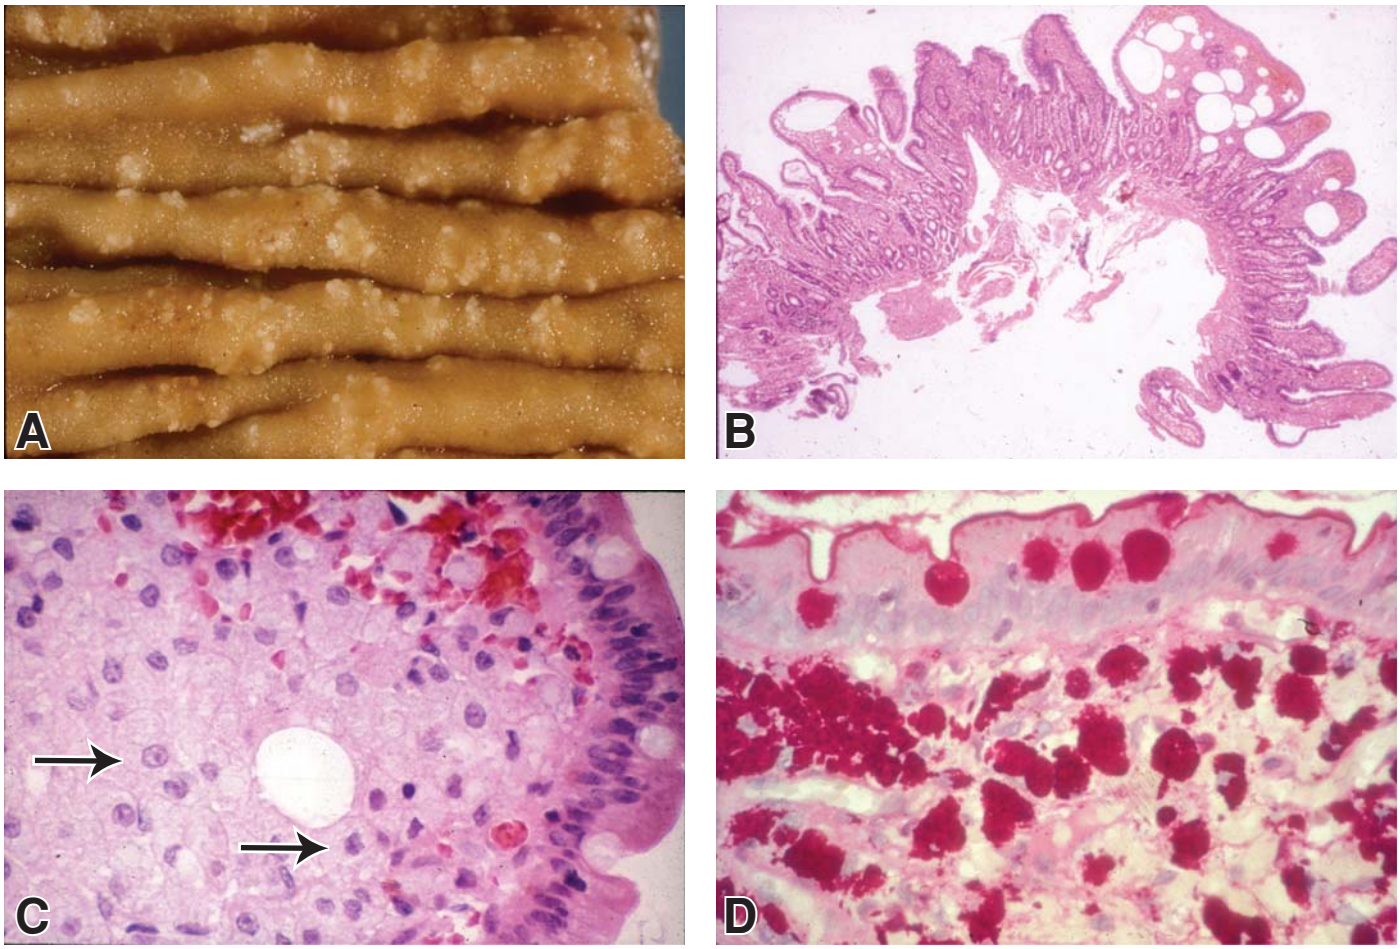

FIGURE 19-47. Whipple disease. A. The gross specimen shows white elevated areas; these are due to lipid collecting in the damaged mucosa. **B.** At low power the villi are short and club shaped; the large cystic-appearing areas represent fat trapped owing to compression of mucosal lymphocytes. **C.** The lamina propria contains abundant foamy macrophages (*arrows*). **D.** The partially digested bacteria in these macrophages impart strong periodic acid–Schiff (PAS) positivity.

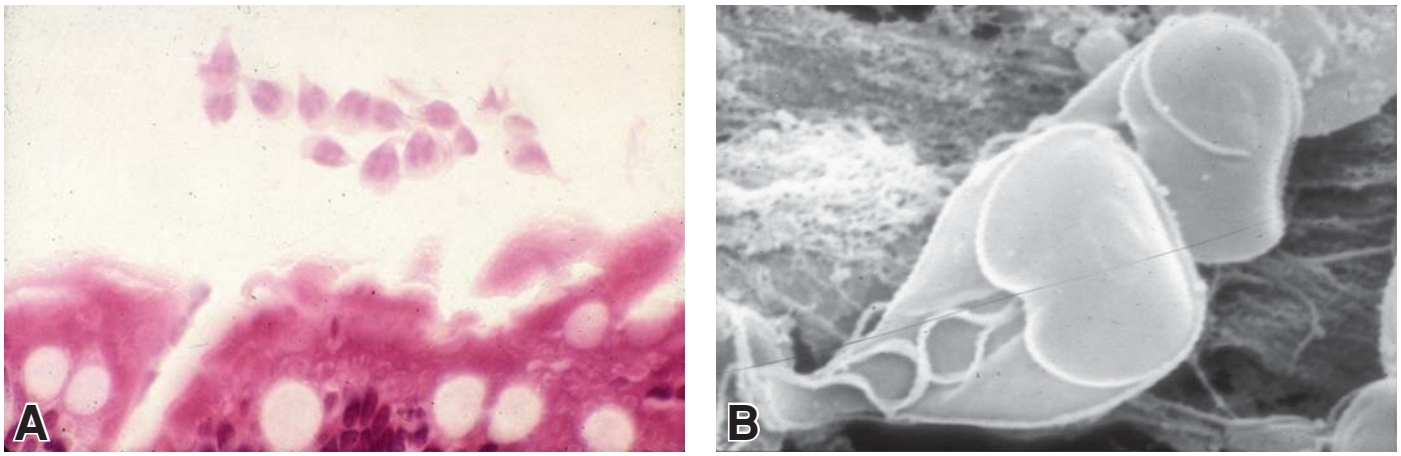

FIGURE 19-48. **A.** A group of ***Giardia*** is seen just above the surface epithelium in this jejunal biopsy. **B.** A single trophozoite from this area is seen here by scanning electron microscopy.

first identified in a duodenal biopsy. While they have a characteristic pear shape when seen in fluids, they tend to be seen in profile as sickle or triangular shapes in biopsies (Fig. 19-48A,B). They are usually very numerous, adhere to the epithelial surface and do not invade. The underlying mucosa is often completely normal or may show mild nonspecific inflammatory changes including a slight increase in IELs. *Giardia* are among the most common infections in common variable immunodeficiency. In such cases, lamina propria plasma cells are sparse to absent and lymphoid aggregate may be present. Identifying *Giardia* in a biopsy should trigger a search for plasma cells to exclude this possibility.

Small Bowel Bacterial Overgrowth Usually Results from Disordered Motility

In this condition, there is an overgrowth of colonic-type anaerobic bacteria in the small bowel. Conditions interfering with overall gut motility, such as diabetes, scleroderma, and pseudo-obstruction, can lead to the syndrome. The term "blind loop syndrome" may be used if the stasis is due to an anatomic defect such as small bowel diverticula or prior surgery such as a Billroth II. The mucosa may appear to be normal or show varying degrees of patchy nonspecific inflammation. It is thought that deconjugation of bile salts by the bacteria or their use of micronutrients is the major contributing pathogenic factor. Diagnosis is by breath test and cultures of intestinal fluid; antibiotic therapy usually results in symptomatic improvement. This and the other multiple causes of malabsorption are depicted in Fig. 19-49.

OBSTRUCTION

Mechanical obstruction can affect any segment of the gastrointestinal tract; the small bowel is frequently involved. The common causes include entrapment of bowel in hernias, intussusception (see above), adhesions from prior surgery or peritoneal infection, and volvulus. In volvulus, a segment of the intestinal tract twists on its mesentery, causing obstruction and ischemic damage. Neoplasms can also cause luminal obstruction with or without intussusception.

Pseudo-Obstruction

In pseudo-obstruction, symptoms and signs of obstruction are present but without any of the mechanical lesions previously discussed. There are both primary and secondary causes for this phenomenon. In primary pseudo-obstruction, the muscle may be affected with prominent replacement of smooth muscle with fibrous tissue leading to profoundly altered motility. Some of these cases are familial. Muscular abnormalities are more common than neural defects, which are often difficult to identify morphologically. Secondary forms of pseudo-obstruction complicate well-defined systemic diseases. Chief among these is scleroderma; amyloidosis and endometriosis affecting the muscularis are other causes of secondary damage.

INTESTINAL ISCHEMIA

Impaired intestinal blood flow for any reason can cause ischemic bowel disease. Manifestations of intestinal ischemia are diverse. The most common type of ischemic bowel disease is acute intestinal ischemia, which causes injury ranging from mucosal necrosis to transmural bowel infarction. Chronic intestinal ischemia syndromes are less common and generally require severe compromise of two or more major arteries, usually by atherosclerosis.

Superior Mesenteric Artery Occlusion

This is the most common cause of acute intestinal ischemia. Sudden occlusion of a large artery by thrombosis or embolization leads to small bowel infarction before collateral circulation can compensate. Depending on the size of the artery, infarction may be segmental or may lead to gangrene of virtually the entire small bowel. Occlusive intestinal infarction is most often caused by embolic or thrombotic occlusion of the superior mesenteric artery. A lesser number are the result of vasculitis, which often involves small arteries. In addition to intrinsic vascular lesions, volvulus, intussusception and incarceration of the intestine in a hernial sac may all lead to arterial as well as venous occlusion.

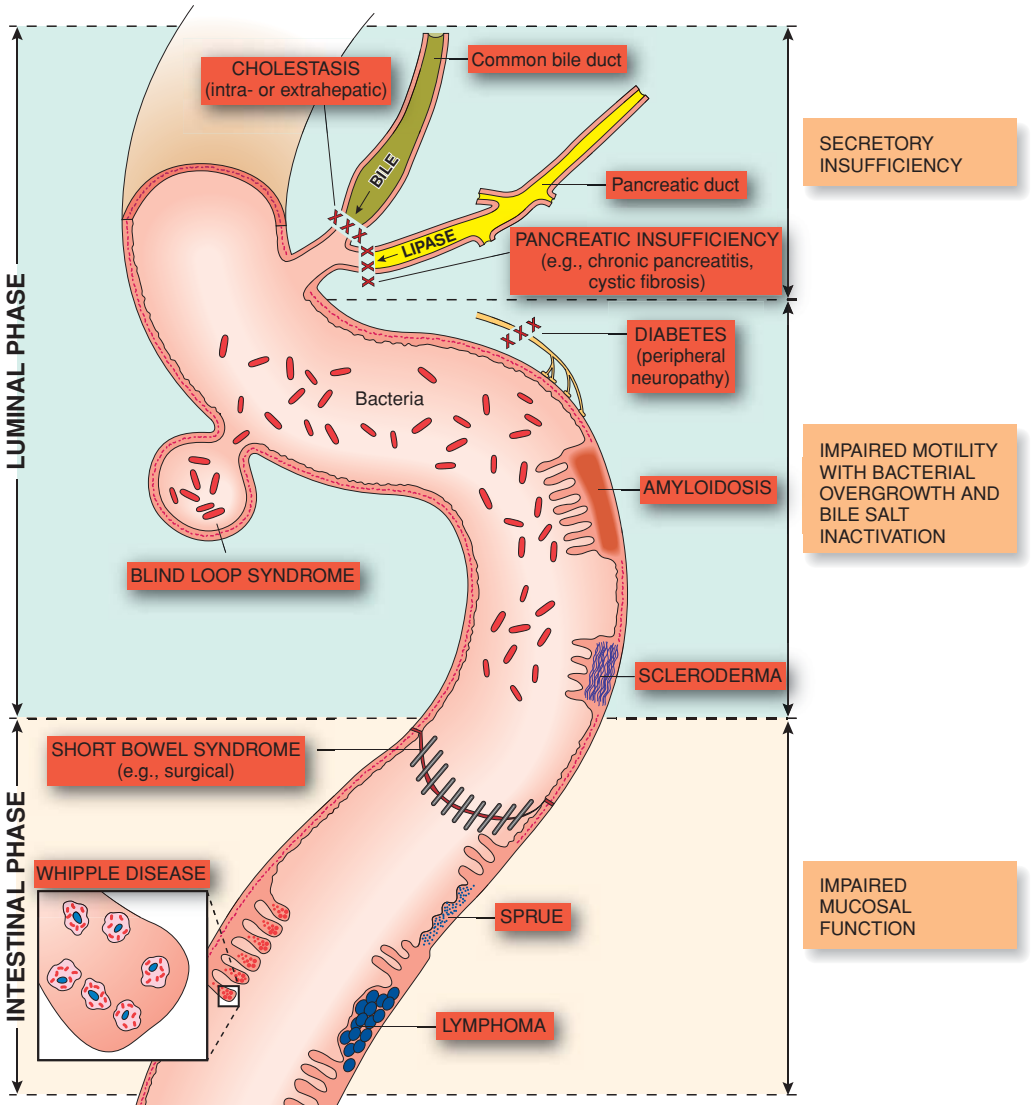

FIGURE 19-49. The causes of malabsorption.

Intestinal Ischemic Necrosis without Acute Vascular Occlusion

This type of vascular insufficiency is more common than the occlusive variety and may be just as extensive. It is seen in hypoxic patients with reduced cardiac output from shock of a variety of causes including hemorrhage, sepsis and acute myocardial infarction. In shock, blood flow redistributes to favor the brain and other vital organs, and patients often received α-adrenergic agents, which further shunt blood away from the intestine. Drastically lowered perfusion pressure leads to arteriolar collapse, aggravating the ischemia.

Mesenteric Vein Thrombosis

Mesenteric vein thrombosis is also a common cause of ischemic damage. Causes of mesenteric vein thrombosis include hypercoagulable states, stasis and inflammation (pylephlebitis). Almost all thromboses affect the superior mesenteric vein; only 5% involve the inferior mesenteric vein. The collateral flow in the distribution of the superior mesenteric vein usually suffices to preclude infarction of the intestine.

Infarcted bowel is edematous and diffusely purple (Fig. 19-50). The demarcation between the infarcted bowel and normal tissue is usually sharp, although venous occlusion may lead to a more diffuse appearance. Hemorrhage is prominent in the mucosa and submucosa, especially in venous occlusion (e.g., mesenteric vein thrombosis). The mucosal surface shows irregular wide areas of sloughing, and the wall becomes thin and distended. Bubbles of gas (pneumatosis) may be present in the bowel wall and mesenteric veins. The serosal surface is cloudy and covered by an inflammatory exudate.

Other Causes of Intestinal Ischemia

SMOOTH MUSCLE DYS FUNCTION: Dysfunctional smooth muscle interferes with peristalsis and leads to adynamic ileus, in which the bowel proximal to the lesion is dilated and filled with fluid. Intestinal organisms may pass through the damaged wall and cause peritonitis or septicemia.

NONOCCLUSIVE INTESTINAL ISCHEMIA: In this setting, the principal lesion is restricted initially to the mucosa. Mucosal changes range from foci of dilated capillaries with a

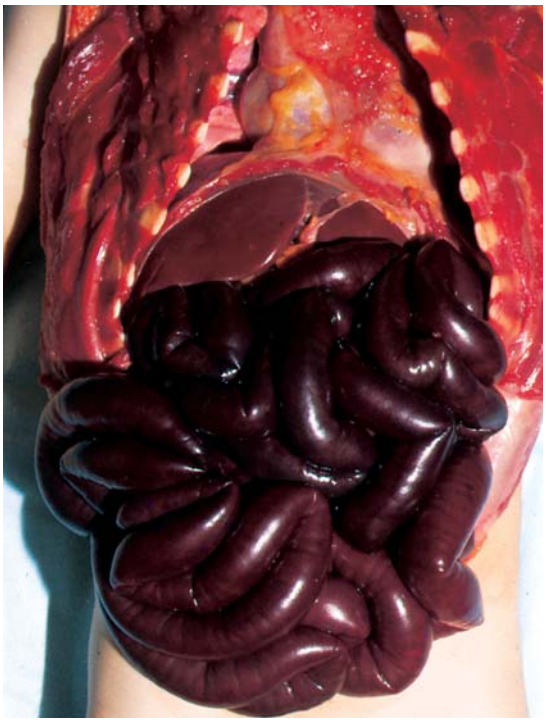

FIGURE 19-50. Infarcted small bowel at autopsy of an infant who died after volvulus had occluded the superior mesenteric artery. The entire small bowel is dilated, hemorrhagic and necrotic.

few extravasated erythrocytes to severe hemorrhagic necrosis and bleeding into the lumen. If the patient survives the episode of hypoperfusion, the bowel may be completely repaired, or it may heal with granulation tissue and fibrosis, with eventual **stricture formation**.

CLINICAL FEATURES: Symptoms of acute ischemia include abdominal pain, which begins abruptly, often with bloody diarrhea, hematemesis and shock. In untreated cases, perforation is frequent. As infarction progresses, systemic symptoms become more severe (multiple organ dysfunction syndrome). In extensive infarction that is a result of occlusion in the proximal superior mesenteric artery, almost the entire small bowel must be resected, a situation not compatible with ultimate survival.

Atherosclerotic narrowing of major splanchnic arteries leads to chronic intestinal ischemia. As in the heart, it causes intermittent abdominal pain, called intestinal (abdominal) angina. The pain usually starts within a half hour of eating and lasts for a few hours. Frank intestinal infarction may be heralded by abdominal angina. Recurrent abdominal pain may also reflect pressure on the celiac axis from surrounding structures, called the celiac compression syndrome.

Chronic Small Bowel Ischemia

Chronic vascular insufficiency of the small intestine may lead to fibrosis and stricture formation. Ischemic strictures of the small bowel may be single or multiple and produce intestinal obstruction or, occasionally, malabsorption owing to stasis and bacterial overgrowth. These strictures are concentric, and the mucosa of this region is atrophic, often with one or more small ulcers. The submucosa is thickened and fibrotic with granulation tissue, which may involve the muscular layers. Hemosiderin deposition may be seen, particularly near the muscularis mucosae.

CROHN DISEASE

Crohn disease can involve any part of the gastrointestinal tract, but the small intestine, in particular the terminal ileum, is its main target. Its involvement is transmural and patchy, marked by an inflammatory process characterized by lymphoid aggregates and often granulomas (Fig. 19-51). Its etiology remains unknown, but in recent years information concerning its genetic associations has been accumulating rapidly. This and the pathologic features are described in more detail in the colonic section. Of note, the "fat wrapping" (Fig. 19-52A), a favorite sign of the disease for surgeons, is best seen in the small intestine; it is a result of transmural disease. Likewise, the phenomenon of cobblestoning (Fig. 19-52B) and the linear ulcers that are so characteristic are also best seen within the small intestine. The transmural involvement with subsequent luminal narrowing often produces obstructive symptoms related to the small intestine, one of the major debilitating symptoms of Crohn disease. Likewise, intestinal fistulas (Fig. 19-53A–C) between loops of intestine are often a major clinical problem.

The differential diagnosis includes NSAID-related damage, infection and radiation-related strictures. NSAIDs are known to cause solitary ulcers and diaphragm-like strictures, usually more proximally in the small intestine. More subtle changes, including erosive and shallow ulcers with associated inflammation that occur in the distal ileum, can occur even with low-dose NSAIDs. These can cause great diagnostic difficulty in terminal ileal biopsies.

INFECTIONS AND TOXINS

Infectious diarrhea is particularly lethal in underdeveloped countries and in infants. In countries with poor sanitation,

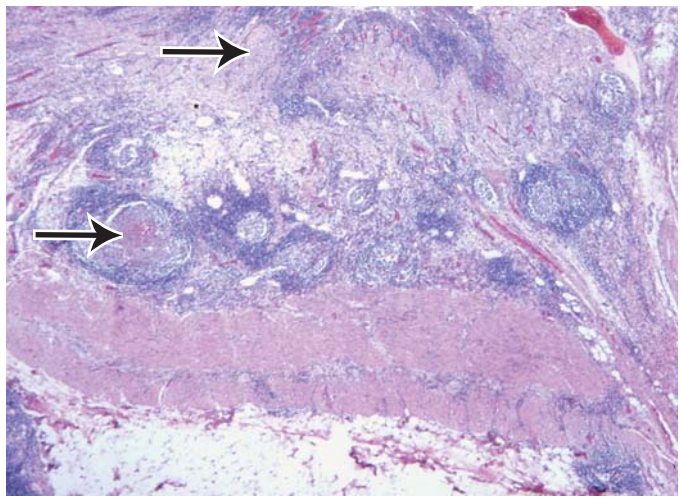

FIGURE 19-51. This full-thickness histologic section shows transmural involvement by lymphoid aggregates and granulomas. The mucosa and submucosa (*arrows*) are most severely affected, but the infiltrate also involves muscle and mesentery. Note the tendency to be more severe in perivascular areas. See also Figure 19-72.

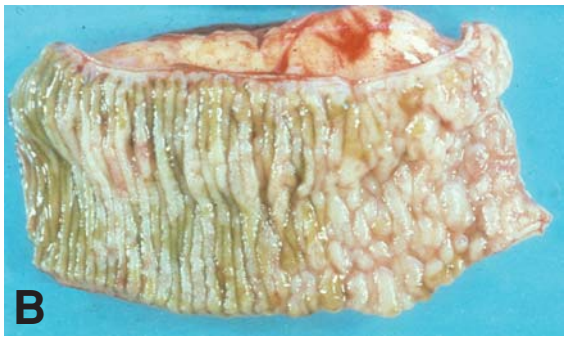

FIGURE 19-52. **A.** Fat wrapping is a manifestation of transmural involvement but is not always evident. **B.** The cobblestoning is a result of the patchy nature of **Crohn** disease. See also Figure 19-71 for a linear ulcer.

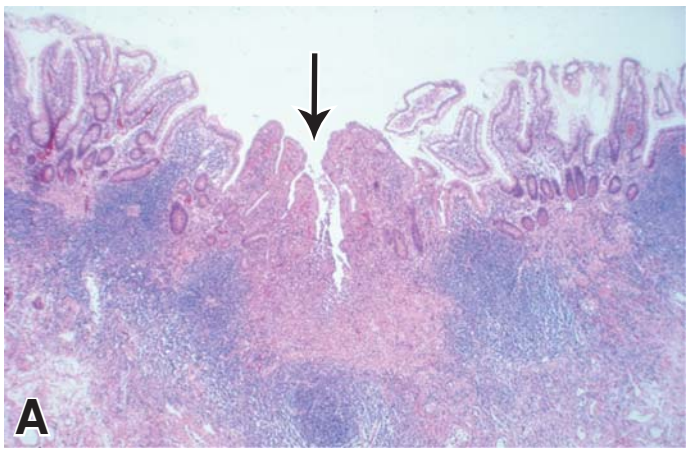
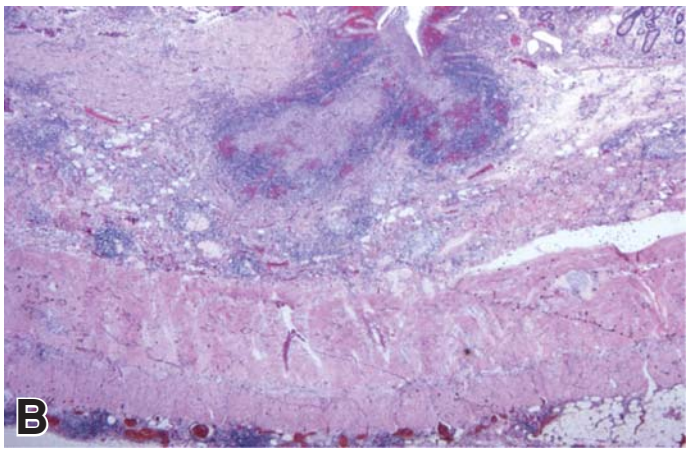
the death toll from childhood diarrhea is staggering: 1.5 million children under 5 years die annually of diarrhea, over 80% of them in Africa and south Asia.

The small bowel normally has few bacteria (usually $<10^4$/mL), mostly such bacilli as lactobacilli. These organisms travel in the food stream and ordinarily do not colonize the small intestine. Infectious diarrhea is caused by bacterial colonization (e.g., with toxigenic strains of *Escherichia coli* and *Vibrio cholerae*). The most significant factor in infectious diarrhea is increased intestinal secretion, stimulated by bacterial toxins and enteric hormones. Decreased absorption and increased peristaltic activity contribute less to the diarrhea.

The colon harbors abundant bacteria, at concentrations seven orders of magnitude greater than in the small intestine. Anaerobic bacteria in the colon (e.g., *Bacteroides* and *Clostridium* species) outnumber aerobic organisms 1000-fold. With the more rapid transit of intestinal contents during diarrhea, flora are shifted to more aerobic populations, including *E. coli, Klebsiella* and *Proteus.* Moreover, offending organisms themselves become conspicuous and pathogens of the small intestine such as *V. cholerae* may be the major isolate in the stool.

Several factors limit the numbers of bacteria in the stomach and small bowel: (1) gastric acid inhibits bacterial growth, which explains bacterial overgrowth in the stomach in achlorhydria; (2) bile has an antimicrobial activity; (3) peristalsis propels intestinal contents, limiting bacterial accumulation; (4) normal flora secrete their own antimicrobial





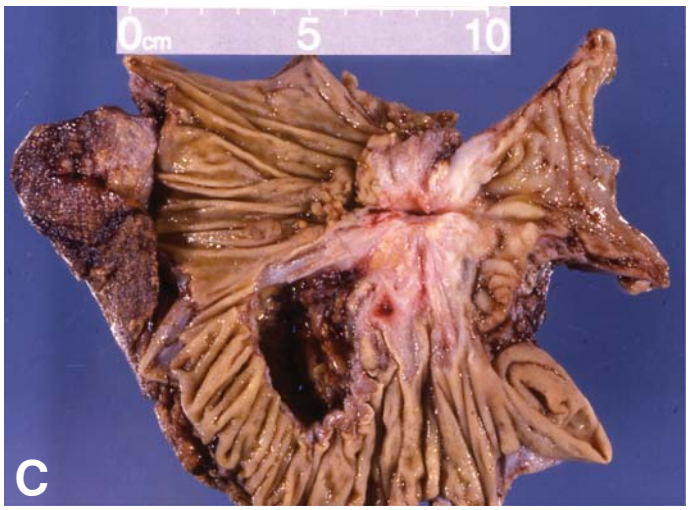


FIGURE 19-53. **A.** A small **fissure ulcer,** here knife-like (*arrow*), often starts over a lymphoid aggregate. **B.** The process continues, causing a fissure extending into the submucosa and beyond, ultimately penetrating the bowel wall. **C.** A **fistula** may result from such transmural involvement. Here an ileocolonic fistula has resulted.

TABLE 19-1
HISTOLOGIC PATTERNS OF BACTERIAL INFECTIONS OF THE GASTROINTESTINAL TRACT

Minimal inflammatory changes	*Vibrio cholerae* Toxigenic *Escherichia coli* *Neisseria* sp.
Acute self-limited colitis	*Shigella* *Campylobacter jejuni* *Aeromonas* *Salmonella* *Clostridium difficile*
Pseudomembranous pattern	*C. difficile* *Shigella* Enterohemorrhagic *E. coli*
Granulomas	*Yersinia* sp. *Mycobacterium bovis* *Mycobacterium avium-intracellulare* *Actinomycosis*

Lymphohistiocytic	*Lymphogranuloma venereum*
Architectural distortion	*Salmonella typhimurium* *Shigella*

substances to maintain an ecologic balance (indeed, treatment with broad-spectrum antibiotics alters the natural flora and allows overgrowth of ordinarily harmless organisms); and (5) plasma cells of the lamina propria secrete IgA into the intestinal lumen.

Individual agents responsible for infectious diarrhea are discussed in Chapter 9. Here we review the major entities only briefly. Agents of infectious diarrhea are classified into **toxigenic** (i.e., producing diarrhea by elaborating toxins) or as adherent or invasive bacteria (Table 19-1 lists reaction patterns).

Toxigenic Diarrhea Is Most Often Due to *Escherichia coli*

The prototypical organisms that cause diarrhea by secreting toxins are *V. cholerae* and toxigenic strains of *E. coli.*

The characteristics of toxigenic diarrhea are:

- Damage to the intestinal mucosal is minimal or absent.
- The organism remains on the mucosal surface, where it secretes its toxin.
- Fluid secreted into the small intestine causes watery diarrhea, which can lead to dehydration, particularly in the case of cholera.

Many organisms have been isolated in so-called travelers' diarrhea, but toxigenic *E. coli* is the most common in almost all studies.

Invasive Bacteria Cause Diarrhea by Direct Mucosal Injury

Among these invasive organisms, *Shigella, Salmonella,* and certain strains of *E. coli, Yersinia* and *Campylobacter* are the most widely recognized. Invasive organisms tend to infect the distal ileum and colon, while toxigenic bacteria mainly involve the upper intestinal tract. The mechanisms by which invasive bacteria produce diarrhea are uncertain. Enterotoxins have been identified, but their role in causing diarrhea is not established. Mucosal invasion by bacteria increases synthesis of prostaglandins in affected tissues, and inhibitors of prostaglandin synthesis seem to block fluid secretion. It also may be that damaged mucosa cannot absorb fluid from the lumen.

Shigella

Shigellosis, caused by any of the four species of the genus *Shigella,* mainly affects the colon, but the terminal ileum is occasionally involved. A granular and hemorrhagic mucosa has many shallow serpiginous ulcers. Inflammation is especially severe in the sigmoid colon and rectum, but is usually superficial. In the early stage, neutrophils accumulate in damaged crypts (crypt abscesses), similarly to in ulcerative colitis (see below), and the lymphoid follicles of the mucosa break down to form ulcers. Unlike ulcerative colitis (see below), signs of chronicity are not present. There is no crypt branching, and the dense lymphoplasmacytic infiltrate in the lamina propria is absent; inflammation tends to be superficial. As infection recedes, ulcers heal and the mucosa returns to normal.

Typhoid Fever

Typhoid fever (*Salmonella typhi* enteritis) is uncommon in the industrialized world but is still a problem in underdeveloped countries. Necrosis of lymphoid tissue, mainly in the terminal ileum, leads to scattered ulcers. Infection of Peyer patches results in oval ulcers, in which the longer dimension is in the long axis of the intestine. Occasionally, lymphoid follicles in the large bowel or the appendix are ulcerated. The base of the ulcer contains black necrotic tissue mixed with fibrin.

Early lesions of typhoid fever show large basophilic macrophages filled with typhoid bacilli, erythrocytes and necrotic debris. Necrosis of lymphoid follicles becomes confluent and mucosal ulceration follows. Similar lymphoid hyperplasia and necrosis are seen in regional lymph nodes. Within a week of the acute symptoms, ulcers heal completely, leaving little fibrosis or other sequelae. Intestinal hemorrhage and perforation, principally in the ileum, are the most feared complications of typhoid fever and tend to occur in the third week and during convalescence.

Nontyphoidal Salmonellosis

Formerly known as **paratyphoid fever,** enteritis caused by *Salmonella* strains other than *S. typhi* is generally far less serious than typhoid fever. The principal target is the ileum, but minor involvement of the colon may also occur. Organisms invade the mucosa, which shows mild ulceration, edema and infiltration with neutrophils. Hematogenous dissemination from the intestine may carry infection to bones, joints and

meninges. People with sickle cell disease tend to develop *Salmonella* osteomyelitis, possibly because phagocytosis of products of hemolysis prevents further cellular ingestion of the organisms and allows their dissemination through the bloodstream.

Escherichia coli

Enteroinvasive, enteroadherent and enterohemorrhagic strains of *E. coli* may uncommonly cause bloody diarrhea similar to shigellosis and are a prominent cause of traveler's diarrhea. Certain strains of *E. coli,* particularly serotype 0157:H7, produce *Shigella*-like toxins, but the role of these proteins in the pathogenesis of the enterocolitis is not understood. Serotype 0157:H7 has also been implicated in the hemolytic–uremic syndrome in children.

Yersinia

Yersinia enterocolitica and *Yersinia pseudotuberculosis* are transmitted by pets or contaminated food, and infection is most common in young children. *Yersinia* infection causes diarrhea, cramps and fever and lasts 1–3 weeks. Peyer patches are hyperplastic, with acute ulceration of overlying mucosa. A fibrinopurulent exudate covering the ulcers often contains many organisms.

In addition to causing enterocolitis, *Yersinia* causes acute mesenteric adenitis and right lower quadrant pain. It may so resemble appendicitis that infected children have mistakenly been taken to laparotomy for *Yersinia* infection. Lymph nodes show epithelioid granulomas with central necrosis in the case of *Y. pseudotuberculosis.* The ileum and appendix may contain similar granulomas, imparting an appearance that resembles that of Crohn disease.

Adults, who are less susceptible to *Yersinia* infection than are children, have acute diarrhea, often followed within a few weeks by erythema nodosum, erythema multiforme or polyarthritis. Patients with chronic debilitating diseases may develop *Yersinia* bacteremia, resistant to antibiotic treatment. Interestingly, people with thalassemia are particularly susceptible to *Y. enterocolitica* infection. Identification by culture can be difficult; PCR analysis is effective.

Campylobacter jejuni

Campylobacter jejuni is one of the most common causes of bacterial diarrhea, with a higher incidence than nontyphoidal *Salmonella* and *Shigella* in some U.S. studies. In a report from Great Britain, *Campylobacter* caused half of bacterial diarrhea. Humans contract the disease mainly by contact with infected domestic animals or by eating poorly cooked or contaminated food. The histology is similar to that of *Shigella.* Adults usually recover in less than 1 week.

Food Poisoning Reflects Bacterial Toxins in Contaminated Food

STAPHYLOCOCCUS AUREUS: *S. aureus* is a common cause of food poisoning. Symptoms result from eating food contaminated with *Staphylococcus* strains that make an exotoxin that damages gastrointestinal epithelium. Severe vomiting and abdominal cramps occur within 6 hours, often followed by diarrhea. Most patients recover in 1–2 days.

CLOSTRIDIUM PERFRINGENS: This bacterium produces an enterotoxin that causes vomiting and diarrhea. The organism is anaerobic but tolerates exposure to air for up to 3 days. Enterotoxin activity is maximal in the ileum. In most cases, watery diarrhea and severe abdominal pain begin 8–24 hours after ingestion of contaminated food and last about 1 day.

Rotavirus and Norwalk Virus Are the Most Common Causes of Viral Gastroenteritis in the United States

ROTAVIRUS: Rotavirus infection is a common cause of infantile diarrhea. It accounts for about half of acute diarrhea in hospitalized children younger than 2 years. Rotavirus has been demonstrated in duodenal biopsy specimens. It is associated with injury to the surface epithelium and impaired intestinal absorption for periods of up to 2 months.

NORWALK VIRUSES: These highly infectious agents account for one third of the epidemics of viral gastroenteritis in the United States. There have been a number of notorious outbreaks on cruise ships of late. The virus targets the upper small intestine, causing patchy mucosal lesions and malabsorption. Vomiting and diarrhea are usual, but symptoms resolve within 2 days.

Other viruses implicated as etiologic agents of infective diarrhea include echovirus, coxsackievirus, cytomegalovirus, adenovirus and coronavirus.

Intestinal Tuberculosis Is Mostly Caused by Ingesting Bacteria in Food or Swallowing Infectious Sputum

The tubercle bacillus (either *Mycobacterium tuberculosis* or *Mycobacterium bovis*) is protected from gastric acid by its waxy capsule and passes into the small bowel. There, it establishes a locus of infection, usually (90% of patients) in the ileocecal region, where lymphoid tissue is abundant. Infection also occurs in the colon, jejunum, appendix, rectum and duodenum, in that order of frequency.

PATHOLOGY: Intestinal tuberculosis may present with ulcers of varying size in the transverse plane of the bowel. As these ulcers heal, reactive fibrosis may cause a circumferential ("napkin ring") stricture of the bowel lumen. Mesenteric lymph nodes are typically enlarged, with caseous necrosis.

Granulomas occur in all layers of the bowel wall, particularly Peyer patches and lymphoid follicles. Tuberculous strictures are difficult to distinguish from other causes of stricture, such as ischemic enterocolitis or Crohn disease.

CLINICAL FEATURES: Almost all patients with intestinal tuberculosis complain of chronic abdominal pain and 2/3 have a palpable abdominal mass, usually in the right lower quadrant. Malnutrition, weight loss, fever and weakness are common. Complications include obstruction, fistulas, perforation and abscess.

NEOPLASMS

Despite the length and large surface area of the small intestine, primary small intestinal neoplasms occur less commonly than do those in the esophagus, stomach or colon.

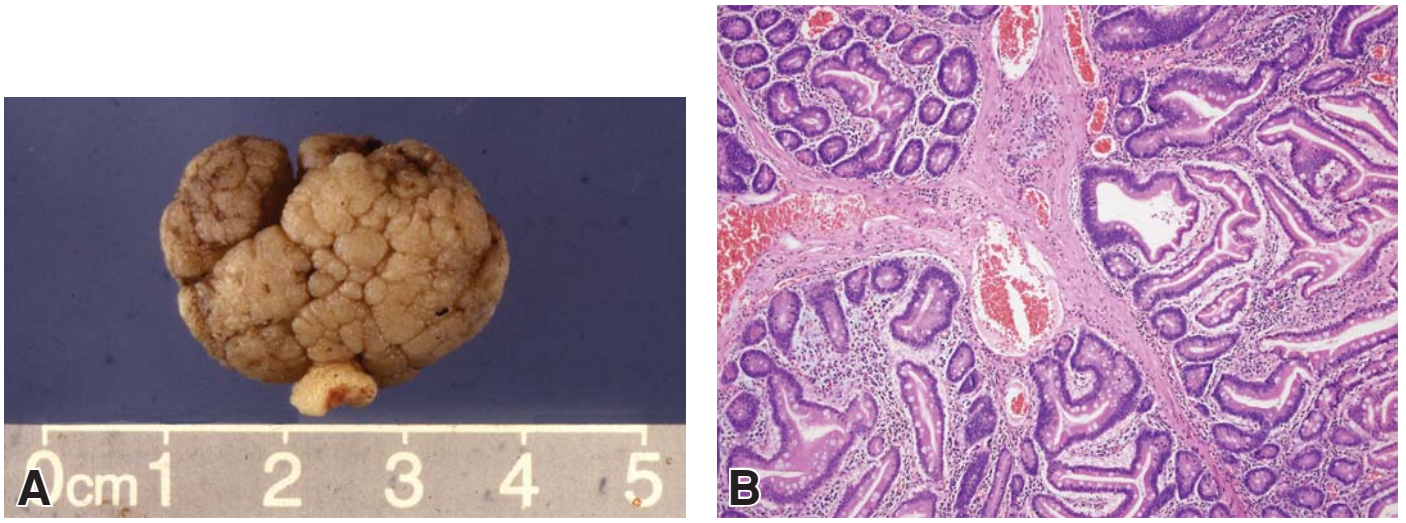

FIGURE 19-54. **A.** This **Peutz-Jeghers polyp** has a characteristic striking bosselated appearance. **B.** The histology is characterized by arborizing bundles of smooth muscle. The epithelium and glands between closely resemble the bland appearance of their normal counterparts but form an unusual architectural configuration.

Benign Neoplasms

Small Bowel Adenomas Resemble Those in the Colon

They are, however, far less common. Also, unlike the colon, they are not known to be frequent precursors to adenocarcinoma. They occur sporadically and are also seen commonly in FAP.

Peutz-Jeghers Polyps Are Hamartomas

Polyps in this syndrome may occur anywhere in the GI tract but are most common in the small intestine. They have a characteristic gross and microscopic (Fig. 19-54A,B) appearance. Bland-appearing small intestinal epithelium, often with an unusual architectural arrangement, is intermixed with large arborizing branches of smooth muscle. This autosomal dominant disorder is characterized by buccal pigmentation and macular lesions on the lips, hands, feet and genitals. Most patients have mutations in the *LKB1* tumor suppressor gene (on chromosome 19p13.3; see Chapter 5). There is an increased risk for cancer, largely outside the gastrointestinal tract, involving the testis, ovary, uterus or pancreas.

Malignant Tumors Are Far Less Common in the Small Intestine Than Elsewhere in the GI Tract

Adenocarcinoma

These tumors resemble their colonic counterparts but are much less frequent. They occur more often proximally, particularly in the duodenum. They can be polypoid or ulcerated or have a peculiar constricted napkin ring appearance (Fig. 19-55A,B). There is a much greater (80-fold) risk of small bowel adenocarcinoma in patients with Crohn disease or celiac disease. In the former, the tumors arise distally, in inflamed intestine. These tumors are also increased in FAP and Peutz-Jeghers syndrome.

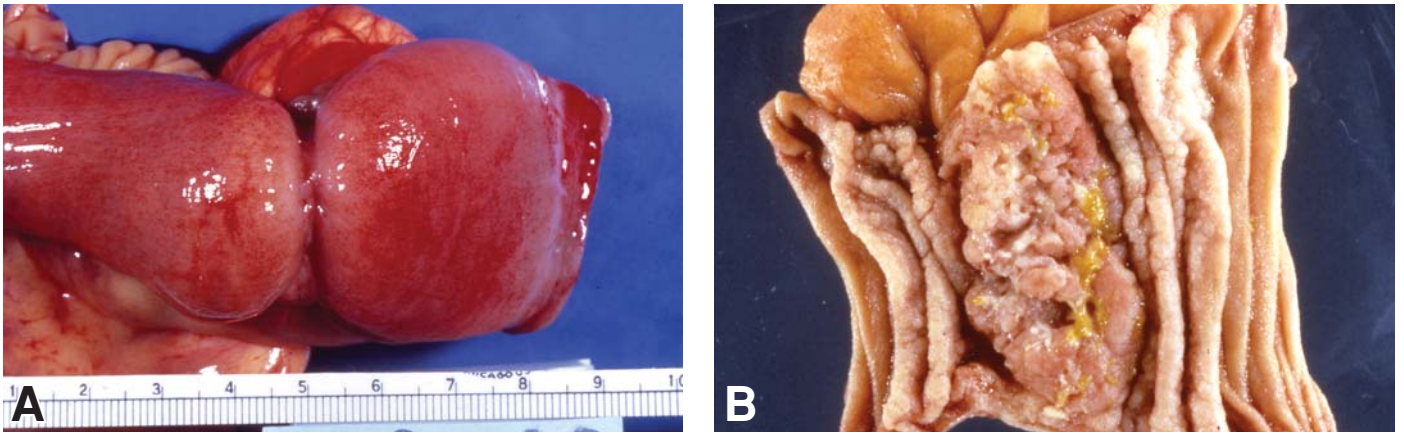

FIGURE 19-55. **A.** The external aspect of a small intestinal **adenocarcinoma** often has this peculiar constricted appearance. **B.** The luminal tumor is usually raised and often ulcerated, resembling its colonic counterpart.

FIGURE 19-56. This mucosal-covered **gastrointestinal stromal tumor (GIST)** has a striking area of deep central ulceration.

Metastases

Secondary carcinomas are about as common as are primary adenocarcinomas in the small intestine. The primary tumor may be of any origin, but melanomas and tumors of the lung, breast, colon and kidney are the most common. Careful attention to historical and histologic detail is necessary to establish the diagnosis.

Gastrointestinal Stromal Tumors

The small intestine is second to the stomach in the incidence of these tumors. Those arising in the small intestine are more likely to behave aggressively. They frequently have a deep central ulceration, which can cause severe bleeding (Fig. 19-56). These GISTs tend more to be composed of spindled cells than gastric GISTs, which often have areas with an epithelioid appearance.

Neuroendocrine Tumors (Carcinoid Tumors)

As noted above, the term **neuroendocrine tumors** has largely replaced "carcinoid" in designating these tumors. All NETs are considered malignant, but they vary greatly in their metastatic potential. The GI tract is the most common site for NETs (the bronchus being the next most common site). In addition to the site of origin, the size, depth of invasion, hormonal responsiveness and presence or absence of function are major indicators of likely aggressiveness.

The appendix is the most common gastrointestinal site of origin, followed by the rectum; these tumors are usually innocuous. Tumors of the ileum are usually small but are often quite aggressive.

PATHOLOGY: Small NETs usually present as submucosal nodules covered by intact mucosa. Larger tumors may grow in polypoid, intramural or annular patterns and often undergo secondary ulceration. Cut surfaces are firm and white to yellow. As they enlarge, the tumors invade the muscular coat and penetrate the serosa, often causing a conspicuous desmoplasia, which can lead to peritoneal adhesions, kinking of the bowel and possible intestinal obstruction. Ileal NETs are multiple in about 40% of cases (Fig. 19-57A,B).

Small, round cells in NETs form nests, cords and rosettes. Occasional gland-like structures are also seen (hence the term "carcinoid"). Nuclei are remarkably regular and mitoses are rare. The abundant eosinophilic cytoplasm contains neurosecretory-type granules. Despite their bland appearance, jejunal and ileal tumors behave more aggressively than do similar-appearing NETs originating at other sites.

When these tumors metastasize to regional lymph nodes, they may produce a bulky mass far larger than the primary tumor. Subsequent hematogenous spread causes metastases at distant sites, particularly the liver. Patients occasionally present with a huge amount of metastatic NETs in the liver, all due to a small, clinically silent primary tumor in the ileum.

CLINICAL FEATURES: **Carcinoid syndrome** occurs in a small percentage of patients with NETs. It is a unique but uncommon clinical condition caused by release of active tumor products. Most NETs are somewhat functional, but carcinoid syndrome mainly occurs in patients with extensive hepatic metastases. *Classic symptoms include diarrhea (often the most distressing symptom), episodic flushing, bronchospasm, cyanosis, telangiectasia and skin lesions.* Half of patients also have right-sided cardiac valvular disease (see Chapter 17). Diarrhea is thought to be caused by serotonin.

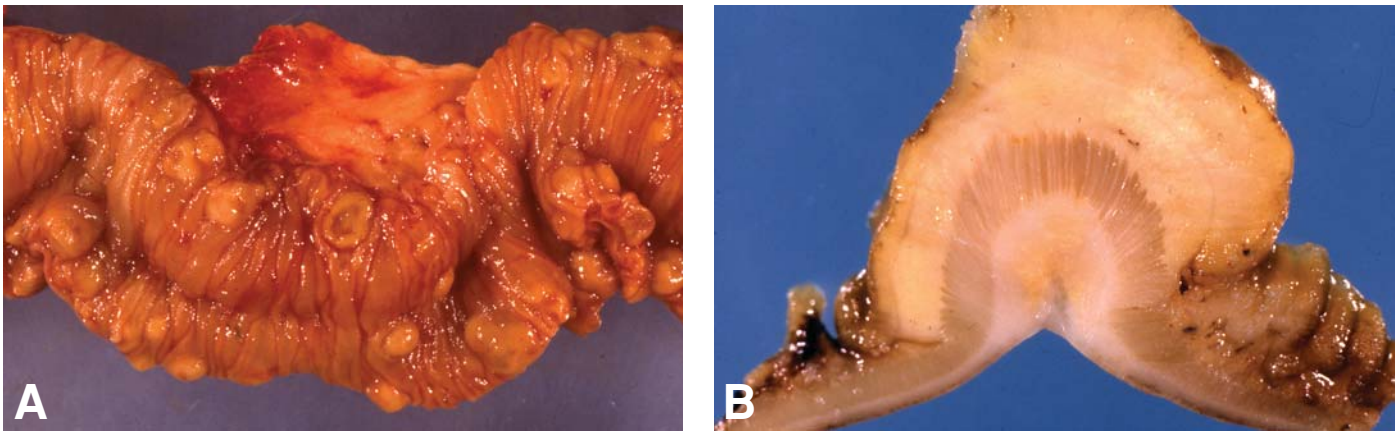

FIGURE 19-57. **A. Ileal neuroendocrine tumors (NETs)** are frequently multiple, here producing several mucosal-covered pale yellow tumors. **B.** The frequent characteristic "knuckling" of the intestinal wall is due to the brisk fibrous response to the invading tumor.

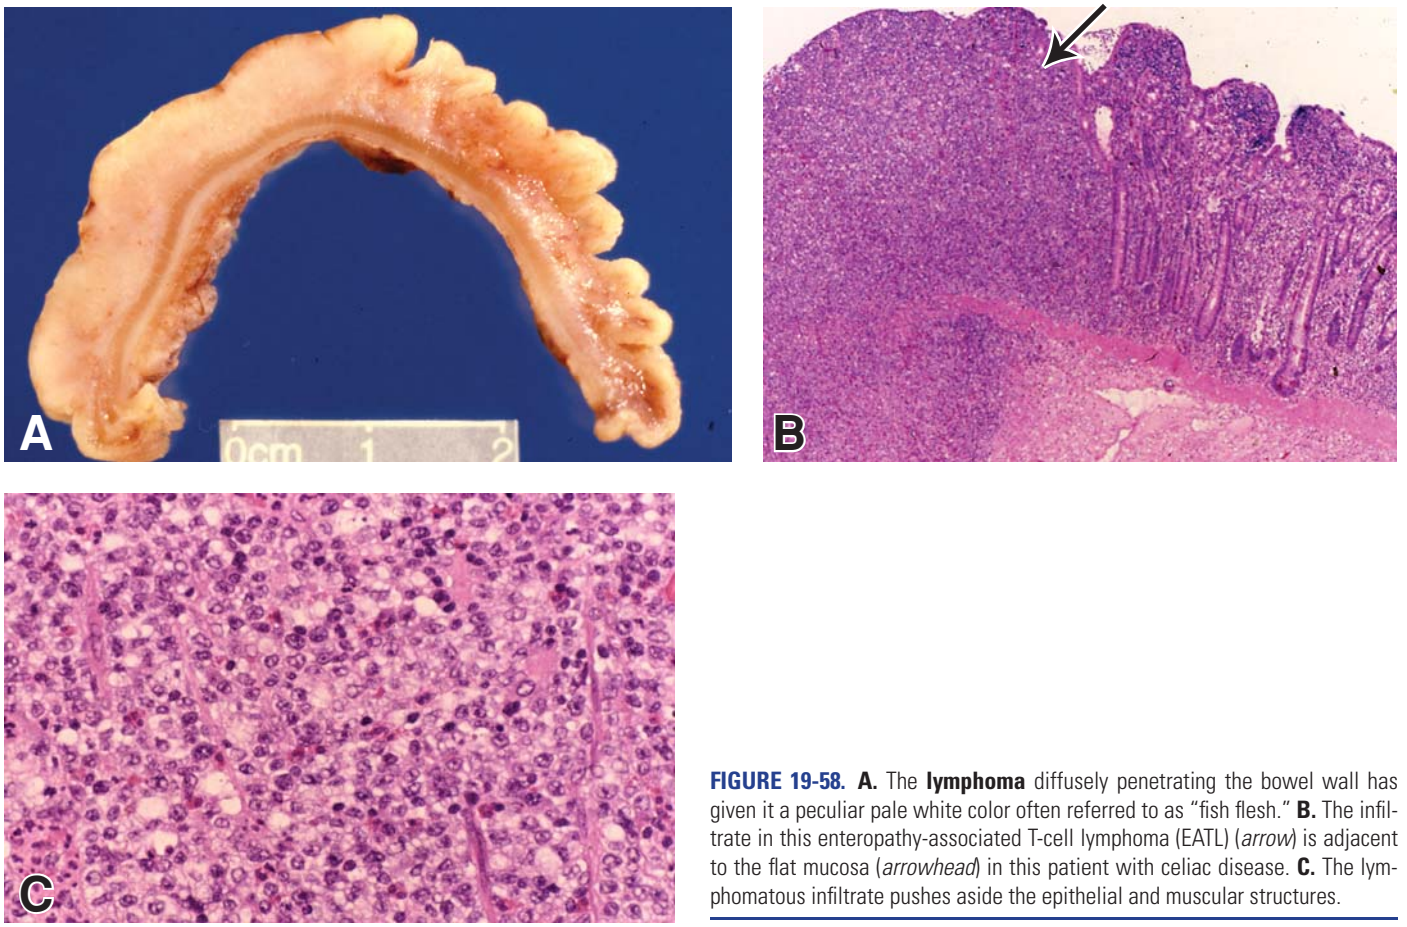

FIGURE 19-58. A. The **lymphoma** diffusely penetrating the bowel wall has given it a peculiar pale white color often referred to as "fish flesh." **B.** The infiltrate in this enteropathy-associated T-cell lymphoma (EATL) (*arrow*) is adjacent to the flat mucosa (*arrowhead*) in this patient with celiac disease. **C.** The lymphomatous infiltrate pushes aside the epithelial and muscular structures.

After its release into the blood, serotonin is metabolized to 5-hydroxyindoleacetic acid (5-HIAA) by monoamine oxidase (MAO) in the liver or other tissues. Urine 5-HIAA is a diagnostic test for carcinoid syndrome. Liver, lung and brain all have high levels of MAO activity, but the right side of the heart is affected mainly when there are metastases in the liver, allowing secreted serotonin to bypass hepatic detoxification. Fibrous plaques form on tricuspid and pulmonic valves, the endocardium of the right-sided cardiac chambers, the vena cava, the coronary sinus and the pulmonary artery. Valvular distortion leads to pulmonic stenosis and tricuspid regurgitation.

Lymphoma

Four major types of lymphoma occur in the small intestine (see Chapter 26): Burkitt lymphoma, immunoproliferative small intestinal disease (Mediterranean lymphoma), diffuse large B-cell lymphoma ("Western" lymphoma) and enteropathy-associated intestinal T-cell lymphoma (EATL).

Burkitt lymphoma develops mainly in the terminal ileum of children, with males predominating. The tumors form bulky masses. The B cells composing the tumor may have a plasmacytoid appearance. Many cases are EBV positive. The process can be seen in young adults who have some immunodeficiency; some are HIV positive.

Patients with immunoproliferative small intestinal disease (IPSID) are most commonly young adults of a lower socioeconomic status living in the Middle East. It appears to be a distinctive type of extranodal marginal B-cell lymphoma. Environmental factors are thought to play a role, and there is evidence implicating *C. jejuni*. Abdominal pain, malabsorption, diarrhea and weight loss dominate the clinical picture. Diffuse mural thickening with luminal dilatation is often present. Free α–heavy chains are often found in the serum. An extensive mucosal lymphoid infiltrate may distort small intestinal villi.

Diffuse large B-cell lymphoma often presents as a large luminal mass in an older adult. It tends to be quite aggressive.

EATL complicates celiac disease, which may be long-standing but can be of short duration (Fig. 19-58A–C). Severe malnutrition despite adherence to a gluten-free diet often heralds its onset. It has the worst prognosis of the intestinal lymphomas.

The Ampulla

ANATOMY

The ampulla is unique and of great importance since it is the confluence of three major organs, the liver, pancreas and small intestine. In most individuals, the common bile duct and the main pancreatic duct meet to form a common chamber, the ampulla (Fig. 19-59). There are several variations in anatomy, the most common being that the two ducts empty

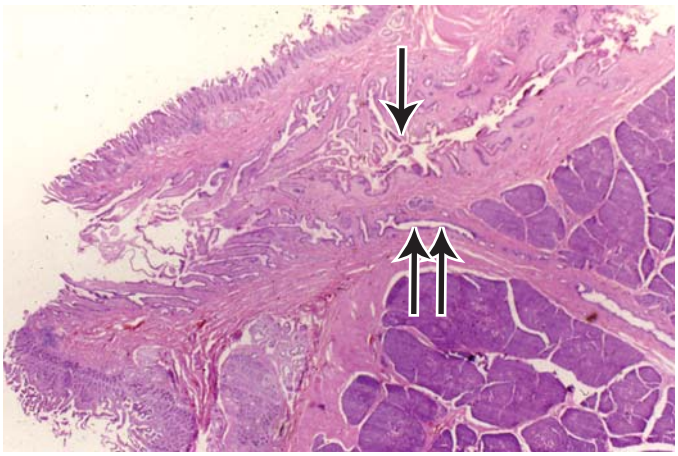

FIGURE 19-59. Small intestinal mucosa covers the protruding **papilla of Vater.** There is a common chamber, the **ampulla** (*arrowhead*), where the common bile duct (*arrow*) and the pancreatic duct (*double arrow*) meet.

separately into the duodenum, separated by a thin septum. Regardless, this meeting of the ducts projects into the duodenal lumen as the papilla of Vater.

The well-known relationship of gallstones to pancreatitis reflects the intimate proximity of the related ducts. Inflammatory processes can affect the periampullary area, causing clinical symptoms, and potentially mimicking neoplasia. The inflammation may be nonspecific or related to infection, such as involvement by *Cryptosporidia* or CMV in immunosuppressed individuals. Significant ampullitis may be a major feature of IgG4-related autoimmune pancreatitis.

NEOPLASMS

The ampulla and periampullary area is a common site for small intestinal neoplasms. There are occasional benign proliferations of smooth muscle and epithelium, so-called adenomyomatous hyperplasia. Adenomas may also occur here. They can be sporadic but are particularly frequent in individuals with familial adenomatous polyposis.

NETs also tend to arise in this location. Some develop as part of neurofibromatosis, produce somatostatin and are known as somatostatinomas.

Adenocarcinoma involving the ampulla may arise from the duct in the head of the pancreas, from the distal common bile duct, from the ampullary epithelial lining itself (Fig. 19-60A,B) or from the duodenal mucosa of the surface of the papilla or periampullary area.

Adenocarcinomas are by far the most common malignancy in the area. Most probably arise from preexisting adenomas. Because of their crucial anatomic location, tumors may present clinically with jaundice even when relatively small. Tumors may have an intestinal or a pancreaticobiliary phenotype. The former tend to have a somewhat better prognosis.

The Appendix

The appendix is a true diverticulum of the cecum. Its histology is the same as that of the colon from which it arises, although the submucosal lymphoid tissue is particularly robust, especially in childhood.

APPENDICITIS

The most important disease of the appendix is acute appendicitis (Fig. 19-61). This may occur at any age, but children and adults over 60 are most affected. The familiar presenting sign is right lower quadrant pain, which, if not treated, is followed by signs of peritoneal inflammation. Treatment is surgical removal. It must be admitted that the genesis of appendicitis remains largely mysterious. In many there appears to be some component of luminal obstruction by lumps of fecal concretions known as fecaliths. However, these are often not present. On occasion, a specific infectious agent is identified, such *Yersinia, Actinomyces* or *Campylobacter.* In some children, a tangle of pinworms (*Enterobius vermicularis*) may contribute to luminal obstruction.

However, in most cases, there is no apparent specific infectious agent. There is often a mucosal erosion or ulceration,

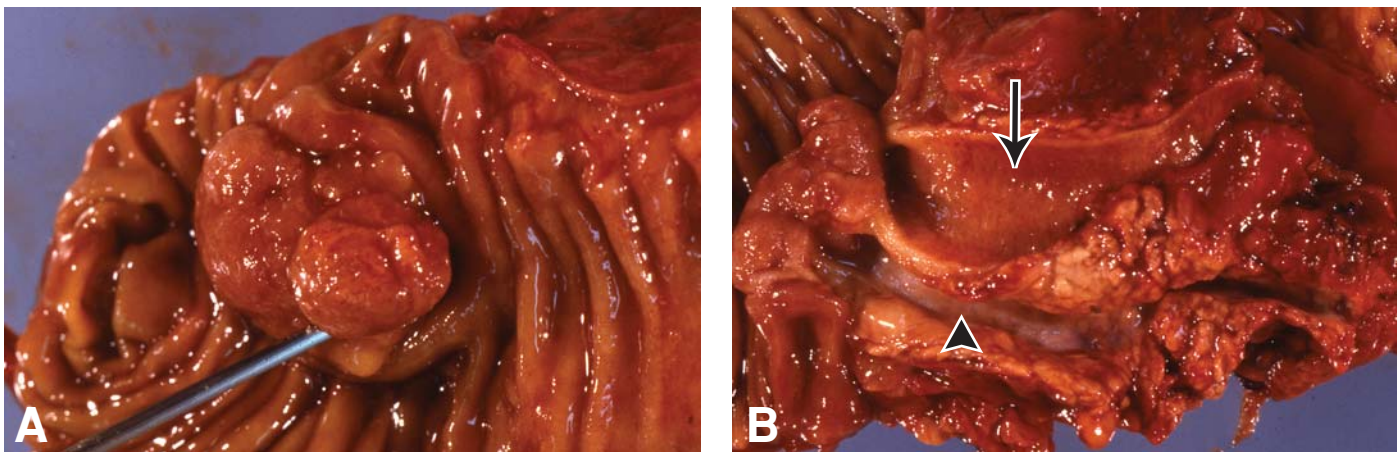

FIGURE 19-60. A. A probe was placed into the ampulla and common bile duct in this carcinoma of the ampulla. **B.** Upon dissection, both the common bile duct (*arrow*) and the pancreatic duct (*arrowhead*) are dilated owing to obstruction by the tumor.

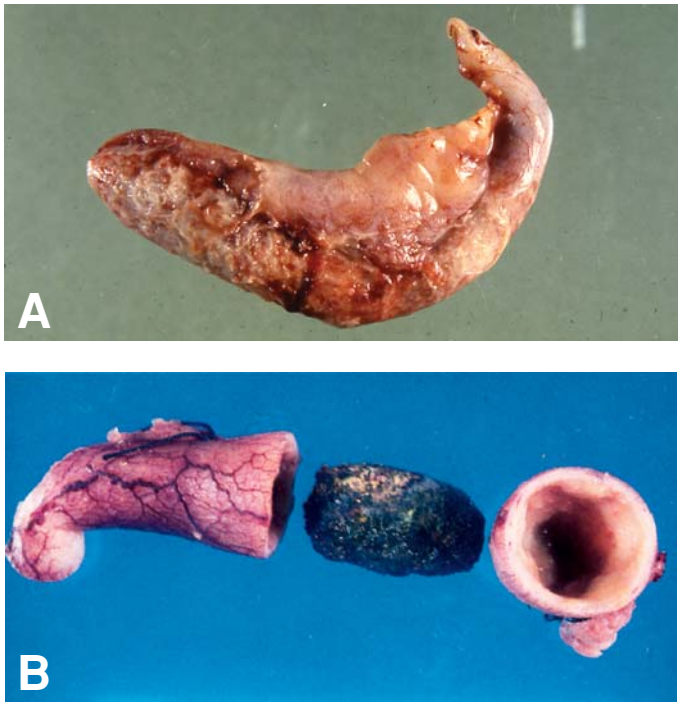

FIGURE 19-61. **A.** The distal appendix is dilated, congested and partly covered by fibrin (*arrow*) in this case of **appendicitis. B.** The lumen in this case of appendicitis was dilated owing to a large **fecalith.**

FIGURE 19-62. An oval yellow 1.1-cm **neuroendocrine tumor** was found incidentally in this appendix removed for appendicitis.

followed by a transmural infiltrate of neutrophils. Care must be taken not to confuse an acute inflammatory process centered in the subserosal area with acute appendicitis. Such periappendicitis reflects secondary involvement of the appendix from an external source, such as pelvic inflammatory disease involving the ovary or fallopian tube.

Granulomatous appendicitis may represent involvement by Crohn disease (see above) or an infectious agent. However, most granulomas involving the appendix involve neither of these entities and are of unknown cause and significance.

A **mucocele** is a distended appendix filled with mucinous material. Rarely these are due to inflammation causing focal luminal obstruction; these lesions rarely exceed 2 cm in diameter. More commonly, a dilated mucin-filled appendix reflects a neoplastic process (see below).

APPENDICEAL NEOPLASMS

Appendiceal NETs Are Generally Benign

Neuroendocrine tumors are very common in the appendix. Most such tumors are quite small and benign and are found incidentally at the time of appendectomy. Large amounts of empirical data show that small (<1.5 cm) NETs of the appendix are of no clinical significance.

Most NETs of the appendix arise from ECs. These tumors are almost always under 1 cm in diameter. At this size, the behavior of these tumors is invariably clinically benign. They tend to be oval and located at the tip of the appendix (Fig. 19-62). Tumors between 1 and 2 cm in diameter show a low rate of metastasis (about 1%). Larger lesions are increasingly aggressive.

Epithelial Tumors Are the Most Clinically Important Appendiceal Neoplasms

The nomenclature and classification of appendiceal tumors is controversial and unsettled. Some lesions resemble hyperplastic polyps, adenomas or the serrated lesions of the colon (see below). When these become larger, they tend to resemble hybrids of these forms, accounting for the difficulty in classification.

Regardless of the precise nomenclature, it is important to realize that these are the most clinically important neoplasms of the appendix. They dilate the lumen and expand its length. Resulting structures have been called mucoceles, but these differ radically from the banal lesions described above. A better descriptive term is **cystadenoma** (Fig. 19-63) or **mucinous tumor**. The neoplastic epithelial lining of these

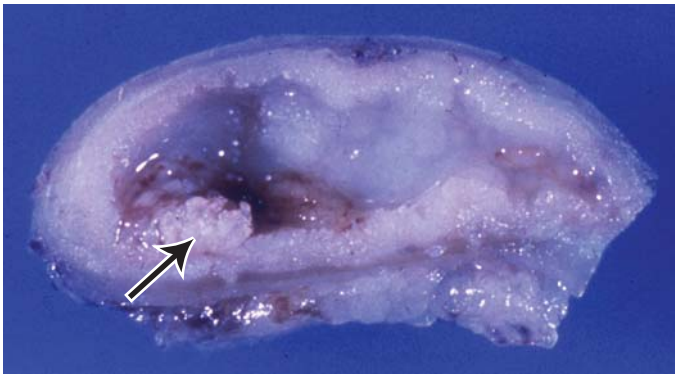

FIGURE 19-63. This **mucinous neoplasm** (*arrow*) has led to the dilatation of the appendix by massive mucin production producing a **cystadenoma.**

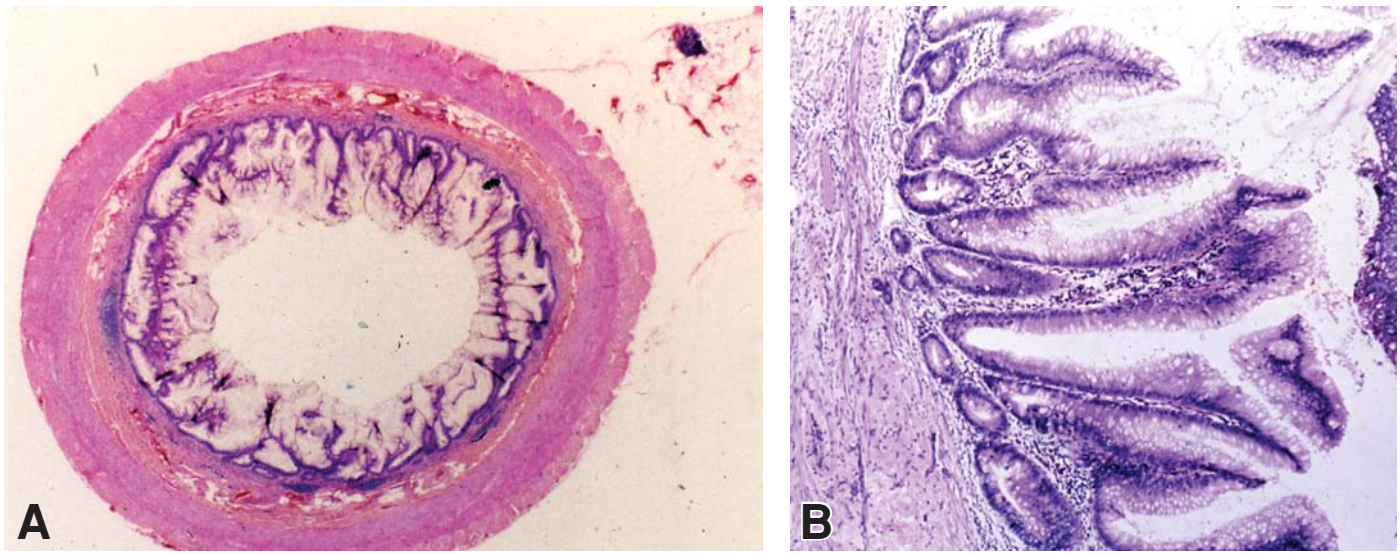

FIGURE 19-64. **A.** The mucinous neoplasm here encircles the entire lumen. **B.** At higher power its peculiar villous configuration is appreciated.

lesions is usually well differentiated (Fig. 19-64A,B) but can invade and penetrate the wall of the appendix. When this happens, abundant mucin may fill the peritoneal cavity, causing a lesion known as **pseudomyxoma peritonei** (Fig. 19-65). Rarely, neoplasms of the pancreas, gallbladder or stomach may cause a similar lesion. Some consider ovary to be another such organ of origin, but these cases usually prove to be appendiceal in origin.

Rarely, frank adenocarcinomas like their colonic counterparts are described.

The Large Intestine

ANATOMY

The large intestine is that portion of the gut from the ileocecal valve to the anus. It is 90–125 cm long in adults and includes the colon and rectum. The proximal colon derives from the embryonic midgut and is supplied by the superior mesenteric artery. The distal large intestine is of embryonic hindgut origin and is supplied by the inferior mesenteric artery. Its main function is to conserve water and salt and to store and dispose of waste material in the form of feces.

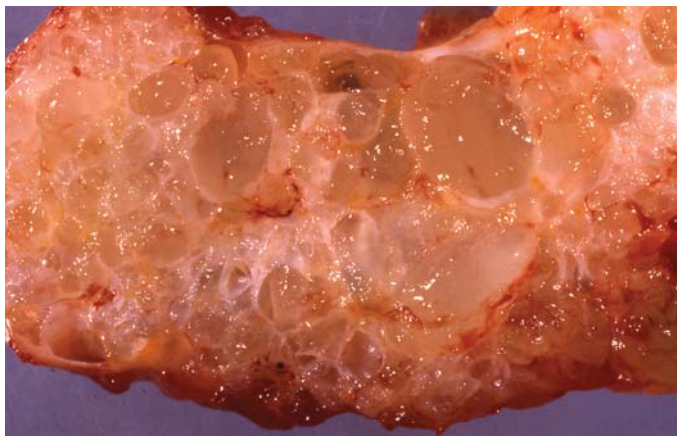

FIGURE 19-65. This large mass of mucin was removed from the abdomen of a patient with **pseudomyxoma peritonei** due to a mucinous tumor of the appendix.

MACROSCOPIC FEATURES: The large intestine has six regions, distally from the ileocecal valve: (1) cecum, (2) ascending colon, (3) transverse colon, (4) descending colon, (5) sigmoid colon and (6) rectum. The bend between the ascending and transverse colon in the right upper quadrant is the **hepatic flexure,** and that between the transverse and descending segments in the left upper quadrant is the **splenic flexure**. The lumen progressively narrows from the cecum to the sigmoid colon.

Like the small intestine, the colon has outer longitudinal and inner circular muscle coats. However, in the colon, the longitudinal muscle has three separate bundles, the **taeniae coli**. Evaginations of the colonic wall between taeniae, the **haustra,** appear as external sacculations. The appendices epiploicae are small serosal masses of fat, invested by peritoneum.

The ileocecal valve is a sphincter that regulates the flow of intestinal contents into the cecum. However, it is an incompetent sphincter, and reflux of cecal contents into the ileum is usual. The internal sphincter of the anal canal is continuous with colonic smooth muscle. The external anal sphincter is the major mechanism by which bowel continence is maintained. It surrounds the anal canal with a layer of skeletal muscle. The mucosal surface of the large bowel has prominent folds, which are less pronounced in the rectum.

MICROSCOPIC FEATURES: Colonic mucosa is flat and punctuated by numerous pits, the **crypts of Lieberkühn**. The surface epithelium is primarily simple columnar cells with occasional goblet cells. The crypts mostly contain goblet cells, except at their bases, where a few undifferentiated cells and a variety of neuroendocrine cells are located. The basal undifferentiated cells are the mucosa reserve cells and divide continuously. Mucosal cells migrate from crypt bases toward the luminal surface. Mucosal cells are sloughed, balancing proliferation and maintaining an equilibrium in the crypt epithelial cell population.

FIGURE 19-66. Hirschsprung disease. A contrast radiograph shows marked dilation of the rectosigmoid colon proximal to the narrowed rectum.

The lamina propria contains lymphocytes, plasma cells, macrophages and fibroblasts, plus occasional eosinophils. Lymphoid aggregates traverse the muscularis mucosae and extend into the submucosa. The submucosa is like that in the small intestine, but lymphatic channels are far less prominent. Colonic lymphatics drain into paracolic nodes in the mesenteric fat, intermediate nodes along the colic blood vessels and central nodes near the aorta. Parasympathetic and sympathetic innervations terminate in Meissner submucosal and Auerbach myenteric plexuses.

CONGENITAL DISORDERS

Hirschsprung Disease Is Due to Segmental Absence of Ganglion Cells

In Hirschsprung disease, colon dilation (Fig. 19-66) is due to defective colorectal innervation: ganglion cells are absent beginning in the internal anal sphincter and extending proximally for variable lengths (Fig. 19-67). In about 10% of cases, the whole colon is aganglionic; rarely, the small intestine is also involved. Hirschsprung disease affects 1 in 5000 live births; 80% of patients are male except in long segment disease where the male:female ratio is equal.

PATHOPHYSIOLOGY: The developmental sequence that leads to innervation of the colon is interrupted in Hirschsprung disease. The normal caudal migration of cells from the neural crest to the intramural ganglion cells is aborted. Since the internal anal sphincter is at the far end of this migration, the aganglionic segment always starts there. It may extend variably proximally, depending on where primitive neuroblast migration halts. Given that the aganglionic rectum, and sometimes the adjacent colon, are permanently contracted because of the absence of relaxation stimuli, fecal contents cannot readily enter the stenotic area. The proximal bowel becomes dilated because of functional distal obstruction.

MOLECULAR PATHOGENESIS: Most cases of Hirschsprung disease are sporadic, but 10% are familial. Half of familial cases, and 15% of sporadic ones, reflect inactivating mutations of the RET receptor tyrosine kinase gene on chromosome 10q (see MEN2 syndrome, Chapter 27). Some cases involve mutations in the endothelin-B receptor or genes that encode ligands of these two receptors.

The incidence of Hirschsprung disease is 1 in 300 in infants with Down syndrome, and Down syndrome is found in approximately 4% of all patients with Hirschsprung disease. Most cases are solitary lesions, but congenital anomalies of the kidneys and lower urinary tract, as well as imperforate anus and ventricular septal defects, are reported.

PATHOLOGY: The large intestine in Hirschsprung disease has a constricted and spastic aganglionic segment. Proximal to this, the bowel is very dilated. Definitive diagnosis requires demonstrating the

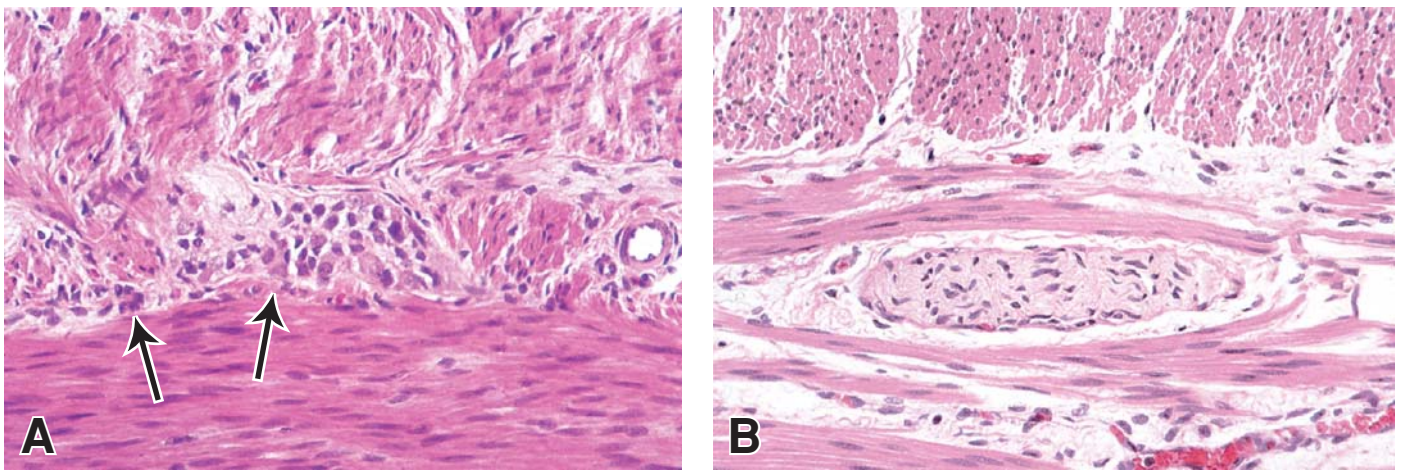

FIGURE 19-67. Hirschsprung disease. A. A photomicrograph of ganglion cells in the wall of a normal rectum (*arrows*). **B.** A rectal biopsy specimen from a patient with Hirschsprung disease shows a nonmyelinated nerve in the mesenteric plexus and an absence of ganglion cells.

absence of ganglion cells on rectal biopsy (Fig. 19-67B). There is also a striking increase in nonmyelinated cholinergic nerve fibers in the submucosa and between muscle coats (neural hyperplasia). The lack of ganglion cells leads to accumulation of acetylcholine and acetylcholinesterase, which are evident using histochemical staining. Calretinin immunohistochemistry aids in diagnosing Hirschsprung disease in rectal suction biopsies. Interestingly, like achalasia, which is caused by destruction of esophageal ganglion cells, Chagas disease may also cause aganglionic megacolon.

CLINICAL FEATURES: ***Hirschsprung disease is the most common cause of congenital intestinal obstruction.*** Typically, newborns show delayed passage of meconium and vomiting in the first few days of life. In some cases, complete intestinal obstruction may require immediate surgical relief. Children whose involved rectal segments are short may experience only partial obstruction, constipation, abdominal distention and recurrent fecal impactions.

The most serious complication is enterocolitis, in which necrosis and ulceration affect the dilated proximal segment of the colon and may extend into the small intestine. Hirschsprung disease is treated by surgical removal of the aganglionic segment and reconstruction.

Acquired Megacolon Is Any Cause of Constipation with Colonic Dilatation

Acquired megacolon sometimes occurs in children and often has a psychogenic component. In adults, acquired megacolon can result from disorders that interfere with bowel innervation or smooth muscle function, such as Chagas disease, diabetic neuropathy, Parkinsonism, myotonic dystrophy, scleroderma, amyloidosis and hypothyroidism.

Anorectal Malformations Often Accompany Other Developmental Defects

These malformations vary from minor narrowing to serious and complex defects. They result from arrested development of the caudal region of the gut in the first 6 months of fetal life. These anomalies are now categorized by their precise anatomic anatomy:

- **Anorectal agenesis and rectal atresia.**
- **Anal agenesis and anorectal stenosis.**
- **Imperforate anus** is a deformity in which the anal opening is covered by a cutaneous membrane behind which meconium is visible. **Anal stenosis** is a variant of imperforate anus.
- **Fistulas** between the rectum and perineum, bladder, urethra or vagina may occur alone or in association with other anorectal anomalies.

INFECTIONS OF THE LARGE INTESTINE

The principal infections of the colon, including tuberculosis and amebiasis, are discussed in Chapter 9 or above, in the context of small intestine infectious diarrhea. Most remaining infectious diseases are sexually transmitted and involve the anorectal region, often in men who have sex with men (MSM). These include gonorrhea, syphilis, lymphogranuloma venereum, anorectal herpes and HPV infections (venereal warts or condylomata acuminata). Immunosuppressed people have a high incidence of colonic infections (e.g., amebiasis, shigellosis). Bone marrow transplant recipients are at high risk for contracting CMV and herpesvirus infections involving the colon.

Pseudomembranous Colitis Usually Follows Antibiotic Treatment

Pseudomembranous colitis is a generic term for an inflammatory disease of the colon that is characterized by **exudative mucosal plaques**. It is most often caused by *C. difficile.*

ETIOLOGIC FACTORS: The major risk factor for developing *C. difficile* infection is antibiotic therapy. Virtually all antibiotics have been implicated, although some have been associated with a higher risk. Hospitalization is another major risk factor. About 1%–5% of adults are *C. difficile* carriers, but 30% of hospitalized patients become carriers. In elderly hospitalized patients, *C. difficile* carriage may approach 70%. Immunosuppression and underlying inflammatory bowel disease are also risk factors.

C. difficile is transmitted via the fecal–oral route and is ingested in vegetative form or as spores. When normal protective gut flora are killed by antibiotics, the more resistant *C. difficile* can gain a foothold and begin producing its toxins: toxins A and B. Toxin A activates and recruits inflammatory mediators, and toxin B is directly cytotoxic. ***It is important to note that* C. difficile *is not invasive and mediates damage via production of toxins.***

Other conditions that can produce pseudomembranes include various diseases of the colon, shock, burns, uremia and chemotherapy.

PATHOLOGY: The characteristic gross feature is raised yellowish plaques up to 2 cm that adhere to the underlying mucosa (Fig. 19-68). The intervening mucosa is congested and edematous, but not ulcerated. In severe cases, plaques coalesce into extensive pseudomembranes. Superficial epithelial necrosis is believed to be the initial pathologic event. Colonic crypts then become disrupted and expanded by mucin and neutrophils. The pseudomembrane consists of debris from necrotic epithelial cells, mucus, fibrin and neutrophils. In milder cases, well-formed pseudomembranes may be absent and the pathology is more subtle, with focal damage to the surface epithelium.

The entire colon is often involved and sometimes the small intestine is as well. If both small and large bowel are affected, the condition is called **pseudomembranous enterocolitis**. Pseudomembranes occur occasionally in ischemic colitis and in other enteric infections, most notably verotoxin-producing *E. coli.*

CLINICAL FEATURES: Antibiotic-associated *C. difficile* infections are virtually always accompanied by mild to moderate watery diarrhea, but the disorder does not usually progress to colitis. In patients with pseudomembranous colitis, fever, leukocytosis and abdominal cramps are superimposed on a severe diarrhea that can be bloody. In some cases, the disease can progress to fulminant colitis, which can lead to serious complications such as colonic perforation, toxic megacolon and death.

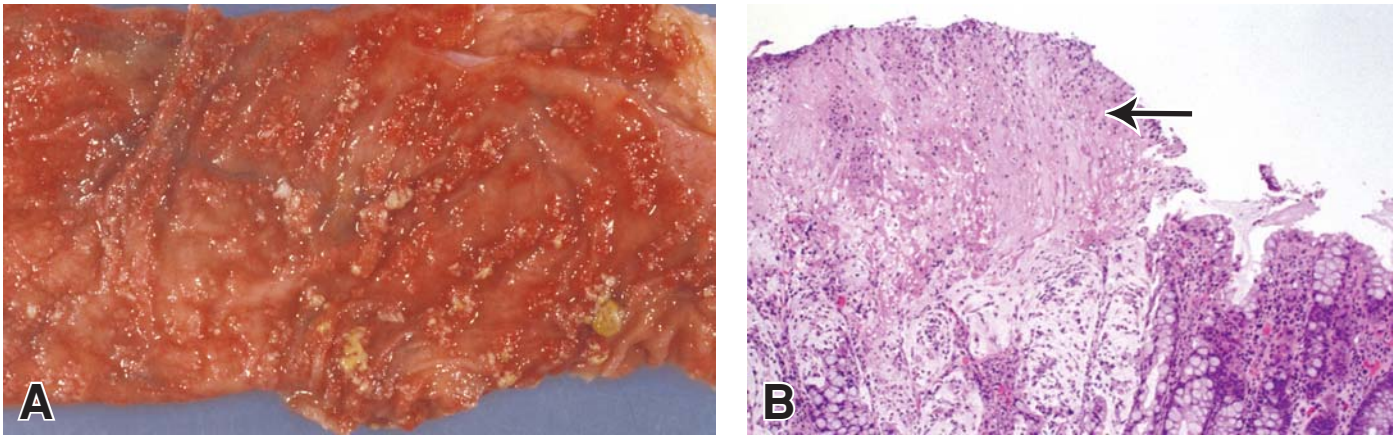

FIGURE 19-68. Pseudomembranous colitis. A. The colon shows variable involvement ranging from erythema to yellow-green areas of pseudomembrane. **B.** Microscopically, the pseudomembrane consists of fibrin, mucin and inflammatory cells (largely neutrophils).

The diagnosis is usually made by identifying toxins in stool by cytotoxin assay, enzyme-linked immunosorbent assay (ELISA) or molecular methods. *C. difficile* infections are treated with antibiotics (metronidazole or vancomycin) and supportive fluid and electrolyte therapy. It is important to withdraw the inciting antibiotic as soon as possible. In cases of fulminant colitis, colectomy may be necessary. *C. difficile* infection recurs in 1/5 of patients. Treatment for patients with multiple recurrences is replenishment of normal gut flora with a **"fecal transplant."** Preventing *C. difficile* transmission in hospitals is critically important in reducing the incidence of the disease.

Neonatal Necrotizing Enterocolitis Complicates Prematurity

Necrotizing enterocolitis is one of the most common acquired surgical emergencies in newborns. It is particularly common in premature infants after oral feeding and is likely related to an ischemic event involving the intestinal mucosa. This event is followed by bacterial colonization, usually with *C. difficile*, which is found in the stool of up to 50% of neonates. Lesions vary from those of typical pseudomembranous enterocolitis to gangrene and perforation of the bowel.

Gastrointestinal Infections Are Common Complications of AIDS

The AIDS epidemic has resulted in many gastrointestinal infections that were once considered rare. Most AIDS patients have chronic diarrhea. Virtually all forms of infectious agents—bacteria, fungi, protozoa and viruses—afflict these patients (Table 19-2).

Kaposi sarcoma in the gut is almost exclusively seen in AIDS patients, and up to half of such patients who have cutaneous Kaposi sarcoma also show digestive tract involvement. In most, intestinal Kaposi sarcoma does produce symptoms, although bleeding, obstruction and malabsorption have been reported.

A common presentation of lymphoma in AIDS patients is involvement of the gastrointestinal tract. Any portion of the gut may be affected. The histology and prognosis of these tumors in AIDS patients are similar to those elsewhere.

DIVERTICULAR DISEASE

Diverticular disease covers two entities: **diverticulosis** and its inflammatory complication, **diverticulitis**.

Diverticulosis Reflects Environmental and Structural Factors

Diverticulosis entails acquired herniation of the mucosa and submucosa through the muscularis propria.

TABLE 19-2

Helminths
Strongyloides
Enterobius

EPIDEMIOLOGY: Diverticulosis shows striking geographic variability: it is common in Western societies but not in Asia, Africa and underdeveloped countries. Diverticulosis increases in frequency with age and is increasing worldwide.

ETIOLOGIC FACTORS: Because of the striking predominance in developed countries and rising incidence throughout the world, diet and lifestyle changes are thought to play a prominent role in the development of diverticulosis. People who consume a vegetarian diet and/or a diet rich in fiber are at lower risk for diverticular disease than those whose diet is rich in refined carbohydrates and meat.

INCREASED INTRALUMINAL PRESSURE: According to the fiber theory, Western diets lack dietary residue, leading to sustained bowel contraction and thus increased intraluminal pressure. Such prolonged increased pressure may lead to herniation of the mucosa and submucosa of the colon.

DEFECTS IN THE WALL OF THE COLON: In addition to pressure, defects in the colon wall are required. The circular muscle of the colon is interrupted by connective tissue clefts at the sites of penetration by the nutrient vessels that supply the submucosa and mucosa. In older people, this connective tissue loses its resilience and thus its resistance to the effects of increased intraluminal pressure. This concept is supported by the fact that people with heritable connective tissue disorders (e.g., Marfan syndrome, Ehlers-Danlos syndrome) acquire precocious diverticulosis, primarily of the small bowel.

PATHOLOGY: True diverticula involve all layers of the intestinal wall. In diverticulosis, the structures are actually pseudodiverticula, in which only the mucosa and submucosa are herniated through the muscle layers. The sigmoid colon is affected in 95% of cases, but diverticulosis can affect any segment of the colon, including the cecum. Diverticula vary in number from a few to hundreds. They measure up to 1 cm and are connected to the intestinal lumen by necks of varying length and caliber. The muscular wall of the affected colon is often thickened.

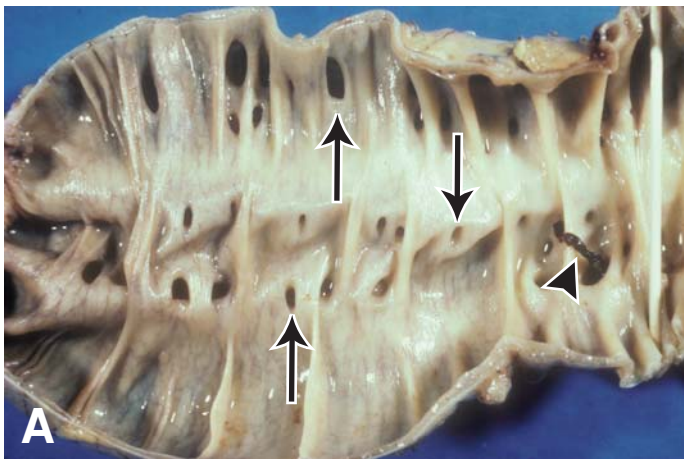
Diverticula are characteristically seen as flask-like structures that extend from the lumen through the muscle layers (Fig. 19-69). Their walls are continuous with the surface mucosa and thus have epithelium *and* submucosa. The outer base is formed by serosal connective tissue.

CLINICAL FEATURES: ***At least 80% of affected individuals are symptom free.*** Symptomatic patients complain of episodic colicky abdominal pain. Both constipation and diarrhea, sometimes alternating, may occur, and flatulence is common. Sudden, painless and severe bleeding from colonic diverticula is a cause of serious lower gastrointestinal hemorrhage in the elderly, occurring in as many as 5% of patients with diverticulosis. Chronic blood loss may lead to anemia.

Diverticulitis Is Inflammation at the Base of a Diverticulum

Of patients with diverticulosis, 10%–20% will develop diverticulitis at some point. Acute diverticulitis is believed to be precipitated by irritation due to retained fecal material. This irritation and obstruction lead to inflammation of the diverticulum, which can eventually rupture. Beyond this acute episode, chronic diverticular disease may develop from a combination of abnormal colonic motility, visceral hypersensitivity, imbalance among intestinal flora (called dysbiosis) and chronic inflammation leading to an irritable bowel–like syndrome.

PATHOLOGY: Diverticulitis produces inflammation of the wall of the diverticulum, which may lead to perforation and release of fecal bacteria into peridiverticular tissues. The resulting abscess is usually contained by the appendices epiploicae and pericolonic adipose tissue. Infrequently, free perforation leads to generalized peritonitis. Fibrosis in response to repeated episodes of diverticulitis may constrict the bowel lumen, causing obstruction. Fistulas may form between the colon and adjacent organs, including the bladder, vagina, small intestine and skin of the abdomen. Additional complications include pylephlebitis and liver abscesses.



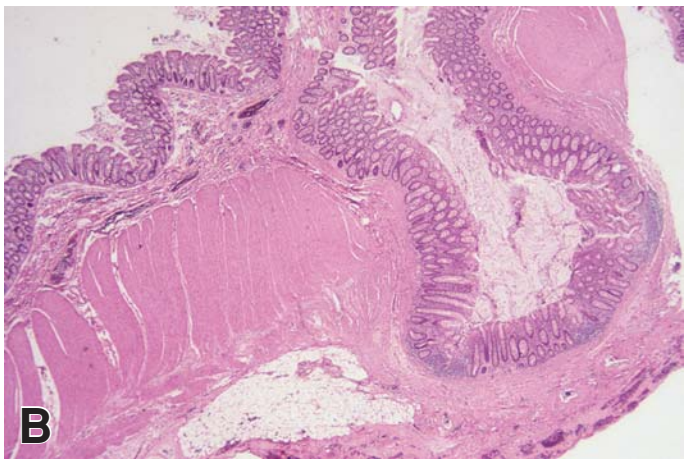


FIGURE 19-69. Diverticulosis of the colon. A. The mouths of numerous diverticula are seen between the taenia (*arrows*). There is a blood clot seen protruding from the mouth of one of the diverticula (*arrowhead*). This was the source of massive gastrointestinal bleeding. **B.** Sections show mucosa including muscularis mucosa and submucosa, which has herniated through a defect in the bowel wall, producing a diverticulum.

CLINICAL FEATURES: The most common symptoms of acute diverticulitis, which usually occur after perforation, are persistent lower abdominal pain and fever. Changes in bowel habits, from diarrhea to constipation, are frequent. Dysuria indicates bladder irritation. Most patients have left lower quadrant tenderness and, often, a palpable mass in that area. Leukocytosis is the rule. Antibiotics and supportive measures usually alleviate acute diverticulitis, but about 20% of patients eventually require surgery. Medical management to prevent subsequent attacks and chronic diverticular disease includes high-fiber diet; long-term, cyclical antibiotic therapy; anti-inflammatory medication (mesalamine); and, potentially, probiotics.

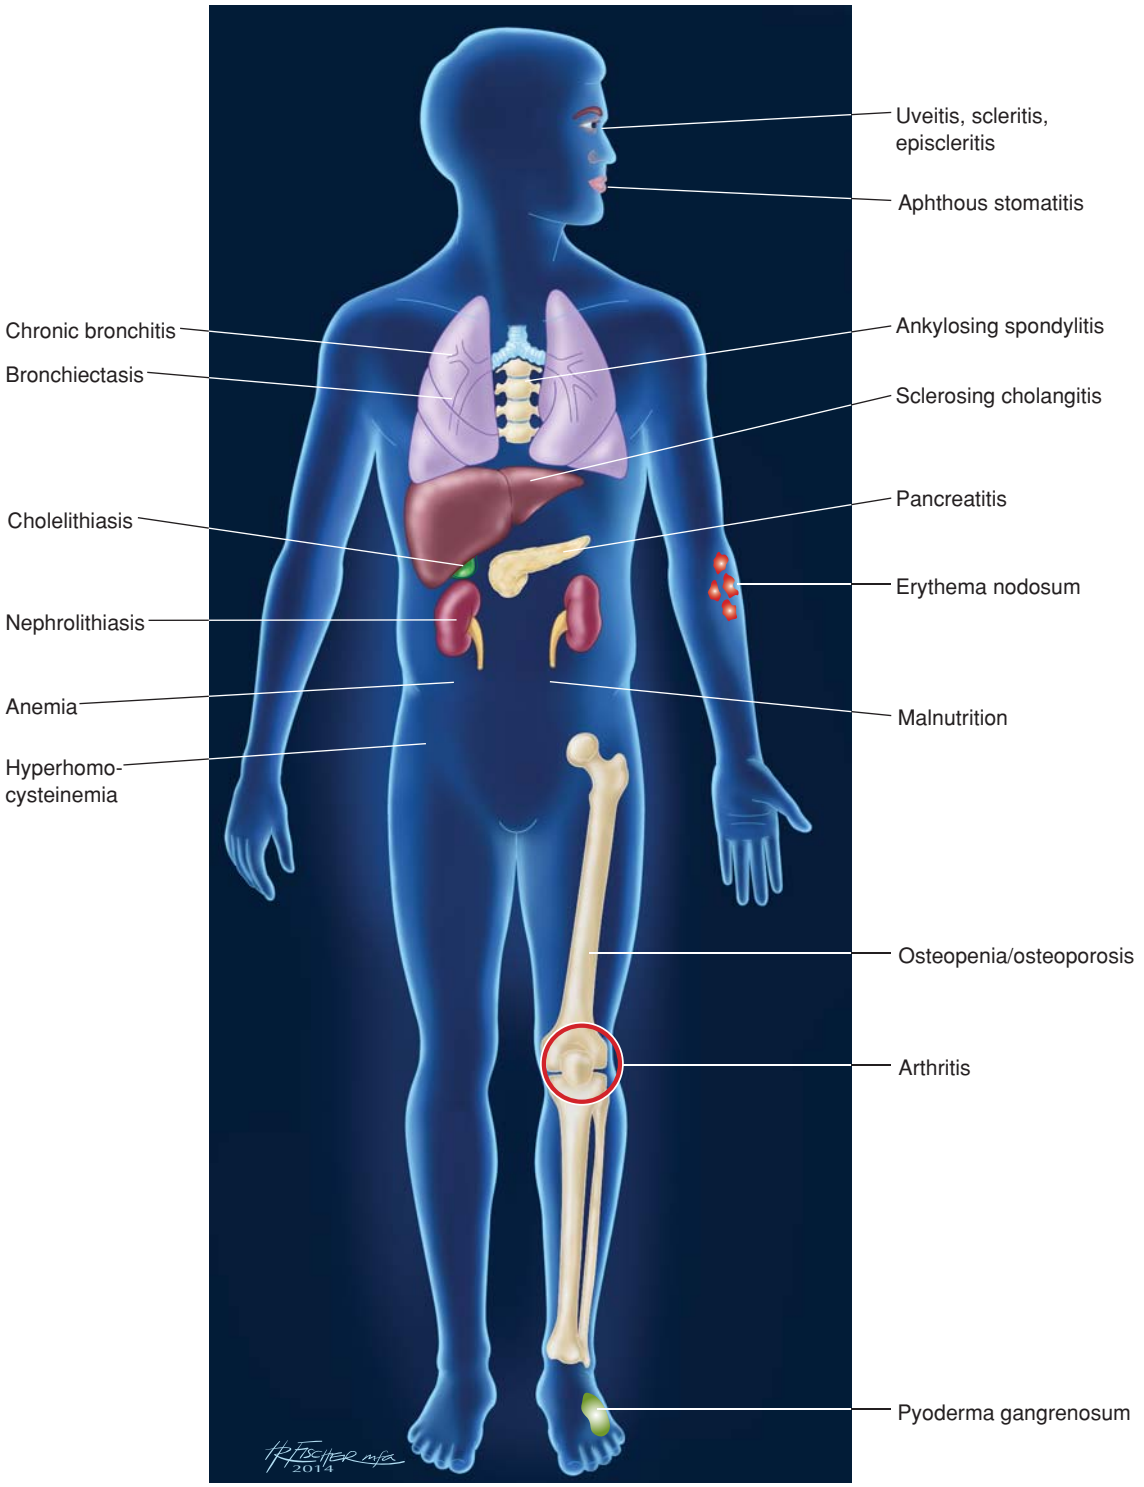

FIGURE 19-70. Systemic complications of inflammatory bowel disease. These conditions are more common with Crohn disease but may also be seen in ulcerative colitis.

INFLAMMATORY BOWEL DISEASE

The term **inflammatory bowel disease** (IBD) encompasses **Crohn disease** and **ulcerative colitis**. These two disorders have certain common features but usually differ enough to be clearly distinguishable. Cases that cannot be distinguished are labeled **indeterminate colitis**.

Both Crohn and ulcerative colitis show histologic features of chronicity including architectural glandular distortion, increased chronic inflammation with or without active neutrophilic inflammation and metaplasia. Extraintestinal complications of IBD are more common with Crohn disease but also occur in ulcerative colitis (Fig. 19-70). While their precise causes are unknown, epidemiologic, clinical and animal studies suggest that mucosal injury accrues from altered immune responses and abnormal interactions of bacteria with intestinal epithelia. The differences between the two diseases are described below.

Crohn Disease Is Chronic Segmental Transmural Intestinal Inflammation

Crohn disease mainly affects the distal small intestine but may involve any part of the digestive tract and even extraintestinal tissues. The colon, particularly the right colon, is often affected.

EPIDEMIOLOGY: Crohn disease has a worldwide incidence of 0.7–14.6 per 100,000 but is more common in developed countries. Its incidence has increased dramatically in the past 30 years, probably owing to a combination of factors related to adoption of a "Western lifestyle." Age distribution is bimodal, with a peak in adolescents or young adults and a second smaller peak in the 50s and 60s. It is most common in people of European origin, with a considerably higher frequency among Ashkenazi Jews. Males predominate among children, but in adults there is a slight female predominance. Smokers are at an increased risk of developing Crohn disease and of having more severe disease, compared with nonsmokers.

MOLECULAR PATHOGENESIS: The cause of Crohn disease is not known. The current leading theories involve a combination of a genetically susceptible host, defective mucosal barrier, intestinal dysbiosis (altered intestinal flora) and inadequate/inappropriate immune response. Genome-wide association studies have identified more than 30 loci that confer susceptibility for Crohn disease, although these account for a minority of cases. Some genetic associations involve genes controlling innate and adaptive immunity. Polymorphisms identified in the innate system are in *NOD2 (CARD15)* and in two genes related to autophagy (*ATG16L1, IRGM*). These defects imply problems in recognition and handling of intracellular bacteria. The T-cell response (adaptive immune system) in Crohn disease involves T_H1 (see Chapter 4), which is mediated by interleukin-12, interferon-γ (IFN-γ) and TNF.

PATHOLOGY: Two key features of Crohn disease differentiate it from other GI inflammatory diseases. First, inflammation usually involves all layers of the bowel wall and is thus referred to as **transmural**. Second, intestinal involvement is discontinuous: areas of inflammation are separated by apparently normal intestine.

Crohn disease may involve different parts of the bowel singly or in combination. It affects the ileum and cecum in half of cases, only the small intestine in 30% and only the colon in 20%. Ileal and cecal disease is more common in younger patients; colitis is common among older patients. Crohn disease sometimes affects the duodenum, stomach and esophagus as focal acute inflammation with or without granulomas. In women with anorectal disease, inflammation may spread to the external genitalia.

The pathology of Crohn disease is highly variable. The bowel and adjacent mesentery are thickened and edematous. Mesenteric fat often surrounds the bowel (so-called creeping fat). Mesenteric lymph nodes are frequently enlarged, firm and matted together. The intestinal lumen is narrowed by edema in early cases and by a combination of edema and fibrosis in long-standing disease. Nodular swelling, fibrosis and mucosal ulceration lead to a "cobblestone" appearance (Fig. 19-71). In early cases, ulcers have either an aphthous or a serpiginous appearance; later they become deeper and appear as linear clefts or fissures (Fig. 19-71B).

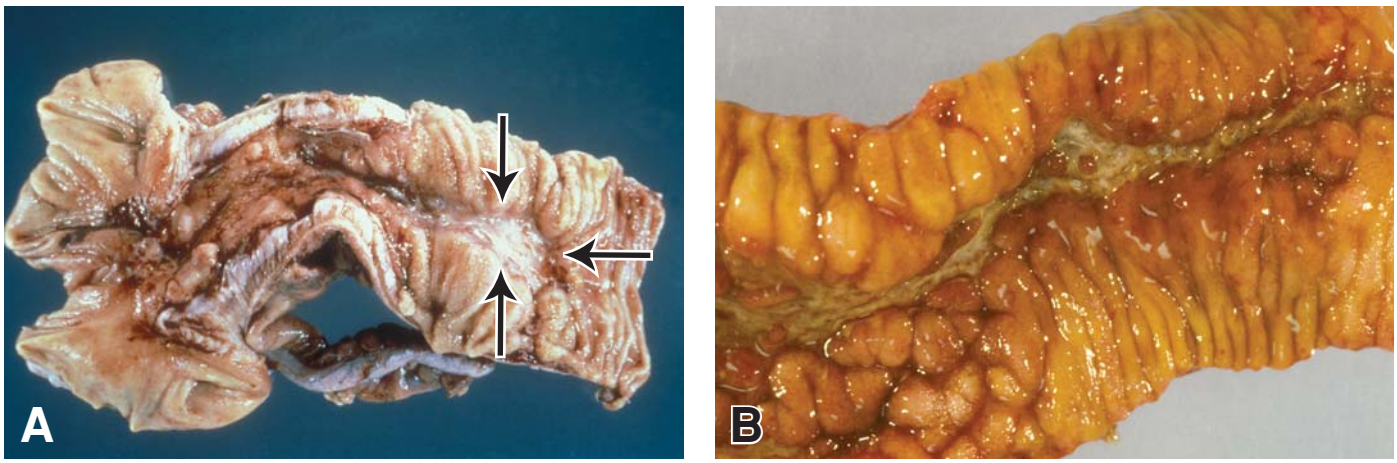

FIGURE 19-71. Crohn disease. A. The terminal ileum shows striking thickening of the wall of the distal portion with distortion of the ileocecal valve. A longitudinal ulcer is present (*arrows*). **B.** Another longitudinal ulcer is seen in this segment of ileum. The large rounded areas of edematous damaged mucosa give a "cobblestone" appearance to the involved mucosa. A portion of the mucosa to the lower right is uninvolved.

The appearance of the bowel wall underscores the fact that the process affects the entire thickness of the bowel wall: there are thickening, edema and fibrosis of all layers. Involved loops of bowel are often adherent. Fistulas may form between such segments. These are late results of deep mural ulcers and may also penetrate from the bowel into, for example, the bladder, uterus, vagina and skin. Most fistulas end blindly, to form abscess cavities in the peritoneum, mesentery or retroperitoneal structures. Lesions in the distal rectum and anus may create perianal fistulas, a well-known presenting feature.

Crohn disease is mainly a chronic inflammatory process. Early in the disease, inflammation may be confined to the mucosa and submucosa. Small, superficial mucosal ulcers (aphthous ulcers) are seen, as are mucosal and submucosal edema and infiltrates of lymphocytes, plasma cells, eosinophils and macrophages. Mucosal architecture is abnormal, often showing regenerative changes in crypts and villous distortion. Pyloric metaplasia and Paneth cell hyperplasia and/or metaplasia are common in the small and large intestines. Later, long, deep, fissure-like ulcers; vascular hyalinization; and fibrosis appear.

Lymphocytes form aggregates throughout the wall and the muscularis mucosae and nerves of the submucosal and myenteric plexuses all proliferate (Fig. 19-72). Discrete, noncaseating granulomas may be present, mostly in the submucosa (Fig. 19-72B). These resemble those of sarcoidosis, with focal aggregates of epithelioid cells, surrounded by a rim of lymphocytes. Multinucleated giant cells may be present. The centers of the granulomas usually have hyaline material but only very rarely necrosis.

Such discrete granulomas strongly suggest Crohn disease. However, their absence does not exclude the diagnosis, as they are present in less than half of cases.

The pathologic features of Crohn disease are summarized in Fig. 19-73.

CLINICAL FEATURES: The clinical manifestations and natural history of Crohn disease are highly variable and reflect the diversity of anatomic sites affected. The most common symptoms are abdominal pain and diarrhea, with passage of blood and/or mucus. Recurrent fever is frequent. If it mainly involves the ileum and cecum, its sudden onset may mimic appendicitis, with right lower quadrant pain, intermittent diarrhea, fever and a tender right lower quadrant mass. When the small intestine is diffusely involved, malabsorption and malnutrition may be major features. Lipid malabsorption may also result from interruption of the enterohepatic cycle of bile salts secondary to ileal disease. Colonic involvement leads to **diarrhea** and sometimes **colonic bleeding**. In a few patients, the major site of involvement may be the anorectal region and recurrent anorectal fistulas may be the presenting sign.

Intestinal obstruction and fistulas are the most common intestinal complications of Crohn disease. Occasionally, free perforation of the bowel occurs. When it begins in childhood, it may slow growth and physical development.

There are many extraintestinal manifestations and associated disorders (Fig. 19-70). Small bowel cancer occurs at least 3-fold more commonly in patients with Crohn disease. Risk of colorectal cancer is also higher, more in patients with more extensive involvement of the colon, a family history of colorectal cancer and/or sclerosing cholangitis.

There is no known cure. Corticosteroids, sulfasalazine, metronidazole, azathioprine, 6-mercaptopurine, methotrexate and anti–TNF-α antibodies such as infliximab may suppress the inflammatory reaction. However, these medications put patients at increased risk for opportunistic infections.

Surgical resection of obstructed or severely involved portions of intestine and drainage of abscesses caused by fistulas are required in some cases. Unfortunately, preanastomotic or prestomal recurrences after an enterostomy is constructed occur often and make clinical management difficult. The

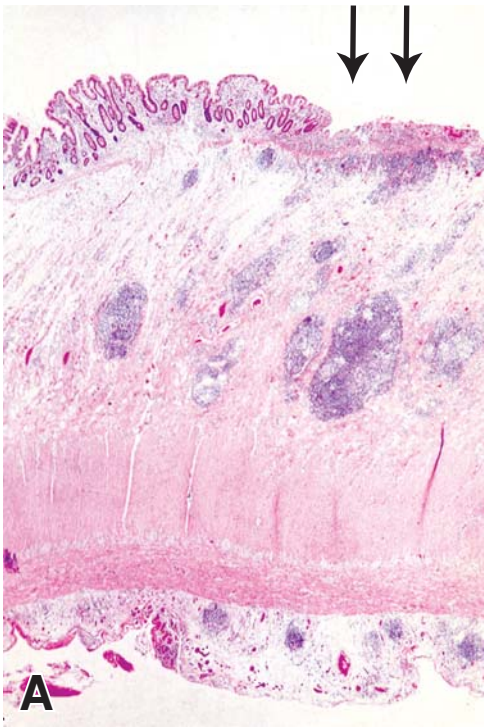

FIGURE 19-72. Crohn disease. A. The colon involved with Crohn disease shows an area of mucosal ulceration, an expanded submucosa with lymphoid aggregates and numerous lymphoid aggregates in the subserosal tissues immediately adjacent to the muscularis propria. **B.** This mucosal biopsy in Crohn disease shows a small epithelioid granuloma (*arrows*) between two intact crypts.

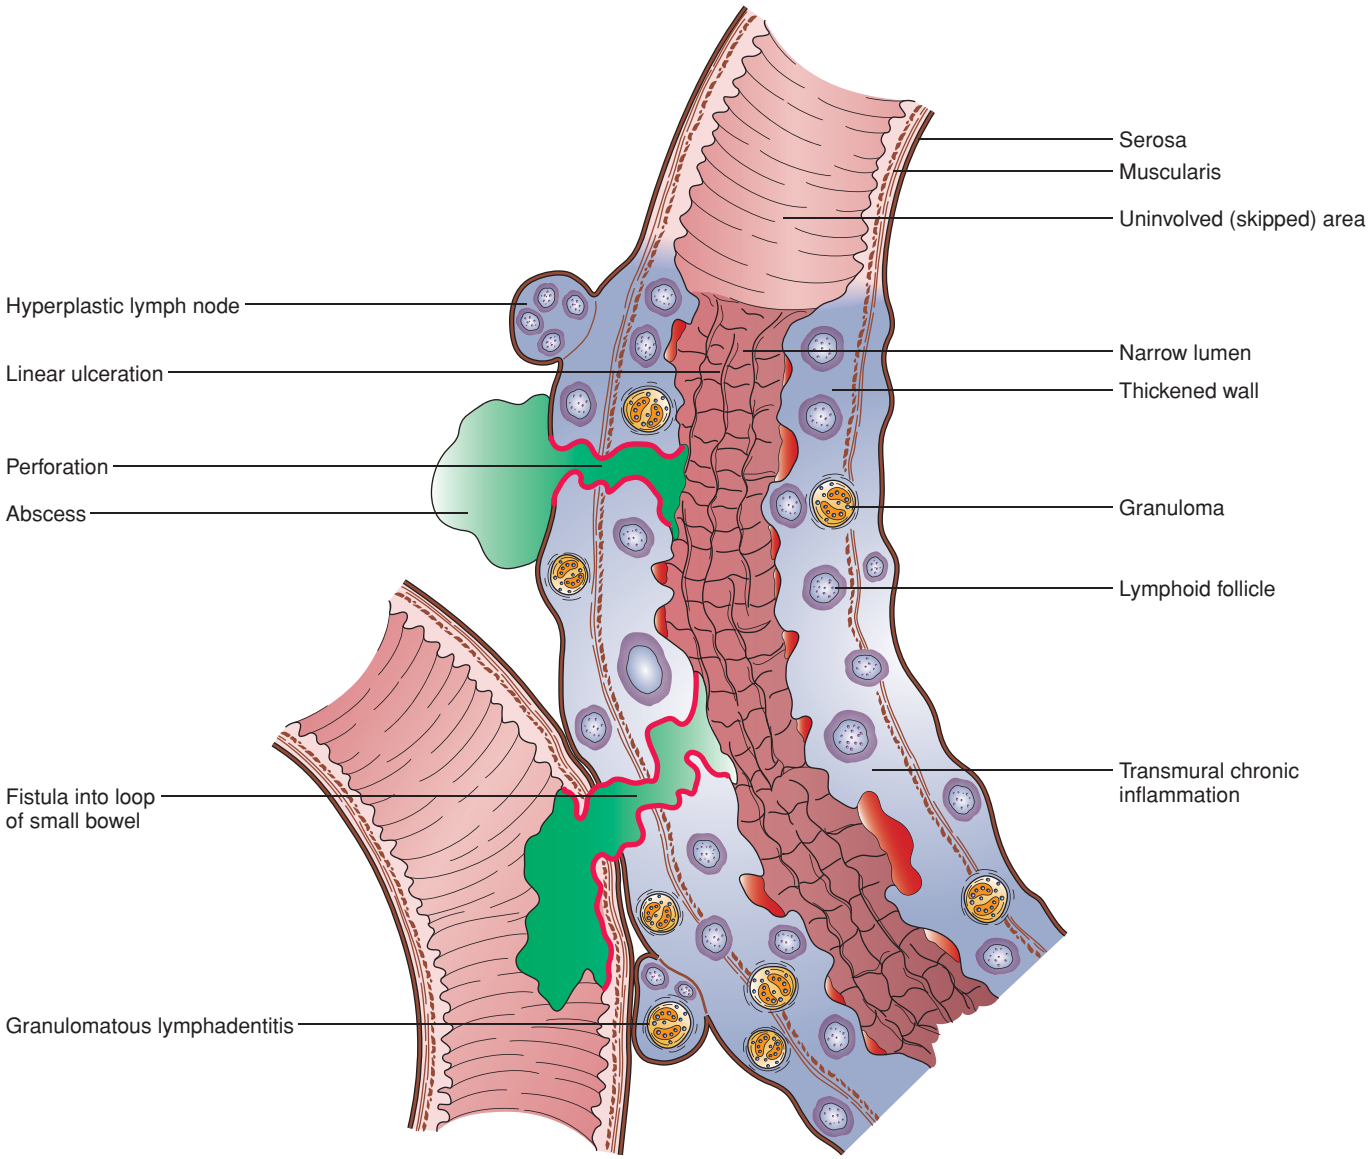

FIGURE 19-73. Crohn disease. A schematic representation of the major features of Crohn disease in the small intestine.

need for repeated resections can lead to short-bowel syndrome in some patients.

Additional adjunct therapies that show possible benefit in small series include dietary modifications, antibiotics, probiotics and fecal transplant.

Ulcerative Colitis Is Chronic, Superficial Inflammation of the Colon and Rectum

It is characterized by chronic diarrhea and rectal bleeding, with episodic exacerbations and remissions.

EPIDEMIOLOGY: Worldwide, ulcerative colitis incidence ranges from 1.5 to 24.5 per 100,000 and occurs more often in developed countries. Like Crohn disease, its incidence is increasing in countries that adopt "Western" lifestyles, suggesting that environmental factors may contribute to the pathogenesis of the disease. It also has a bimodal age distribution, with a peak from 15 to 30 years and another between 50 and 70. In the United States, whites are affected more than blacks. Smoking seems to inhibit development of ulcerative colitis, but ex-smokers are at an increased risk. People with a family history of IBD have a higher risk of developing ulcerative colitis, although this relationship is not as strong as that in Crohn disease.

MOLECULAR PATHOGENESIS: ***The cause of ulcerative colitis is unknown.*** Leading theories suggest that genetically predisposed individuals develop dysregulated mucosal immune responses to gut flora, leading to bowel inflammation. Over 40 susceptibility loci are associated with ulcerative colitis. Of these, 20 overlap with Crohn disease. Some encode proteins involved in epithelial cell adhesion and so perhaps contribute to mucosal barrier dysfunction. The T-cell response in ulcerative colitis is T_H2 dominant and mediated by natural killer T cells. This combination of factors leads to mucosal hyperresponsiveness to commensal bacteria and an exaggerated immune response causing chronic inflammation and damage.

FIGURE 19-74. Ulcerative colitis. Prominent erythema and ulceration of the colon begins in and are most severe in the rectosigmoid area and extend into the ascending colon.

PATHOLOGY: Major pathologic features of ulcerative colitis that help to differentiate it from other inflammatory conditions, particularly Crohn disease, are:

- **Ulcerative colitis is diffuse.** It begins in the distal rectum and extends proximally for a variable distance (Fig. 19-74). Isolated rectal involvement is **ulcerative proctitis,** while extension to the splenic flexure is called **proctosigmoiditis** or **left-sided colitis**. If the entire colon is involved, it is called **pancolitis**. The disease is confluent without skip lesions. The exception to this rule is that occasionally patients with left-sided colitis may have an area involved in the cecum, a "cecal patch." Sparing of the rectum is possible but should raise the possibility of Crohn disease.
- **Inflammation in ulcerative colitis is limited to the colon and rectum.** If the cecum is affected, the disease ends at the ileocecal valve, although minor inflammation of the adjacent ileum **(backwash ileitis)** may sometimes occur.
- **Ulcerative colitis is a mucosal disease.** Deeper layers are involved mainly in infrequent fulminant cases and are usually associated with toxic megacolon.

This morphologic sequence may develop rapidly or it may take years.

EARLY COLITIS: Early in the disease, the mucosal surface is raw, red and granular. It is frequently covered with a yellowish exudate and bleeds easily. Later, small superficial ulcers or erosions may appear. These occasionally coalesce into irregular, shallow, ulcerated areas that seem to surround islands of intact mucosa.

The histology of early ulcerative colitis correlates with colonoscopic appearances and includes (1) mucosal congestion, edema and tiny hemorrhages; (2) diffuse chronic inflammation in the lamina propria (Fig. 19-75); and (3) damage and distortion of colorectal crypts, which are often surrounded and infiltrated by neutrophils (cryptitis). Neutrophils in the crypts and suppurative necrosis of crypt epithelium cause crypt abscesses (dilated crypts filled with neutrophils) (Fig. 19-75B).

PROGRESSIVE COLITIS: As disease progresses, mucosal folds are lost (atrophy). Lateral extension and coalescence of crypt abscesses can undermine the mucosa, leaving areas of ulceration adjacent to hanging fragments of mucosa. Such mucosal excrescences are inflammatory polyps (Fig. 19-76). Tissue repair accompanies tissue destruction, and granulation tissue develops in denuded areas. Importantly, the strictures characteristic of Crohn disease are absent. In late stages, crypts may appear tortuous, branched and shortened (Fig. 19-75C), with diffuse mucosal atrophy.

ADVANCED COLITIS: In long-standing cases, the large bowel is often shortened, especially on the left side. Mucosal

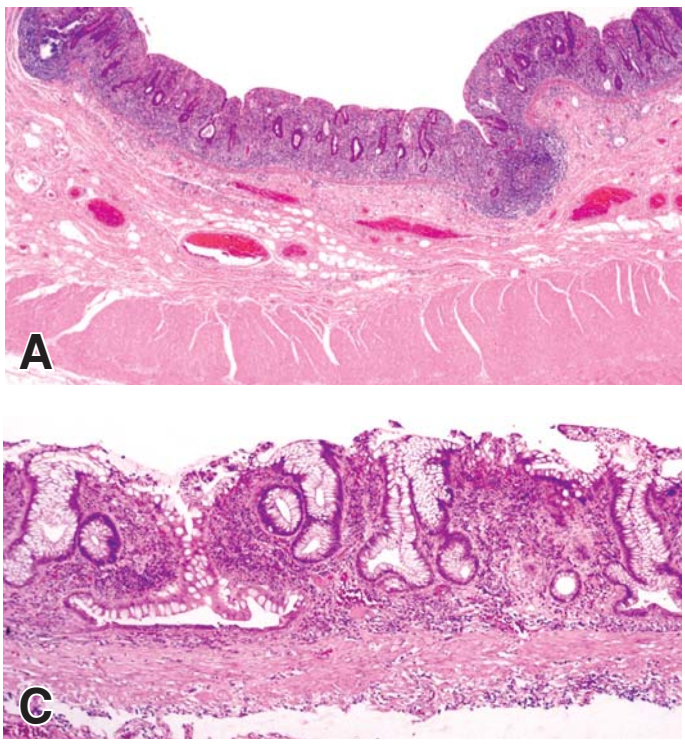

FIGURE 19-75. Ulcerative colitis. A. A full-thickness section of colon resected for ulcerative colitis shows inflammation affecting the mucosa with sparing of the submucosa and muscularis propria. **B.** A mucosal biopsy from a patient with active ulcerative colitis shows expansion of the lamina propria and several crypt abscesses (*arrows*). **C.** Chronic ulcerative colitis shows significant crypt distortion and atrophy.

FIGURE 19-76. Inflammatory polyps of the colon in ulcerative colitis. Nodules of regenerative mucosa and inflammation surrounded by denuded areas provide a diffuse polypoid appearance of the mucosa.

folds are indistinct and are replaced by a granular or smooth mucosal pattern. In advanced ulcerative colitis, mucosal atrophy and chronic inflammation are present in the mucosa and superficial submucosa. Paneth cell metaplasia is common.

The pathologic features of ulcerative colitis are summarized in Fig. 19-77B.

CLINICAL FEATURES: The clinical course and manifestations are quite variable. Most patients have intermittent attacks, with partial or complete remissions in between. A few (<10%) have a very long remission (several years) after their first attack. About 20% have continuous symptoms without remission.

MILD COLITIS: Half of patients with ulcerative colitis have mild disease. Their major symptom is rectal bleeding, sometimes with **tenesmus** (rectal pressure and discomfort). In these patients, disease is usually limited to the rectum but may extend to the distal sigmoid colon. Extraintestinal complications are uncommon. In most patients in this category, the disease remains mild throughout their lives.

MODERATE COLITIS: About 40% of patients have moderate disease. They usually have episodic loose bloody stools, crampy abdominal pain and often low-grade fever, lasting days or weeks. Anemia is commonly due to chronic fecal blood loss.

SEVERE COLITIS: About 10% of patients have severe or fulminant disease. The disease may start out this way, but more often severe colitis supervenes during a flare of activity. They have many (sometimes >20) bloody bowel movements daily, often with fever and other systemic symptoms. Blood and fluid loss rapidly lead to anemia, dehydration and electrolyte depletion. Massive hemorrhage may be life-threatening. Toxic megacolon—extreme dilation of the colon that carries a high risk for perforation—is particularly dangerous. Fulminant ulcerative colitis is a medical emergency. It requires immediate, intensive medical therapy and, sometimes, prompt colectomy. Despite aggressive management, some patients with fulminant disease die.

The medical treatment of ulcerative colitis depends on the sites involved and the severity of the inflammation. The 5-aminosalicylate–based compounds (e.g., mesalazine) are mainstays of treatment for patients with mild to moderate disease. Corticosteroids and immunosuppressive/immunoregulatory agents (azathioprine, ciclosporin or anti–TNF-α agents) are used in patients with severe and refractory disease. Because infection with *C. difficile* or CMV can precipitate or exacerbate an attack of ulcerative colitis, these should be ruled out and treated if identified. There may be some benefit of fecal transplant in patients with refractory disease.

Differential Diagnosis

The most important conditions to be distinguished from ulcerative colitis are other forms of chronic colitis due to specifically treatable causes, and Crohn disease. Other conditions in the differential diagnosis of ulcerative colitis are bacterial infections and amebic colitis, especially in areas where it is endemic. If inflammation is limited to the rectum, other infectious agents, including viruses, chlamydia, fungi and other parasites, merit consideration. Proctitis due to these agents is common in MSM and a variety of opportunistic bowel infections occur in patients with AIDS (see above). Other conditions that may mimic ulcerative colitis are ischemic colitis, antibiotic-associated colitis, radiation injury and solitary rectal ulcer syndrome.

The distinction between ulcerative colitis and Crohn colitis is based on different anatomic localization and histopathology (Table 19-3). Ulcerative colitis is a diffuse process, usually more severe distally, while Crohn colitis is patchy or segmental and often spares the rectum. Inflammation in ulcerative colitis is superficial (i.e., usually limited to the mucosa), but that in Crohn colitis is transmural and involves all layers, with granulomas in some of the specimens.

If disease stops at the ileocecal valve or is limited to the distal colon, ulcerative colitis is more likely. Involvement of the terminal ileum suggests Crohn colitis, unless there is pancolitis with backwash ileitis.

In 10% of cases, definitive discrimination is impossible and the disease is denoted as indeterminate colitis. This occurs mostly in fulminant colitis.

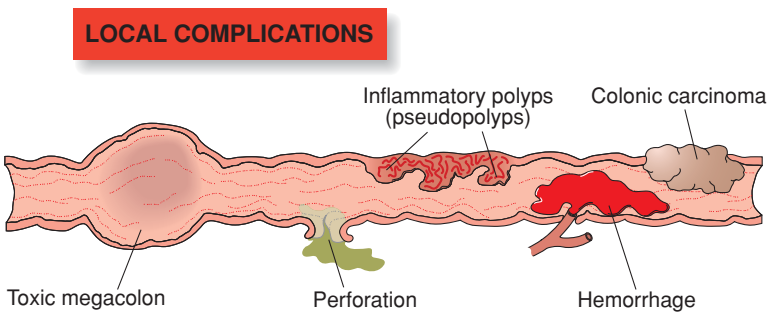

FIGURE 19-77. Ulcerative colitis. A schematic representation of the major features of ulcerative colitis in the colon.

TABLE 19-3
COMPARISON OF THE PATHOLOGIC FEATURES IN THE COLON OF CROHN DISEASE AND ULCERATIVE COLITIS

Lesion	Crohn Disease	Ulcerative Colitis
Macroscopic		
Thickened bowel wall	Typical	Uncommon
Luminal narrowing	Typical	Uncommon
"Skip" lesions	Common	Absent
Right colon predominance	Typical	Absent
Fissures and fistulas	Common	Absent
Circumscribed ulcers	Common	Absent
Confluent linear ulcers	Common	Absent
Inflammatory polyps	Absent	Common
Microscopic		
Transmural inflammation	Typical	Rare
Submucosal fibrosis	Typical	Absent
Fissures	Typical	Rare
Granulomas	Common	Absent
Crypt abscesses	Typical	Typical

Distinguishing between ulcerative colitis and Crohn colitis is important because (1) surgical approaches are different (Crohn disease often recurs, so continent ileostomy and ileoanal pouches may be contraindicated), (2) ulcerative colitis carries a higher risk of cancer and (3) medical treatments differ.

Ulcerative Colitis and Colorectal Cancer

Patients with long-standing ulcerative colitis have a much higher risk of colorectal cancer than does the general population. The magnitude of this increased risk is related to the extent and duration of the disease. It is greater if the entire colon is involved. If inflammation is limited to the rectum, the risk of colorectal cancer is like that of the general population. After 10 years with ulcerative colitis, chances for colorectal cancer are estimated to be 2% after 10 years of disease, 8% after 20 years and 18% after 30 years. Patients with ulcerative colitis who develop primary sclerosing cholangitis are at a higher risk of dysplasia and colorectal cancer.

Colorectal epithelial dysplasia is a neoplastic epithelial proliferation and precursor to colorectal carcinoma (Fig. 19-78). The dysplasia can be flat, adenoma-like or a non–adenoma-like lesion called dysplasia-associated lesion or mass (DALM), based on its endoscopic appearance. Epithelial dysplasia entails variation in nuclear size, shape and staining qualities and may be low grade or high grade, depending on the degree of cytologic and architectural atypia. Extensive inflammation may preclude a definitive diagnosis of dysplasia, in which case the term "indefinite for dysplasia" is used. High-grade dysplasia has a high risk for eventual colorectal cancer. When identified in a biopsy, it is a strong indication for colectomy.

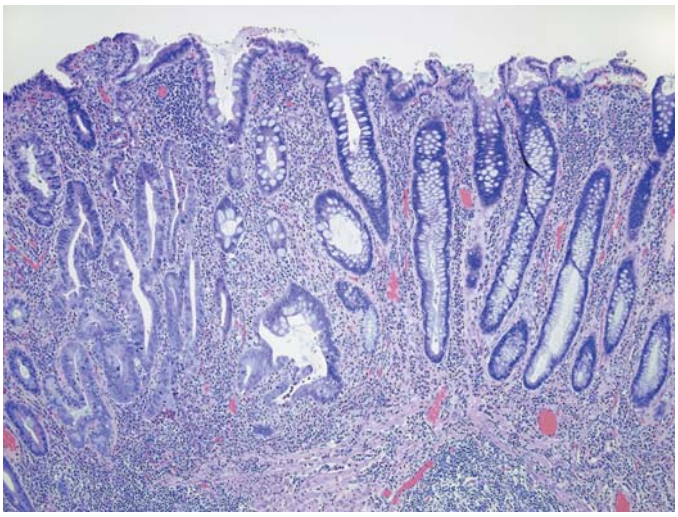

FIGURE 19-78. Dysplasia in ulcerative colitis. The colonic mucosa shows the chronic changes of ulcerative colitis (see Fig. 19-53C). The crypts to the left are dysplastic, showing architectural distortion, hyperchromatic nuclei and lack of glandular maturation.

The appropriate follow-up for low-grade dysplasia is controversial. Routine colonoscopy and biopsy of all patients with ulcerative colitis are recommended after 8–10 years of pancolitis, after 15 years of left-sided colitis or immediately in patients with primary sclerosing cholangitis. Newer technologies such as chromoendoscopy (applying a topical dye to the mucosa during endoscopy) or confocal laser endomicroscopy (enhancing magnification of the endoscopic picture down to the cellular level) may increase biopsy yields of dysplastic lesions via colonoscopy. With surveillance endoscopy with routine biopsies and chemoprevention to reduce inflammation, dysplasia and cancer risk can be reduced.

Microscopic Colitis Causes Chronic Diarrhea

This entity encompasses lymphocytic colitis and collagenous colitis, which can be distinguished histologically. The incidence of microscopic colitis has been increasing over the past 20 years. At least part of this increase reflects greater awareness of the disease. The main presenting symptom is chronic watery diarrhea. Patients may also have abdominal pain and weight loss, which are typically mild.

Microscopic colitis is so named because the colon appears grossly normal and only microscopic evaluation reveals an abnormality. The disease increases with age, is more common in women and is associated with some medications, autoimmune diseases and smoking. Treatment involves removing potentially offending medications, stopping smoking, antidiarrheal medications and immune suppressants/modulators. In rare refractory cases, colectomy may be indicated.

ETIOLOGY: The causes for collagenous colitis and lymphocytic colitis are unknown. Autoimmunity has been suggested, based on occasional association with autoimmune diseases such as rheumatoid arthritis,

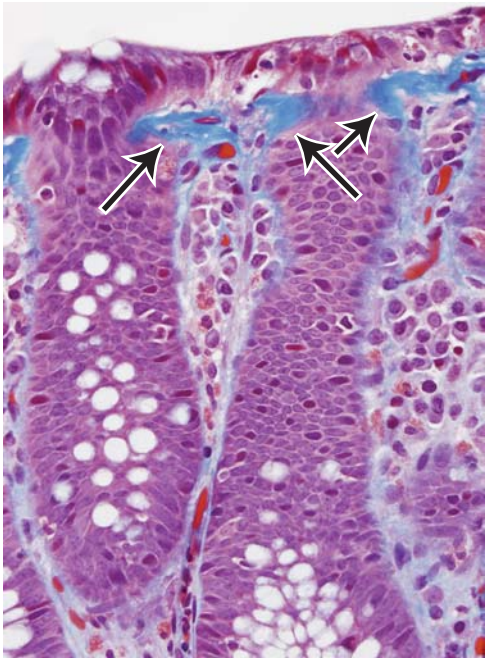

FIGURE 19-79. Collagenous colitis. A trichrome stain highlights the characteristic thickening of the collagen table (*blue*, note *arrows*) with entrapment of capillaries. The intercryptal surface epithelium is flattened and contains an increased number of intraepithelial lymphocytes.

thyroid dysfunction and psoriasis. Microscopic colitis is also frequently associated with celiac disease. Several medications are associated with both diseases; most are NSAIDs, but whether this association is causal or incidental is unclear, as many of these patients use NSAIDs for arthralgias.

PATHOLOGY: Lymphocytic colitis has surface damage with increased intraepithelial lymphocytes (>20 per 100 epithelial cells). Chronic inflammation of the lamina propria is increased, and typically more prominent more superficially. Mild acute inflammation may also be present. Gland architecture is normal, unlike IBD, as is the collagen table. Changes may be more pronounced in the right colon, so random biopsies of the whole colon are useful in evaluating microscopic colitis.

Collagenous colitis typically shows similar changes to the colonic mucosa as lymphocytic colitis (normal architecture, surface damage, increased lamina propria inflammation, intraepithelial lymphocytosis), plus an irregularly thickened subepithelial collagen band, usually greater than 10 µm, which entraps capillaries (Fig. 19-79). The collagen table is usually thickened irregularly, and thus multiple biopsies may be needed to make this diagnosis (Fig. 19-79).

VASCULAR DISEASES

Extensive Infarction of the Colon is Uncommon

Segmental, and sometimes chronic, ischemic disease is the rule. ***The parts of the colon most vulnerable to nonocclusive ischemia (usually due to hypotension) are areas between adjacent arterial distributions, so-called watershed areas.*** For example, the splenic flexure is between the regions supplied by the superior and inferior mesenteric arteries. Also, the rectosigmoid area shares blood from the inferior mesenteric and internal iliac arteries. The rectum itself, however, is usually spared because it has a dual blood supply, from the splanchnic and systemic arterial systems. Most cases of ischemic colitis are caused by atherosclerosis of major intestinal arteries, and recurrent bouts of abdominal pain due to ischemic colitis are called **intestinal angina**. Increasing age, especially older than 65 years, and female gender are risk factors. Patients with IBD may have reduced bowel perfusion and thus develop ischemic injury.

Infections with *E. coli* O157:H7 and *Shigella* spp. can cause ischemic injury via direct toxin damage to vascular endothelium. Thrombophilic states, several prescription medications and the illicit drug cocaine also increase the risk of ischemic bowel disease.

PATHOLOGY: On endoscopy, multiple ulcers, hemorrhagic nodular lesions or a pseudomembrane may be seen. Biopsy shows ischemic necrosis: coagulative necrosis of surface epithelium with ghost cells, mucosal ulceration, crypt abscesses, edema and hemorrhage (Fig. 19-80). In more severe cases, necrosis affects deeper layers of bowel and can evolve to full-thickness necrosis. Patients may recover completely or develop a stricture, in which case surgical removal of the obstructed segment may be necessary. Segments of ischemic stricture show variable mucosal ulceration and inflammation, submucosal granulation tissue, fibrosis and hemosiderin-laden macrophages.

CLINICAL FEATURES: Acute bowel ischemia usually presents with bright red blood in stools or with maroon stools, depending on the location of the bleeding. Patients without bleeding may have a worse prognosis. Ischemic colitis may be indistinguishable clinically from other forms of colitis (infectious, IBD). Prognosis and treatment depend on the primary cause and extent of involvement. The goal is to improve blood supply to the colon by treating patients' overall cardiovascular status and providing bowel rest. There may also be a role for antibiotics. In severe cases, mortality exceeds 50%, and urgent removal of the involved bowel may be necessary.

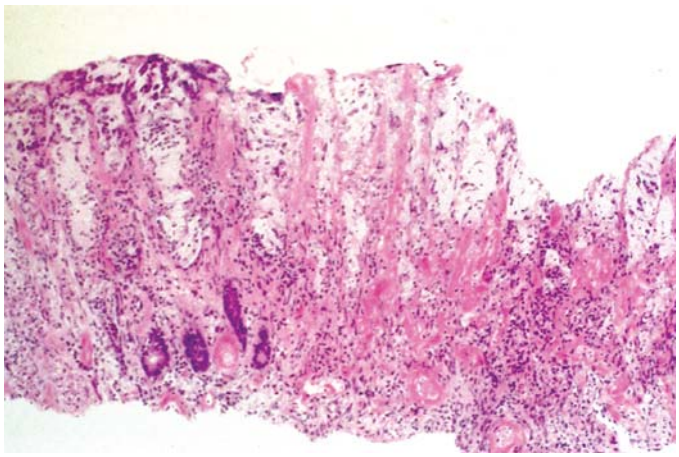

FIGURE 19-80. Ischemic colitis. A mucosal biopsy shows coagulative necrosis with "ghostly" outlines of the preexisting crypts. Only a small portion of the base of several crypts remains.

Angiodysplasia (Vascular Ectasia) May Cause Intestinal Bleeding

Angiodysplasia (vascular ectasia) is localized arteriovenous malformations, mainly in the cecum and ascending colon. These may cause lower intestinal bleeding, especially in people over 60. Younger people may have lesions at other sites, including the rectum, stomach and small bowel. Aortic valvular disease may be associated in some cases.

It has been suggested that angiodysplasia results from chronic intestinal circulatory insufficiency, intestinal muscle hypertrophy and consequent venous obstruction. Patients complain of multiple bleeding episodes, but chronic bleeding may also be occult. Radiologic studies and examination at laparotomy are usually negative. Thus, the diagnosis is difficult and often requires selective mesenteric arteriography or colonoscopy. Colonoscopic interventions are usually sufficient to stop the bleeding, but surgical removal of the affected segment may be necessary in some cases.

PATHOLOGY: The resected specimen often has multiple vascular lesions, usually less than 0.5 cm. Submucosal veins and capillaries are tortuous, thin walled and dilated. These vessels have attenuated walls, presumably accounting for their propensity to bleed.

RADIATION ENTEROCOLITIS

Radiation therapy for malignancies in the pelvis or abdomen may be complicated by injury to the small intestine (radiation enteritis) and colon (radiation colitis).

PATHOLOGY: Clinically significant radiation colitis occurs most often in the rectum (radiation proctitis). Lesions vary from reversible intestinal mucosal injury to chronic inflammation, ulceration and fibrosis of the intestine. In the short term, radiation damages epithelium and endothelium, impairs normal bowel mucosal renewal and, in the small bowel, leads to villous shortening. Mucosal inflammation is conspicuous and abscesses may be seen in colonic crypts. Failure of epithelial renewal may lead to ulceration. Chronic changes occur 9–14 months after radiation therapy, after the mucosa has healed. Damage to submucosal vessels leads to thrombosis and chronic mucosal ischemia. The submucosa becomes fibrotic and often has bizarre fibroblasts.

Complications of radiation enterocolitis include perforation and subsequent development of internal fistulas, hemorrhage and strictures. These may be severe enough to obstruct the intestines.

SOLITARY RECTAL ULCER SYNDROME

Internal rectal mucosal prolapse can cause mucosal changes that are easily mistaken clinically and pathologically for chronic inflammatory disease or a tumor. Patients often have a history of severe straining during defecation. Despite the name, some patients have no ulcers, while others have multiple erosions, ulcers or even polypoid lesions/masses that can simulate a neoplasm. While often found in the rectum, other regions of the colon can be affected. The hallmark of solitary rectal ulcer syndrome is smooth muscle proliferation from the muscularis mucosae into the lamina propria often with accompanying mucosal hyperplastic changes. Dilated glands can be trapped in the rectal wall, a condition called **colitis cystica profunda**.

POLYPS OF THE COLON AND RECTUM

A gastrointestinal polyp is a mass that protrudes into the gut lumen. Polyps are classified by their attachment to the bowel wall (e.g., sessile, or pedunculated with a discrete stalk), their histology (e.g., hyperplastic or adenomatous) and their neoplastic potential (i.e., benign or malignant). By themselves, polyps are not usually symptomatic and their clinical importance lies in their potential for malignant transformation.

Lymphoid Polyps Are Solitary Submucosal Lymphoid Accumulations

They are normally present in the colorectal mucosa and vary in size from pinpoint to up to 5 cm. On occasion, multiple lesions impart a cobblestone appearance to the mucosa. They are covered by intact mucosa and contain prominent lymphoid follicles with germinal centers. Lymphoid polyps are benign and usually asymptomatic.

Nodular lymphoid hyperplasia occurs mainly in children or patients with **common variable immunodeficiency syndrome** (see Chapter 4) and is characterized by excessive accumulation of normal colonic lymphoid follicles. The condition is rarely related to malignant lymphoma, but its radiologic appearance can be mistaken for FAP.

Inflammatory Polyps Are Elevated Areas of Inflamed, Regenerating Epithelium

They are commonly found in patients with ulcerative colitis and Crohn disease but may result from any cause of colitis. They also occur without demonstrable colonic disease and may be related to prior, resolved acute/infectious colitis. These polyps have variable components of distorted and inflamed mucosal glands, often intermixed with granulation tissue. They are not precancerous but must thus be distinguished from adenomatous polyps, which are potentially precancerous (see below).

Hamartomatous Polyps Typically Have Both Stromal and Epithelial Elements

They are composed of an overgrowth of cells and tissue native to the anatomic location. They occur sporadically and may also be associated with a variety of syndromes.

Juvenile Polyps (Retention Polyps)

Juvenile polyps occur most commonly in children younger than 10 years, although 1/3 may be in adults. They develop sporadically or may be part of a polyposis syndrome. When sporadic, they typically arise in the rectum and present with rectal bleeding or with the polyp prolapsing through the rectum.

A juvenile polyposis syndrome can be diagnosed if there are:

1. Five or more juvenile polyps in the colorectum
2. Juvenile polyps occurring outside the colon
3. Any number of juvenile polyps, plus a family history of juvenile polyposis

MOLECULAR PATHOGENESIS: Mutations of *SMAD4* or *BMPR1A,* which affect the TGF-β pathway, have been identified in some families with this syndrome. However, 30%–40% of patients do not have an identified mutation. Patients with juvenile polyposis syndrome have an increased risk for gastrointestinal and pancreatic carcinomas. By contrast, people who present with sporadic juvenile polyps do not have an increased risk of malignancy.

PATHOLOGY: Juvenile polyps are single or (rarely) multiple. They occur mostly in the rectum but may be anywhere in the small or large bowel. Most are pedunculated lesions up to 2 cm, with smooth, rounded surfaces. Dilated and cystic epithelial tubules are filled with mucus and inflammatory cells and are embedded in a fibrovascular lamina propria (Fig. 19-81). Surface epithelial erosion with underlying granulation tissue is common, as is reactive epithelial proliferation. But the epithelium usually lacks dysplasia.

Peutz-Jeghers Syndrome

This is a rare, autosomal dominant syndrome with variable penetrance. It may entail polyps anywhere in the GI tract and has been described above.

Cowden Syndrome

This syndrome is associated with germline *PTEN* mutations (see Chapter 5), is rare and is inherited as an autosomal dominant trait, with near-complete penetrance. These patients develop hamartomas of the skin, intestine, breast and thyroid gland. Gastrointestinal polyps in these patients are indistinguishable in appearance from juvenile polyps. Thus, the diagnosis of Cowden syndrome is made clinically and by identifying extraintestinal manifestations. Patients with Cowden syndrome are at increased risk of developing breast, thyroid, ovarian, cervical, uterine and bladder cancers as well as meningiomas (see Chapter 32). They do not appear to be at increased risk of gastrointestinal cancers.

Cronkhite-Canada Syndrome

Cronkhite-Canada syndrome is characterized by hamartomatous polyps of the GI tract, indistinguishable from juvenile polyps. However, unlike juvenile polyposis or Cowden syndrome, these polyps show changes in the mucosa between polyps (edema, cystically dilated glands, increased inflammatory cells). Such patients can develop a protein-losing enteropathy, anemia and electrolyte disturbances. They also present with scalp and body alopecia, nail dystrophy and skin hyperpigmentation. It is not entirely clear, but these patients may be at an increased risk for gastric and colorectal cancers.

Hyperplastic Polyps Are Benign Serrated Lesions

Hyperplastic polyps are small, sessile mucosal protrusions with exaggerated crypt architecture. They are the most common polyps of the colon, especially in the rectum. Hyperplastic polyps are present in 40% of rectal specimens in

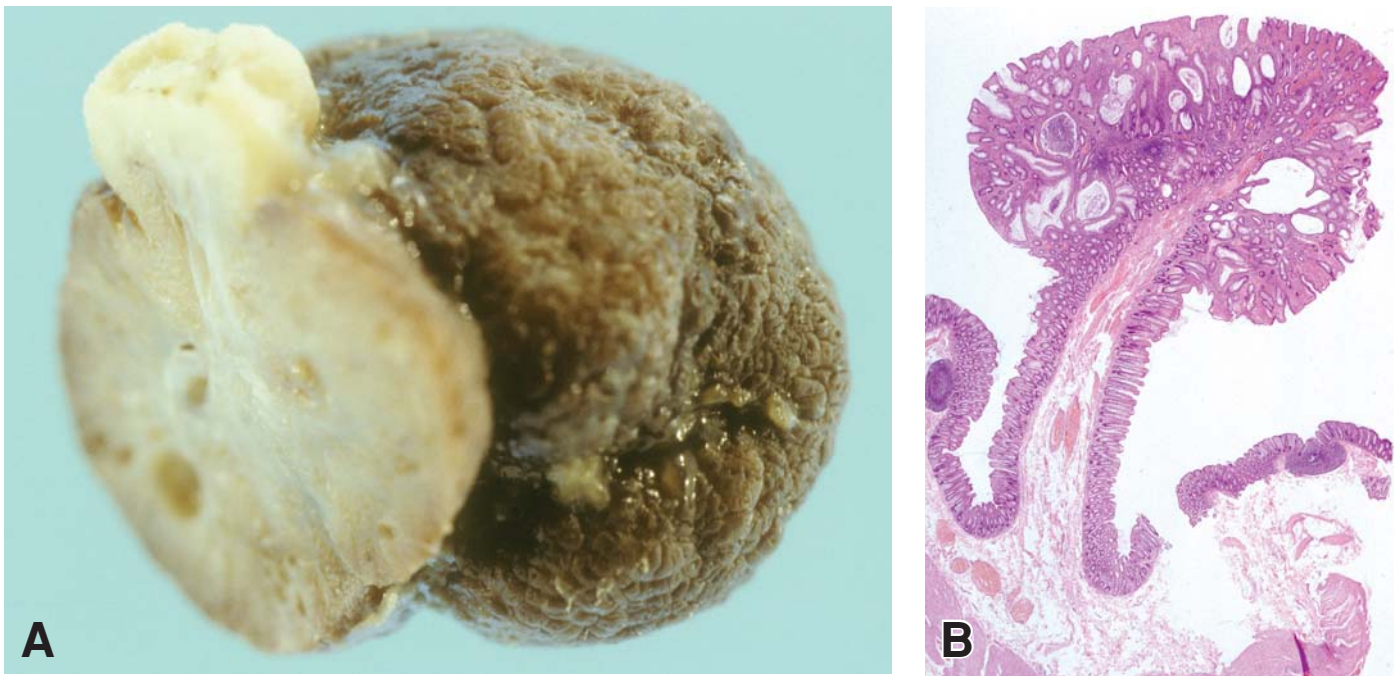

FIGURE 19-81. Juvenile polyp. A. The resected specimen shows a rounded surface. The cut surface (*left*) is cystic. **B.** Microscopically, the polyp displays cystically dilated glands.

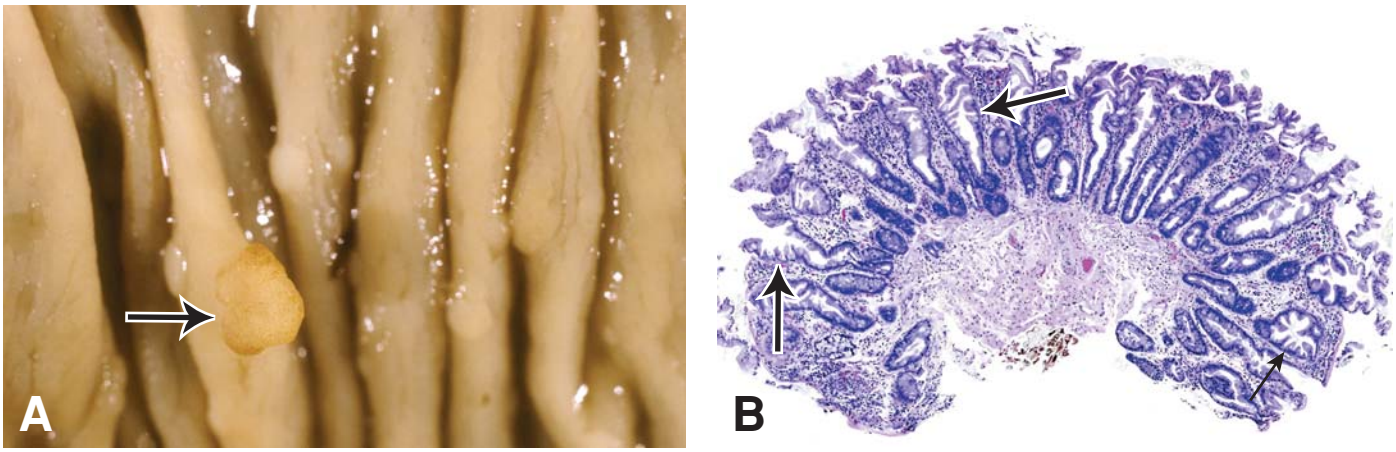

FIGURE 19-82. Hyperplastic polyp. A. This hyperplastic polyp is small, sessile and pale (*black arrow*). The larger adjacent polyp (*white arrow*) is an adenoma. **B.** Microscopically, there is a "sawtooth" appearance to the surface (*arrows*) with relatively normal-appearing crypt bases.

people younger than 40 and in 75% of older people. They are more common in colons with adenomatous polyps and in populations with higher rates of colorectal cancer. Hyperplastic polyps are felt to be due to defective proliferation and maturation of normal epithelium. Thus, cell proliferation occurs at the base of the crypt, and upward migration of the cells is slowed. The epithelial cells differentiate and acquire absorptive characteristics lower in the crypts and persist at the surface longer than do normal cells.

PATHOLOGY: Hyperplastic polyps are small, sessile, raised mucosal nodules, up to 0.5 cm, but occasionally larger (Fig. 19-82A). They are almost always multiple. The crypts of hyperplastic polyps are elongated and show relatively normal crypt bases. The epithelium in the upper third of the crypts contains hyperplastic goblet and mucinous cells and absorptive cells, with no dysplasia, giving them a serrated contour and tufted surface (Fig. 19-82B).

Sessile Serrated Adenomas Resemble Hyperplastic Polyps but Have Malignant Potential

Also called sessile serrated polyps, these lesions typically arise in the right colon and show hypermethylation of the promoter for the mismatch-repair enzyme, *MLH1;* mutations in *BRAF;* and a high incidence of microsatellite instability. **The carcinomas that arise from sessile serrated adenomas tend to be bulky, mucinous and right sided. Because of their malignant potential, these polyps should be entirely resected.**

PATHOLOGY: These lesions are sessile or flat; may appear as misshapen, abnormal mucosal folds; and often have abundant adherent mucin (Fig. 19-83A). They are typically larger than 1 cm. They show irregular, asymmetric cell proliferation in which cells may divide anywhere along the crypt. Intermixed goblet and mucin cells extend to the base. Some crypt bases are dilated with abundant mucin, while others show boot-, "L"- or inverted "T"-shaped crypts (Fig. 19-83B). These lesions may develop low- to high-grade dysplasia (Fig. 19-83C) and eventually invasive carcinoma.

Traditional Serrated Adenomas Occur Mainly in the Distal Colon and May Be Premalignant

These polyps are much less common than hyperplastic polyps or sessile serrated adenomas. They show diverse molecular abnormalities: some have *BRAF* mutations, some have *KRAS* mutations and some show a CpG island methylator phenotype that involves methylation of the promoter for *MGMT* (see Chapter 5). Like sessile serrated adenomas, these polyps should be entirely removed.

PATHOLOGY: Traditional serrated adenomas typically show tubulovillous or villous architecture. Lining epithelial cells have abundant eosinophilic cytoplasm with an elongated nucleus and open or hyperchromatic chromatin. The most characteristic feature of these polyps is formation of ectopic crypts (Fig. 19-83D).

Serrated Polyposis Syndrome Is Characterized by Multiple Serrated Polyps

Also called hyperplastic polyposis syndrome, this rare disorder is characterized by multiple serrated colorectal polyps, usually hyperplastic polyps and sessile serrated adenomas. Risk factors are European descent and increased age, although younger people are sometimes affected. There is no gender preference. No specific mutation has yet been identified, although the disease shows familial clustering. Environmental factors may impact phenotypic expression. People are diagnosed with this syndrome if there are:

1. At least 5 serrated polyps proximal to the sigmoid colon, and 2 or more >1 cm
2. Any number of serrated polyps proximal to the sigmoid colon in an individual with a first-degree relative with serrated polyposis syndrome
3. Over 20 serrated polyps of any size, distributed throughout the colon

Because of their increased risk of colorectal cancer, patients with a first-degree relative with serrated polyposis syndrome should begin screening colonoscopy at age 40, or 10 years younger than age at diagnosis of the youngest

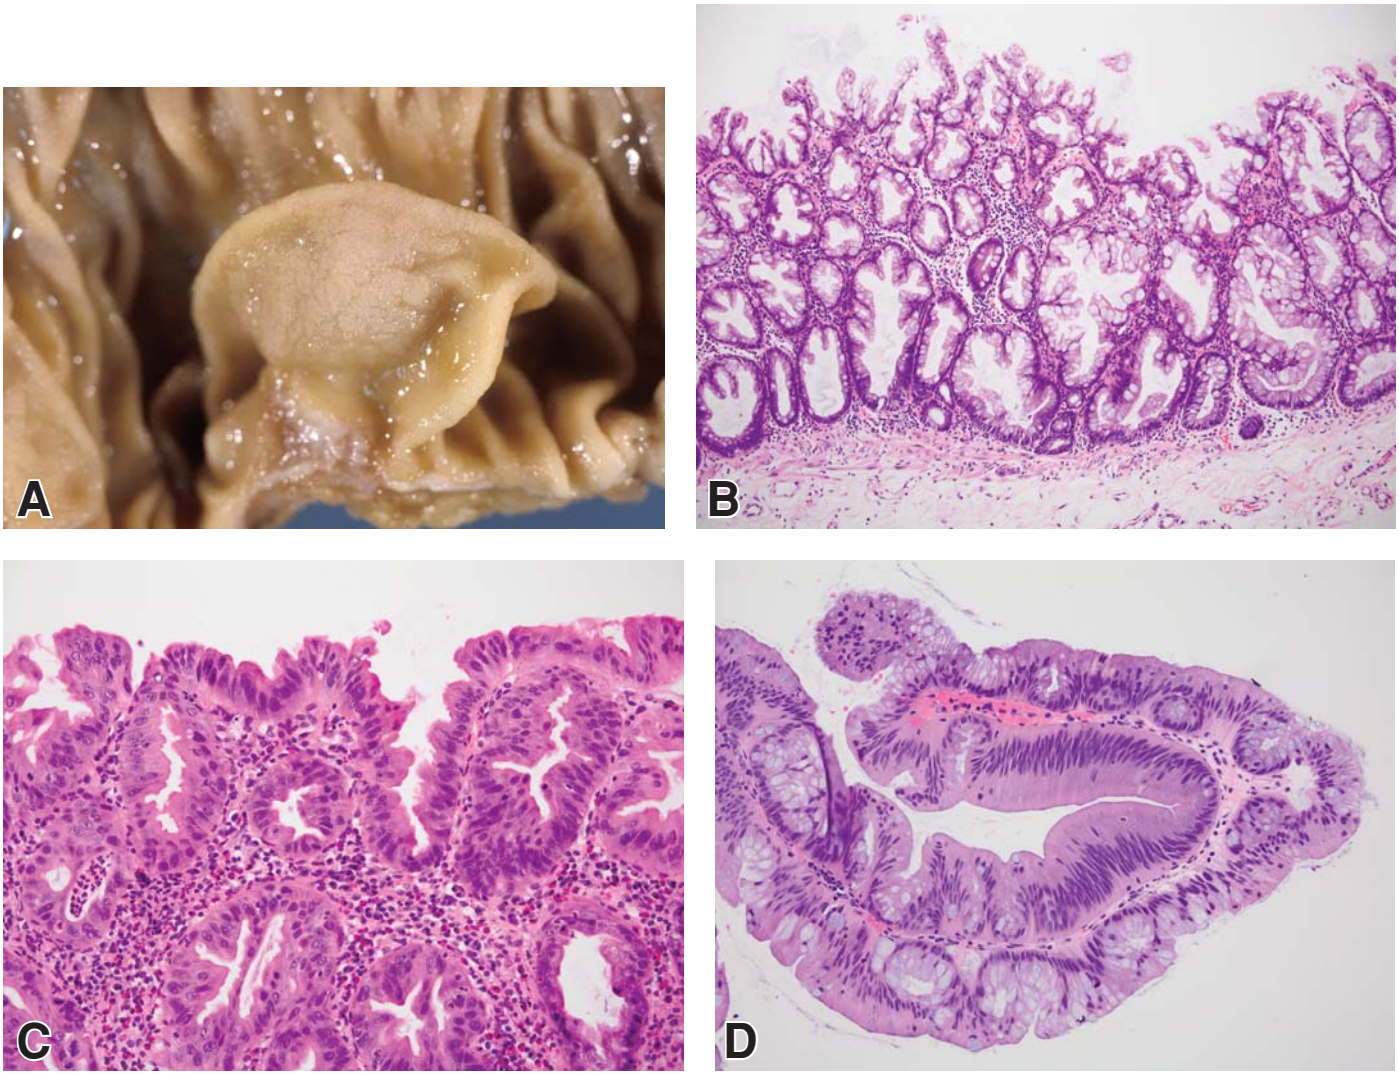

FIGURE 19-83. Premalignant serrated polyps. A. Sessile serrated adenoma. The gross appearance is often that of an enlarged flattened mucosal fold. **B. Sessile serrated adenoma.** Microscopically, the abnormal proliferation of goblet cells gives the crypts a serrated appearance down to the bases, causing the bases to become dilated with abundant mucin and the characteristic formation of boot-, "L"- or inverted "T"-shaped crypts. **C. Sessile serrated adenoma** with cytologic high-grade dysplasia. **D. Traditional serrated adenoma.** The most characteristic feature of this polyp type is formation of ectopic crypts, often with a villous architecture and lining epithelial cells with abundant eosinophilic cytoplasm.

affected relative. All lesions greater than 5 mm, especially if right sided, should be removed.

Adenomatous Polyps Are Premalignant

Adenomatous polyps (tubular adenomas) are neoplasms of colonic epithelium. They are composed of neoplastic epithelial cells that migrated to the surface and accumulated beyond the needs for replacement of the cells sloughed into the lumen.

EPIDEMIOLOGY: These polyps occur most in industrialized countries. As with diverticular disease, the only known consistent environmental difference between high-risk and low-risk populations is a "Western" diet. After age 50, the incidence of adenomas rises rapidly such that in the United States, at least one adenomatous polyp is present in half of the adult population. This proportion reaches greater than 2/3 among those older than 65. Smoking, obesity and a family history of colon adenomas or carcinoma increase the risk of having adenomas.

PATHOLOGY: Almost half of adenomatous polyps of the colon in the United States are in the rectosigmoid. The remaining half are evenly distributed throughout the rest of the colon. Adenomas vary from barely visible nodules or small, pedunculated adenomas to large, sessile (flat) lesions. They are classified by architecture into tubular, villous and tubulovillous types. These polyps are the usual precursors to colon carcinoma, and their epithelium is by definition dysplastic.

TUBULAR ADENOMAS: These represent 2/3 of large bowel adenomas. They are typically smooth-surfaced lesions, less than 2 cm, often with a stalk (Fig. 19-84). Some tubular adenomas, particularly the smaller ones, may be sessile.

Tubular adenomas show closely packed epithelial tubules, which may be uniform or irregular and excessively branched (Fig. 19-84C). Tubular adenomas show at least low-grade

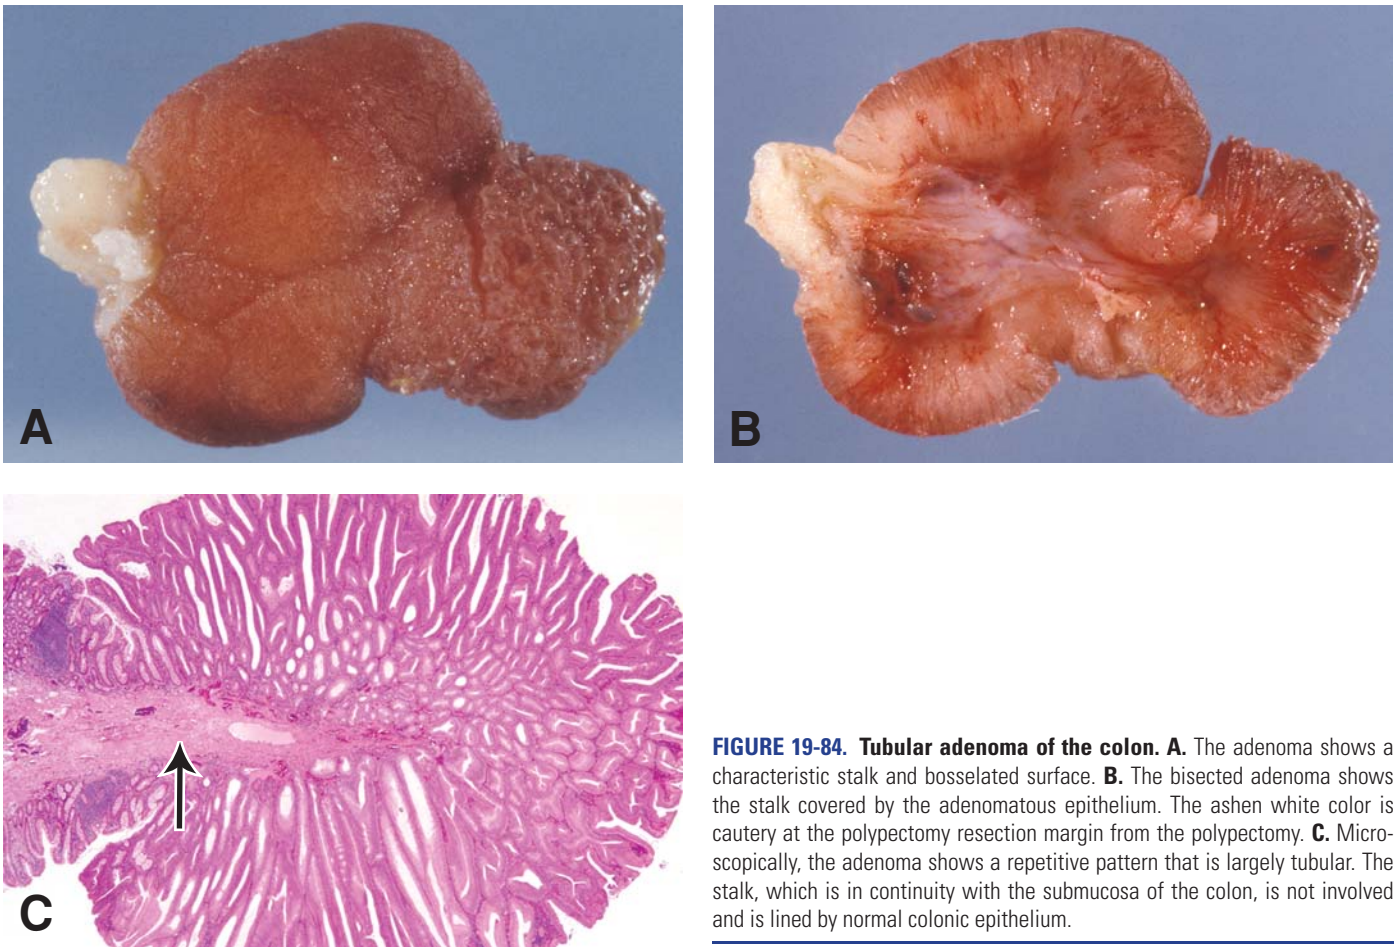

FIGURE 19-84. Tubular adenoma of the colon. A. The adenoma shows a characteristic stalk and bosselated surface. **B.** The bisected adenoma shows the stalk covered by the adenomatous epithelium. The ashen white color is cautery at the polypectomy resection margin from the polypectomy. **C.** Microscopically, the adenoma shows a repetitive pattern that is largely tubular. The stalk, which is in continuity with the submucosa of the colon, is not involved and is lined by normal colonic epithelium.

epithelial dysplasia and may occasionally show progression to high-grade dysplasia with increased nuclear pleomorphism and complex architecture. High-grade dysplasia can progress to invasive adenocarcinoma, the diagnosis of which requires neoplastic glands below the muscularis mucosae (Fig. 19-85). As long as dysplasia is confined to the mucosa, the lesion is cured by complete polypectomy. Invasive adenocarcinoma may be cured by polypectomy alone if the tumor shows low-risk features and there is an adequate margin of resection at the base.

The risk of invasive carcinoma correlates with the size of the adenoma. Only 1% of tubular adenomas less than 1 cm

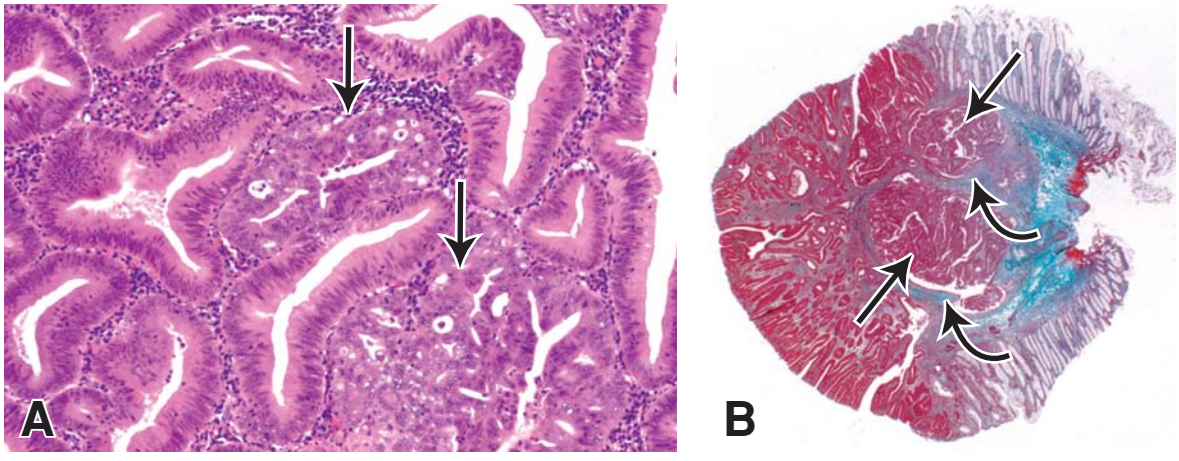

FIGURE 19-85. Adenocarcinoma arising in a pedunculated adenomatous polyp. A. Both low-grade dysplasia and high-grade dysplasia are present. The former is characterized by elongated, hyperchromatic, pseudostratified nuclei. The latter is characterized by a cribriform pattern and increased nuclear pleomorphism (*arrows*). **B.** Trichrome stain showing tumor invading the stalk (*blue*). Since there was a margin of resection of over 1 mm, polypectomy was sufficient therapy.

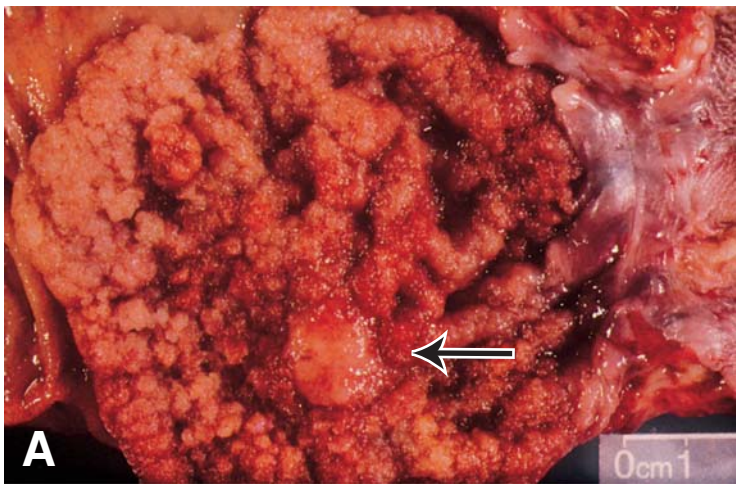

FIGURE 19-86. Villous adenoma of the colon. A. The colon contains a large, broad-based, elevated lesion that has a cauliflower-like surface. A firm area near the center of the lesion proved on histologic examination to be an adenocarcinoma. **B.** Microscopic examination shows finger-like processes with fibrovascular cores lined by low-grade dysplastic epithelium.

have invasive cancer at the time of resection; of those 1–2 cm, 10% harbor malignancy; and of those greater than 2 cm, 35% are malignant. Small flat adenomas may be missed during conventional endoscopy and thus have a high risk of progression to cancer.

VILLOUS ADENOMAS: These polyps constitute 1/10 of colonic adenomas and are found mainly in the rectosigmoid region. They are typically large, broad-based, elevated lesions with shaggy, cauliflower-like surfaces (Fig. 19-86A), but they can be small and pedunculated. Most exceed 2 cm, and they may reach 10–15 cm. Villous adenomas are composed of thin, tall, finger-like processes that resemble the villi of the small intestine. They are lined externally by neoplastic epithelial cells and are supported by a core of normal lamina propria (Fig. 19-86B).

Dysplasia in villous adenomas resembles that in tubular adenomas. However, villous adenomas contain foci of carcinoma more often than do tubular adenomas. In villous adenomas under 1 cm, the risk of cancer is 10 times higher than that for tubular adenomas of comparable size. Half of villous adenomas greater than 2 cm harbor invasive carcinoma. Since most villous adenomas exceed 2 cm, more than 1/3 of all resected villous adenomas contain invasive cancer.

TUBULOVILLOUS ADENOMAS: Many adenomatous polyps have both tubular and villous features. Polyps with 25%–75% villous architecture are **"tubulovillous."** These tend to be intermediate in distribution and size between tubular and villous forms, with 1/3 being greater than 2 cm. Tubulovillous polyps are also intermediate between tubular and villous adenomas in the risk of invasive carcinoma.

PATHOPHYSIOLOGY: The precursor to colorectal carcinoma is dysplasia, usually in the form of an adenoma. The pathogenesis of adenomas of the colon and rectum involves neoplastic alteration of crypt epithelial homeostasis with (1) diminished apoptosis, (2) persistent cell replication and (3) failure of epithelial cells to mature and differentiate as they migrate toward crypt surfaces. Normally, DNA synthesis stops when cells reach the upper 1/3 of crypts, after which they mature, migrate to the surface and then are sloughed into the lumen. Adenomas represent focal disruption of this orderly sequence, in that epithelial cells may proliferate throughout the entire depth of the crypt: mitotic figures are present along the entire length of the crypt and on the mucosal surface. As the lesion evolves, the proliferation rate exceeds that of sloughing, and cells accumulate in upper crypts and on the surface.

Familial Adenomatous Polyposis Is an Autosomal Dominant Trait That Invariably Leads to Cancer

Also called adenomatous polyposis coli (APC), FAP accounts for less than 1% of colorectal cancers. It is caused by a heritable, germline mutation in the APC gene on the long arm of chromosome 5 (5q21-22) (see below). Most cases are familial, but 30%–50% reflect new mutations. In FAP, there are hundreds to thousands of adenomas carpeting the colorectal mucosa, sometimes throughout its entire length, but particularly in the rectosigmoid region (Fig. 19-87). These are

FIGURE 19-87. Familial polyposis. The colon contains thousands of adenomatous polyps with several exceeding 1 cm in diameter.

mostly tubular adenomas, but tubulovillous and villous adenomas may also be present. Microscopic adenomas, sometimes involving a single crypt, are numerous. A few polyps are usually already present by age 10, but symptoms usually begin by age 36. By this time cancer is often already present. Carcinoma of the colon and rectum is inevitable in FAP patients, with the mean age of onset at 40 years. Total colectomy before the onset of cancer is curative, but some patients may also have tubular adenomas in the small intestine and stomach, and these have the same malignant potential as those in the colon.

FAP mutations are found in only 3/4 of familial cases. Some APC mutation-negative patients have mutations in MYH (a distinct, rare, autosomal recessive, polyposis syndrome that clinically overlaps FAP). Subtypes of FAP include:

- **Attenuated FAP:** In this condition there are fewer than 100 adenomas in the colon. Colorectal cancer develops an average of 15 years later than in classical FAP and carries a 70% risk of invasive cancer by age 80.
- **Gardner syndrome:** In this variant, extracolonic lesions include osteomas of the skull, mandible and long bones; epidermoid cysts; desmoid tumors; and congenital hypertrophy of retinal pigment epithelium. *APC* mutations do not predict this phenotype.
- **Turcot syndrome:** This rare disorder combines FAP with malignant CNS tumors. Many cases, especially those with medulloblastoma, are due to germline mutations of the *APC* gene.

Colorectal Adenocarcinomas Mostly Arise in Adenomatous Polyps

In Western societies, colorectal cancer is the third most common cause of cancer and the second leading cause of cancer death. There is a marked geographic difference in the incidence of this cancer, with rates differing by 10-fold between developing and developed countries. This difference is largely attributed to environmental factors since countries that more recently adopted "Western" diets and lifestyles have seen marked increases in colorectal cancer rates, and people who migrate from low-incidence regions to high-incidence regions develop these cancers at rates similar to the high-incidence region. The term "colorectal" is used because cancers of the colon and rectum share certain biological features, but there are also differences between colonic and rectal cancers. For instance, colon cancer rates are about equal between men and women, but rectal cancer shows a slight male predominance. The two tumors are also treated differently.

ETIOLOGIC FACTORS: Most colorectal cancers arise in adenomatous polyps; thus, factors that lead to the development of such polyps favor colorectal cancer as well. There are several modifiable and nonmodifiable risk factors (see below). While no one feature of a "Western" lifestyle is identified as causative, multiple factors contribute to higher incidence, and diet seems to have the greatest impact—either via a direct effect or because of its effect on altering gut flora.

Risk Factors for Colorectal Carcinoma

AGE: Increasing age is probably the single most important risk factor for colorectal cancer in the general population. The risk is low (but not zero) before age 40. It then increases steadily to age 50, after which it doubles each decade.

PRIOR COLORECTAL CANCER: Patients with one colorectal cancer are at increased risk for a subsequent tumor. In fact, 5%–10% of patients treated for colorectal cancer develop a second such malignancy. Moreover, 2%–5% of those with a new colorectal cancer have a simultaneous (synchronous) colorectal primary cancer.

ULCERATIVE COLITIS AND CROHN DISEASE: These chronic inflammatory diseases increase colorectal cancer risk in proportion to their duration and extent of large bowel involvement.

GENETIC FACTORS: Risk of colorectal cancer is increased in relatives of patients with the disease, suggesting a genetic contribution to tumorigenesis. People with two or more first- or second-degree relatives with colorectal cancer constitute 20% of all patients with this tumor. Some 5%–10% of colorectal cancers are inherited as autosomal dominant traits, the most common syndrome being hereditary nonpolyposis colorectal carcinoma (HNPCC, Lynch syndrome [see below]).

DIET: Consumption of animal products including fat, cholesterol and protein parallels incidence of colorectal cancer. Moreover, certain ethnic and religious groups in the United States whose diets are lower in animal products have less colorectal cancer. Possibly, ingestion of animal products favors bacterial flora that degrade bile salts to N-nitroso compounds, which may contribute to tumorigenesis.

Diets low in fruits, vegetables and whole grains (fiber) have also been implicated in colorectal carcinogenesis. Reasons for this are not entirely clear but may be related to an effect on gut flora and stool transit time.

PHYSICAL ACTIVITY AND OBESITY: These factors combined are thought to account for up to 1/3 of colorectal cancers. While not well understood, physical inactivity decreases gut motility. Obesity increases circulating estrogens and decreases insulin resistance, factors that are believed to influence cancer risk.

CIGARETTE SMOKING AND ALCOHOL: Cigarette smoking and heavy alcohol consumption are independent risk factors for colon cancer. If present together, they may act synergistically. DNA mutations induced by smoking are repaired less efficiently in the presence of alcohol. Nutritional deficiencies may also play a role in heavy alcohol users.

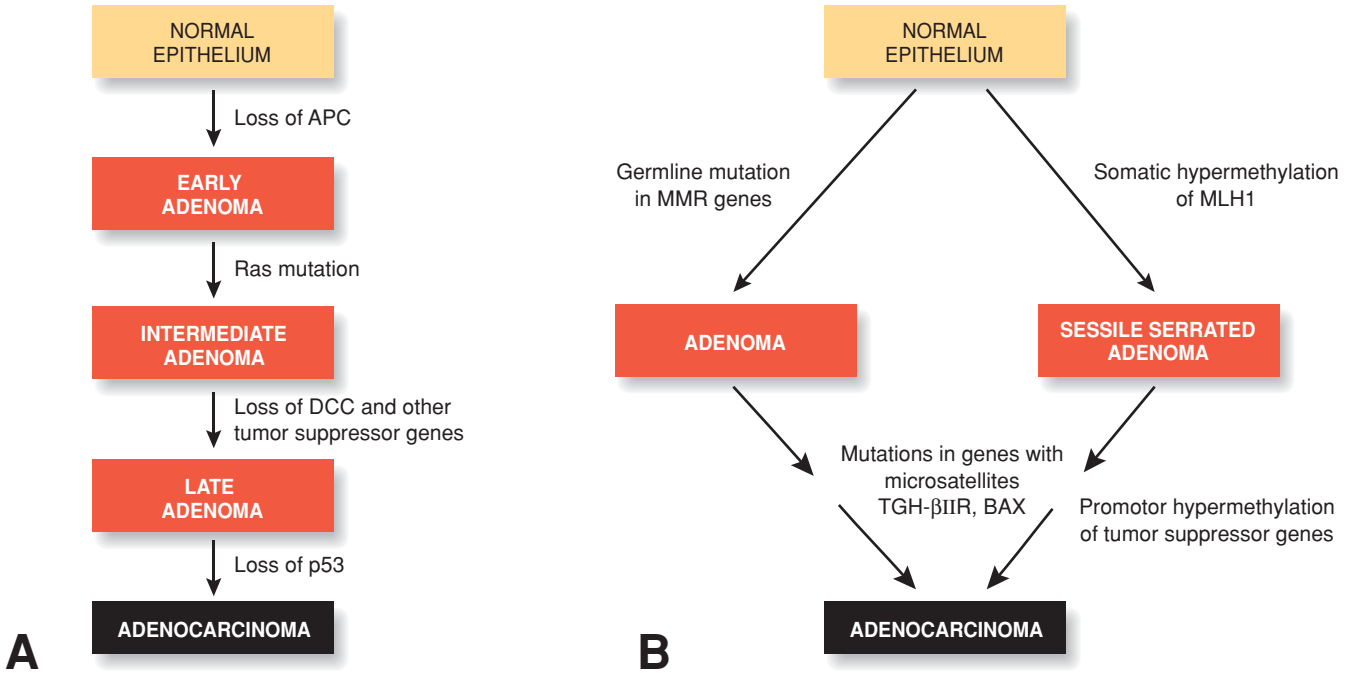

FIGURE 19-88. Model of some of the genetic alterations involved in colonic carcinogenesis. A. The tumor suppressor pathway. **B.** The mismatch repair (MMR) defect pathway. *APC* = adenomatous polyposis coli; *DCC* = deleted in colon cancer; *MLH1* = MutL homolog 1; *TGF-βIIR* = transforming growth factor-β2 receptor; *BAX* = BCL2 associated X protein.

MOLECULAR PATHOGENESIS: In 85% of cases of colorectal carcinoma, it is estimated that at least 8–10 mutational events must accumulate before an invasive cancer with metastatic potential develops. This process is initiated in histologically normal mucosa, proceeds through an adenomatous precursor stage and ends as invasive adenocarcinoma (see Chapter 5).

The most important mutational events involve (Fig. 19-88A):

- ***APC* gene:** As noted above, germline mutations in the *APC* (adenomatous polyposis coli) tumor suppressor gene lead to familial adenomatous polyposis. Normal APC is a negative regulator of β-catenin: it binds β-catenin and causes its phosphorylation, followed by ubiquitination and proteasomal degradation. Mutant APC allows β-catenin to accumulate in the nucleus, where it is a transcriptional activator of key proliferation genes (e.g., *cyclin D1* and *MYC*). ***APC is somatically mutated in 70%–80% of sporadic colorectal cancers.*** Some tumors with normal *APC* have mutations in the **β-catenin gene** itself. A specific *APC* mutation (isoleucine → lysine at codon 1307) occurs in 6% of Ashkenazi Jews, renders surrounding regions of the gene susceptible to inactivating frame-shift mutations and increases risk of colon cancer. *APC* mutations in normal colonic mucosa precede development of sporadic adenomas. Thus, *APC* is central to the early development of most colorectal neoplasms.
- ***KRAS:*** Activating mutations of the *KRAS* proto-oncogene occur early in tubular adenomas of the colon.
- ***DCC*** gene: A putative tumor suppressor gene, *DCC* ("deleted in colon cancer") is located on chromosome 18 and is often missing in colorectal cancers.
- ***TP53:*** Mutations in p53 facilitate the transition from adenoma to the most common type of adenocarcinoma and are late events in colon carcinogenesis.

In 15% of colorectal cancers, the process of **DNA mismatch repair** (MMR; see Chapter 5) is impaired, leading to deficient repair of spontaneous replication errors, particularly in regions with simple repetitive sequences (microsatellites). MMR deficiencies occur via two mechanisms. In a hereditary form (HNPCC; see below), a germline mutation in one of the MMR genes is followed by somatic mutation of the other allele ("second hit"; see Chapter 5) later in life. In sporadic tumors, hypermethylation of an MMR promoter, usually for the *MLH1* gene, inactivates transcription of the gene (Fig. 19-88B).

PATHOLOGY: Grossly, colorectal cancers resemble adenocarcinomas elsewhere in the gut. They tend to be polypoid and ulcerating or infiltrative, and may be annular and constrictive (Fig. 19-89). Polypoid cancers are more common in the right colon, particularly the cecum, where the large lumen allows unimpeded intraluminal growth. Annular constricting tumors occur more often in the distal colon. Tumors often ulcerate, regardless of growth pattern.

The vast majority of colorectal cancers are adenocarcinomas that resemble their counterparts elsewhere in the digestive tract (Fig. 19-89B)**.** About 15% secrete abundant mucin and are called **mucinous** adenocarcinomas. Degree of differentiation influences prognosis; better-differentiated tumors tend to have a more favorable outlook.

Colon cancers spread by direct extension or vascular invasion. The former is common in resected specimens. Serosal connective tissue offers little resistance to tumor spread, and

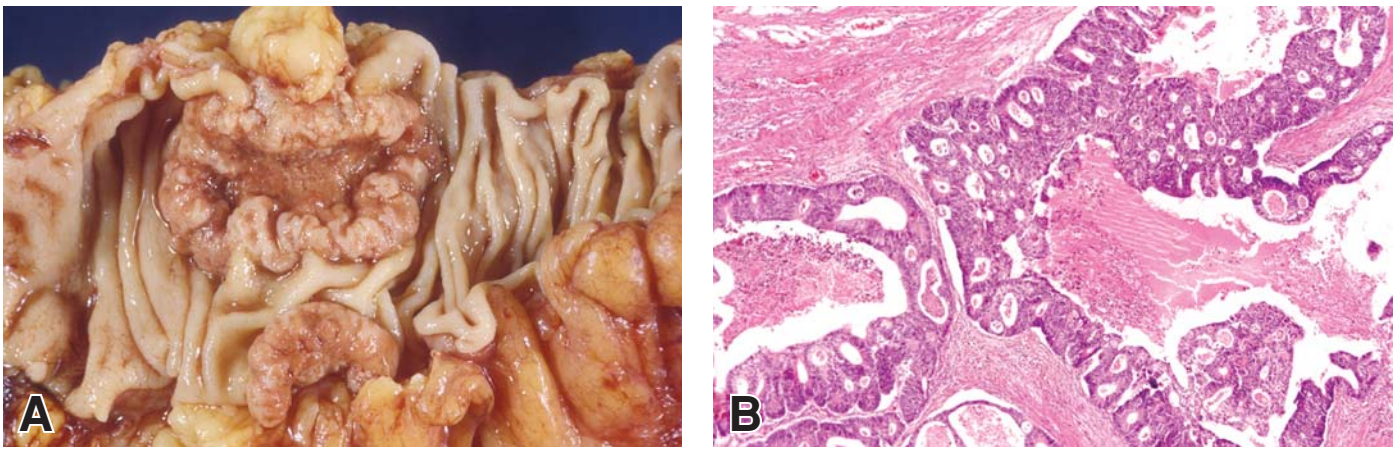

FIGURE 19-89. Adenocarcinoma of the colon. A. A resected colon shows an ulcerated mass with enlarged, firm, rolled borders. **B.** Microscopically, this colon adenocarcinoma consists of moderately differentiated glands with a prominent cribriform pattern and frequent central necrosis.

cancer cells are often seen in the pericolorectal fat far from the primary site. The peritoneum is occasionally involved, in which case there may be multiple deposits throughout the abdomen.

Colorectal cancer invades lymphatic channels and initially involves lymph nodes just below the tumor. The liver is the most common metastatic organ site, but the tumor may spread widely. The prognosis of colorectal cancer is more closely related to tumor extension through the large bowel wall than to its size or histopathology.

Staging of these tumors uses the TNM system (tumor, lymph nodes, metastasis; see Chapter 5). T1 tumors invade the submucosa; T2 tumors infiltrate into, but not through, the muscularis propria; T3 tumors invade pericolorectal soft tissue; and T4 tumors penetrate the serosa (T4a) or involve adjacent organs (T4b). N reflects the presence or absence of lymph node metastases, and M the presence or absence of distant metastases.

CLINICAL FEATURES: Initially, colorectal cancer is clinically silent. As the tumor grows, the most common sign is **fecal occult blood** when the tumor is in the proximal colon. Both occult blood and **bright red blood** in the feces may occur if a lesion is in the distal colorectum.

Cancers on the left side of the colon, where the lumen is narrow and feces are more solid, often constrict the lumen and produce **obstructive symptoms**. These include changes in bowel habits and abdominal pain. Colorectal cancers may **perforate** early and cause peritonitis. By contrast, right-sided cancers may grow large without causing obstruction, especially in the cecum where the lumen is large and fecal contents are liquid. As a result, right-sided tumors can lead to asymptomatic chronic bleeding. **Iron-deficiency anemia** may be the first indication of colorectal cancer. A tumor that spreads beyond the colorectum may cause enterocutaneous and rectovaginal **fistulas,** tumor masses in the abdominal wall, bladder symptoms and sciatic nerve pain. Spread within the abdomen may cause **small intestinal obstruction** and malignant **ascites**.

A positive test for fecal occult blood predicts the presence of a cancer or an adenoma in 50% of cases. Periodic fiberoptic colonoscopy and testing for occult blood in feces can detect tumors at early stages and have improved survival in colorectal cancer.

Resection is the only curative treatment for colorectal cancer. Small polyps are easily removed endoscopically; large lesions require segmental resection. Tumors near the anal verge often necessitate abdominal–perineal resection and colostomy, although newer surgical techniques may preserve sphincter function. Preoperative (neoadjuvant) chemotherapy and radiotherapy are typically used in all but very early rectal cancers.

Hereditary Nonpolyposis Colorectal Cancer (Lynch Syndrome)

HNPCC is an autosomal dominant inherited disease that accounts for 3%–5% of colorectal cancers.

MOLECULAR PATHOGENESIS: Lynch syndrome is caused by germline mutations in a DNA MMR gene. Usually, *hMSH2* (human MutS homolog 2) on chromosome 2p and *hMLH1* (human MutL homolog 1) on chromosome 3p are affected. Less common mutations involve *hMSH6* (human MutS homolog 6) or *hPMS2* (human postmeiotic segregation 2) on chromosomes 2p and 7p, respectively. In HNPCC, there is a germline mutation in one allele of one MMR gene. The fact that one allele is mutated hinders repair of any second sporadic mutation in the other (formerly) wild-type allele: a somatic "second hit" (see Chapter 5). Thereafter, repair of spontaneous replication errors is ineffective. Widespread genomic instability results, particularly in simple repetitive sequences (microsatellites), which are particularly prone to replication errors. Thus, genes that regulate growth and differentiation, and other mismatch repair genes, are disabled by unrepaired mutations.

Mismatch repair deficiency can be identified by sequencing MMR genes, testing for microsatellite instability and immunostaining to assess levels of MMR proteins in a tumor. A specific mutation can be used to evaluate other family members.

PATHOLOGY AND CLINICAL FEATURES: Lynch syndrome tumors more often show mucinous, signet ring cell and

TABLE 19-4

LYNCH SYNDROME/HEREDITARY NONPOLYPOSIS COLORECTAL CANCER (HNPCC)

Amsterdam II Criteria (must meet all criteria)
At least three relatives must have histologically verified HNPCC-associated cancer
One must be a first-degree relative of the other two
At least two successive generations must be affected
At least one of the relatives with colorectal cancer must have received the diagnosis before the age of 50 years
Familial adenomatous polyposis must have been excluded
Revised Bethesda Guidelines (only one criterion needs to be met)
Diagnosed with colorectal cancer (CRC) before the age of 50 years
Individuals with more than one CRC or other HNPCC-related tumor
CRC with high-microsatellite instability morphology, diagnosed before the age of 60 years
CRC and a first-degree relative with CRC or other HNPCC-related tumor. One cancer must have been diagnosed at younger than age 50 years or one adenoma at younger than age 40 years
CRC with at least two relatives with CRC or other HNPCC-related tumor, regardless of age

solid (medullary) histologies than sporadic tumors, with many intratumor lymphocytes and Crohn-like lymphocytic reactions. HNPCC patients tend to (1) present with cancer at a young age; (2) have few adenomas (hence "nonpolyposis"); (3) develop tumors proximal to the splenic flexure (70%); (4) have multiple synchronous or metachronous colorectal cancers; and (5) develop extracolonic cancers, especially of the endometrium, ovary, stomach, small intestine, urinary tract, pancreas, hepatobiliary tract, skin and CNS. Patients with Lynch syndrome who have skin involvement (sebaceous adenomas and carcinomas) are said to have **Muir-Torre syndrome** (see Chapter 28). Specific criteria for the diagnosis of Lynch syndrome are listed in Table 19-4.

OTHER TUMORS OF THE LARGE INTESTINE

Colonic Mesenchymal Tumors Encompass the Range of Benign and Malignant Soft Tissue Tumors

Mesenchymal tumors arising from tissues normally in the colon include lipoma, liposarcoma, neurofibroma, ganglioneuroma, peripheral nerve sheath tumors, leiomyoma, leiomyosarcoma, vascular tumors and GISTs (see above). Of these, the most common are submucosal lipomas and leiomyomas.

Colonic Neuroendocrine Tumors Resemble NETs of the Small Intestine

These tumors were also called carcinoid tumors (see above). Half of colorectal NETs have metastasized by the time they are discovered.

Large Bowel Lymphomas Are Usually B-Cell Tumors

Primary lymphoma of the colorectum is uncommon. It may be seen with (1) segmental mucosal involvement, (2) diffuse polypoid lesions or (3) a mass extending beyond the colorectum. Symptoms are like those of other intestinal cancers, but the diffuse polypoid form may resemble inflammatory or adenomatous polyps. Most colonic lymphomas are tumors of B cells.

Endometriosis Involving the Colon Can Mimic Colorectal Cancer

Colorectal endometriosis is mostly asymptomatic and is discovered incidentally during laparotomy for other reasons. If symptoms occur (abdominal pain, constipation, intestinal obstruction), they may be mistaken for those of colorectal cancer. As a result of repeated hemorrhage, the lesions are surrounded by reactive fibrosis, which, when severe, can lead to a classic "apple core" appearance to the colon or rectum and grossly mimic a primary colorectal carcinoma (see Chapter 24).

The Anus

The anal canal extends from the level of the pelvic floor to the proximal margin of the anal verge. It is about 4 cm long and is divided into 3 parts, based on its lining epithelium: the colorectal zone (lined by glandular mucosa), the transition zone (varying, transitional mucosa) and the distal, squamous zone (lined by squamous mucosa). The dentate (pectinate) line (formed by the anal valves, roughly midway through the anal canal) is easily identified, and the superior border of the anal canal may be defined as 2 cm above this line.

BENIGN LESIONS OF THE ANAL CANAL

Hemorrhoids Are Dilated Venous Channels of the Hemorrhoidal Plexuses

They result from downward displacement of the anal cushions. Internal hemorrhoids arise from the superior hemorrhoidal plexus above the dentate (pectinate) line. They are covered by rectal or transitional mucosa. External hemorrhoids originate from the inferior hemorrhoidal plexus, below that line, and are covered by squamous mucosa. ***Hemorrhoids affect at least 5% of people in Western countries (likely a gross underestimate since most people treat themselves for this condition).*** They are most common in whites between 45 and 65 years old. Pregnancy is another risk factor, presumably related to increased abdominal pressure.

PATHOLOGY: Hemorrhoids are dilated vascular spaces with excess smooth muscle in their walls. Hemorrhage and thrombosis are common.

CLINICAL FEATURES: Hemorrhoids cause painless rectal bleeding associated with bowel movements. While chronic blood loss may lead to **iron-deficiency anemia,** other causes must be ruled out before

it is attributed to hemorrhoidal bleeding**. Rectal prolapse** is common and may cause perineal irritation or anal itching. Prolapsed hemorrhoids may become irreducible and lead to painful, strangulated hemorrhoids. **Thrombosed** external hemorrhoids are exquisitely painful and require evacuation of the offending clots. Hemorrhoids are treated with dietary and lifestyle modifications aimed at improving the quality of stools and reducing straining on the toilet. Medical and surgical interventions are also available.

Anal Condylomata Acuminata (Anal Warts) Are Related to HPV Infection

These lesions are typically benign but may potentially develop into squamous cancers.

PATHOLOGY: Condylomata have a cauliflower-like growth pattern of papillary excrescences lined by squamous epithelium that is often hyperkeratotic. The squamous cells show characteristic koilocytic change, having enlarged nuclei with irregular nuclear contours, often binucleated, with perinuclear cytoplasmic clearing. These can develop dysplasia—graded mild, moderate or severe, similarly to the grading scheme in the cervix (see Chapter 24).

MALIGNANT TUMORS OF THE ANAL CANAL

Anal Canal Cancers Are Mostly Squamous Cell Carcinomas

These cancers, while increasing in frequency, are relatively uncommon. They are more common in women than in men, and their incidence is 1.4 per 100,000. In the highest-risk group, people who practice anal-receptive intercourse, incidence approaches 35 per 100,000.

PATHOLOGY: Anal cancers have various histologic patterns (e.g., squamous or basaloid [cloacogenic]). But all tumor types tend to behave similarly and so are simply classified as **squamous cell carcinomas. Bowen disease of the anus** is squamous carcinoma in situ. Anal carcinomas spread directly into surrounding tissues, including internal and external sphincters, perianal soft tissues, the prostate and the vagina.

CLINICAL FEATURES: The major risk factor for anal squamous cell carcinoma is infection with HPV. Other risk factors include HIV infection, immunosuppression in organ transplantation, presence of an immune disorder and smoking.

The usual symptom of anal cancers is bleeding, but pain and/or a palpable mass are also possible. Often a tumor is not first recognized as malignant and may be discovered only in a hemorrhoidectomy specimen. Combined chemotherapy and radiation therapy is the customary treatment, although abdominal–perineal resection is sometimes used. The 5-year survival rate averages 75%, but patients with more advanced tumors (greater size, lymph node and/or distant metastases) do worse.

Extramammary Paget Disease May Involve the Anus

Paget disease is classically described in the breast (Chapter 25) but also occurs elsewhere, including the anogenital region. It can be primary when it arises from the epidermis or secondary if it is associated with an underlying adenocarcinoma.

PATHOLOGY: Grossly involved areas may appear normal or be erythematous, scaly or ulcerated. The epidermis often shows reactive changes including hyperplasia and hyperkeratosis. The hallmark finding is malignant cells with pale, granular or vacuolated cytoplasm scattered throughout the epidermis (Fig. 19-90).

Figs. 19-91 through 19-94 summarize the causes of gastrointestinal bleeding and obstruction and the major benign and malignant tumors of the GI tract.

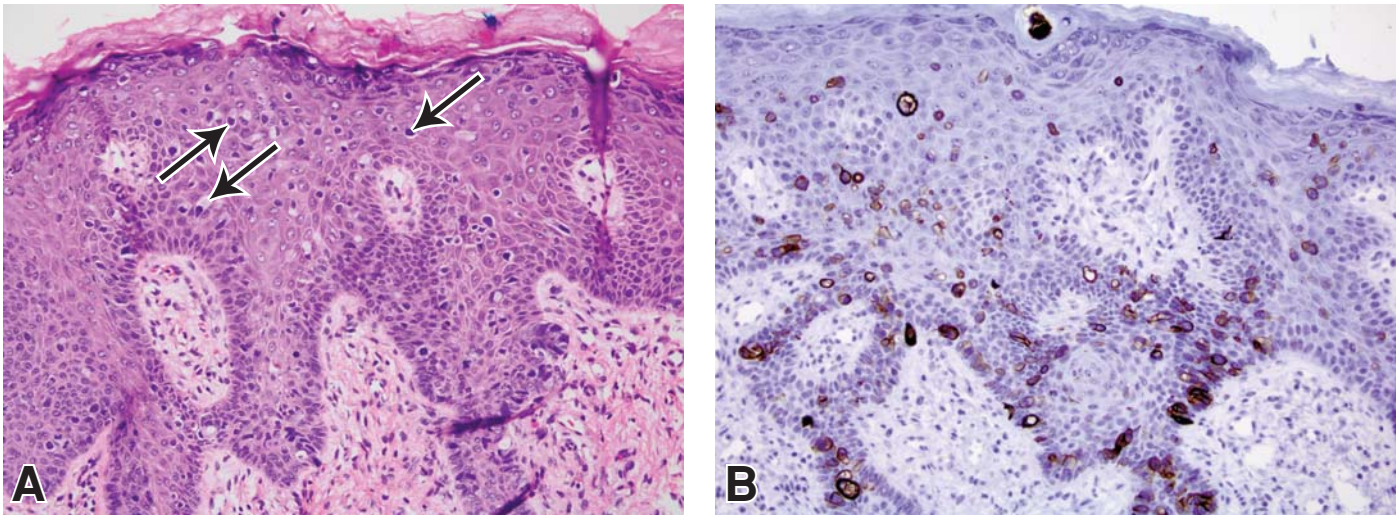

FIGURE 19-90. Paget disease of the anal canal. A. Microscopic image showing squamous epithelium with scattered malignant cells with pale or vacuolated cytoplasm seen throughout the epidermis (*arrows*). **B.** Immunohistochemical stain for CK20 highlights the malignant cells.

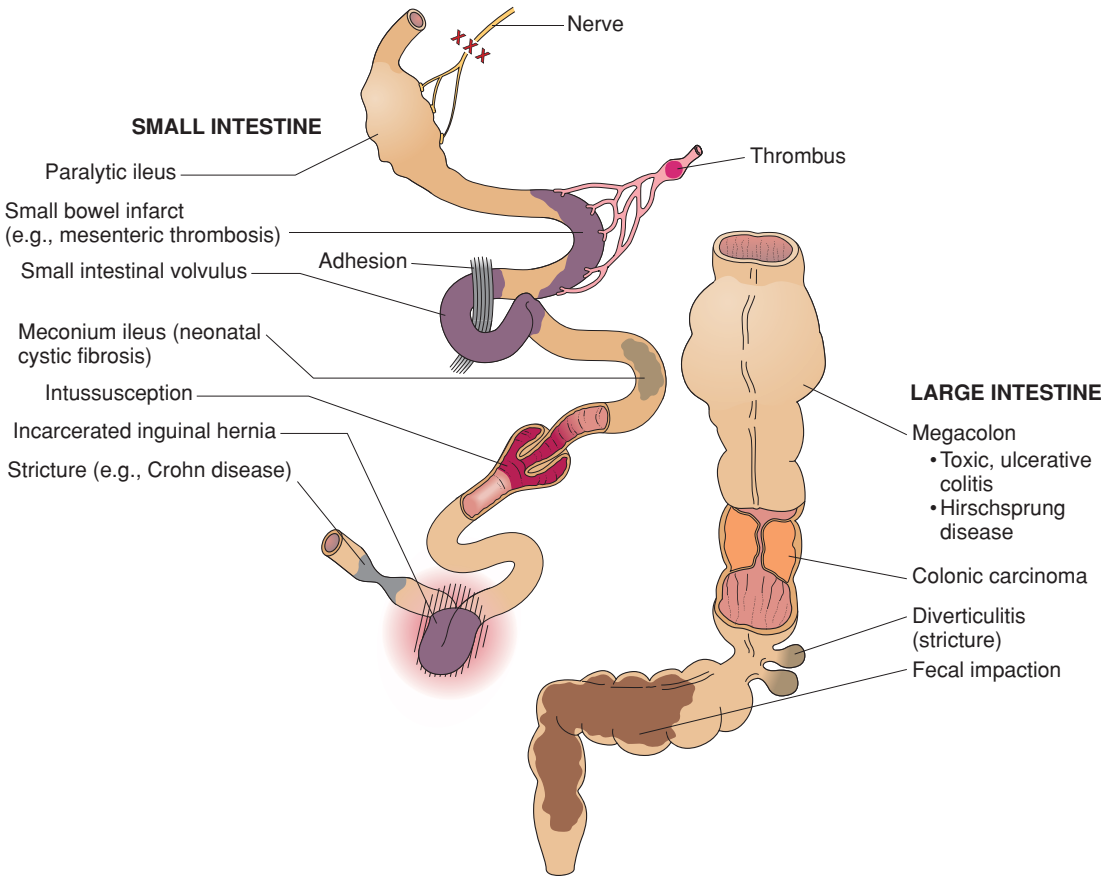

FIGURE 19-92. Causes of gastrointestinal obstruction.

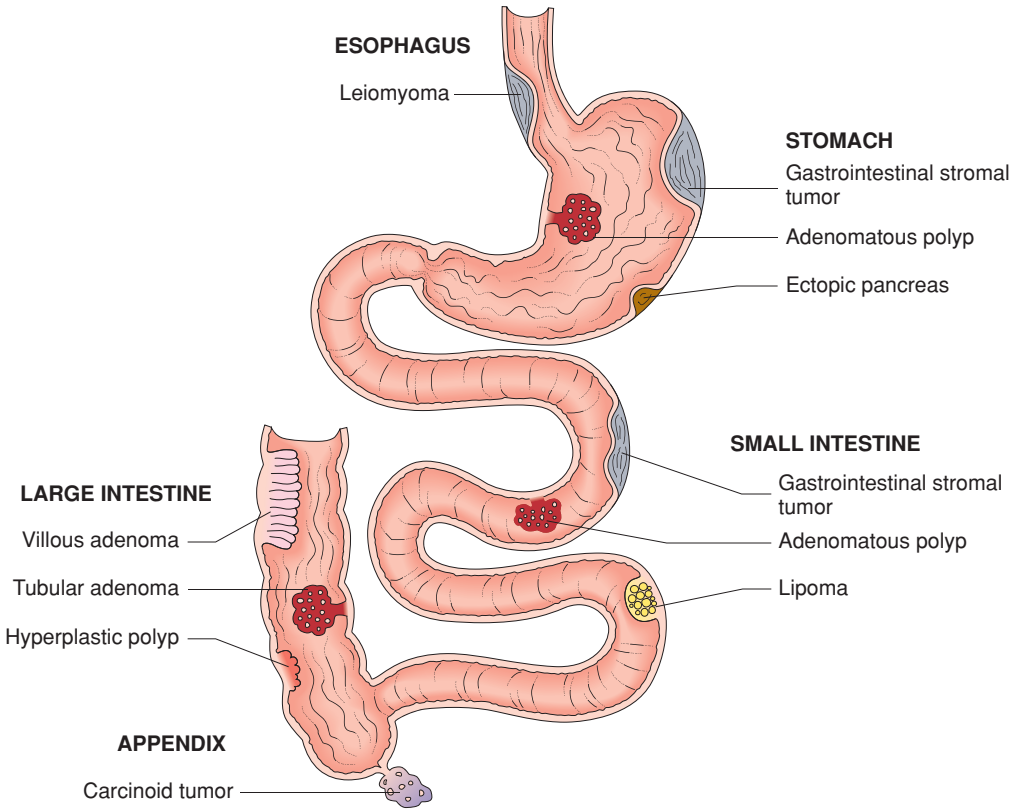

FIGURE 19-93. Major benign tumors of the gastrointestinal tract.

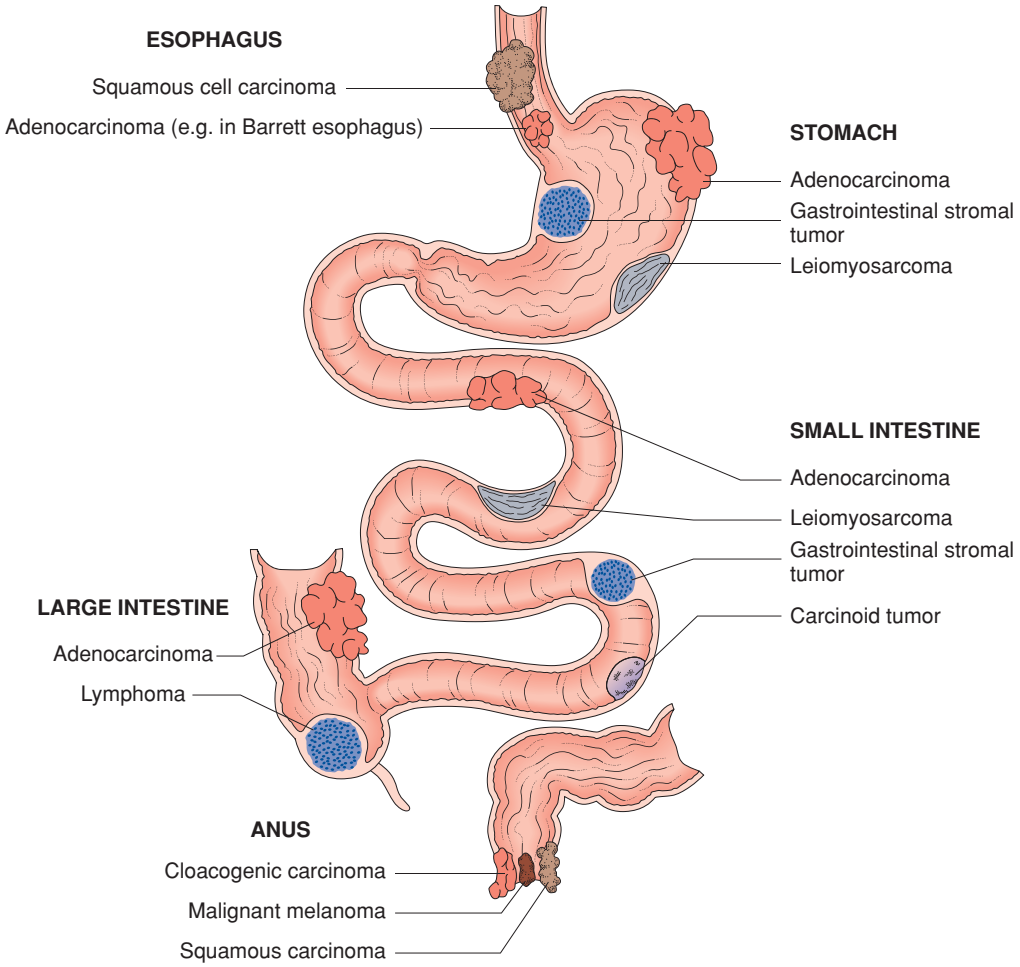

FIGURE 19-94. Major malignant tumors of the gastrointestinal tract.

The Peritoneum

The peritoneum is the mesothelial lining of the abdominal cavity and its viscera. The visceral peritoneum invests the gastrointestinal tract from stomach to rectum and encircles the liver. The parietal peritoneum lines the abdominal wall and retroperitoneal space. The omentum, which has a double layer of peritoneum, encloses blood vessels and a variable amount of fat.

PERITONITIS

Bacterial Peritonitis Is Usually Caused by Intestinal Organisms

ETIOLOGIC FACTORS: ***PERFORATION: The most common cause of bacterial peritonitis is perforation of an abdominal viscus*** (e.g., an inflamed appendix, peptic ulcer or colon diverticulum). Peritonitis results in an acute abdomen, with severe abdominal pain and tenderness. Nausea, vomiting and a high fever are usual. In severe cases, generalized peritonitis, paralytic ileus and septic shock (see Chapter 12) ensue. Often the perforation is "walled off," in which case a peritoneal abscess results.

The bacteria released into the peritoneal cavity from the gastrointestinal tract vary according to the site of perforation and the duration of the peritonitis. Diverse aerobic and anaerobic species usually participate, including *E. coli, Bacteroides* sp., various *Streptococcus* spp. and *Clostridium.* Despite antibiotic treatment, surgical drainage and supportive measures, generalized peritonitis still carries substantial mortality and is especially dangerous in the elderly.

PERITONEAL DIALYSIS: Chronic peritoneal dialysis is a frequent cause of bacterial peritonitis, due to contamination of instruments or dialysate. The clinical course is usually milder than with a perforated viscus; *Staphylococcus* and *Streptococcus* spp. are most often responsible. Chronic dialysis can also cause aseptic peritonitis, presumably due to a chemical in the dialysate to which the peritoneum is sensitive.

SPONTANEOUS BACTERIAL PERITONITIS: Sometimes, peritoneal infection lacks a clear cause. ***Such spontaneous bacterial peritonitis occurs most often in adults with cirrhosis complicated by portal hypertension and ascites*** (see Chapter 20). Enteric organisms, mainly gram-negative bacilli, appear to move from the gut to mesenteric lymph nodes. From there, they seed the ascitic fluid, where phagocytic and antibacterial activities are low.

In children, spontaneous bacterial peritonitis can complicate the **nephrotic syndrome** (see Chapter 22). Spontaneous peritonitis in children is mostly due to gram-negative organisms, usually from urinary tract infections. The disease causes symptoms of an acute abdomen and usually leads to surgical intervention, unless the child is known to have nephrotic syndrome. Even with antibiotic treatment, mortality is 5%–10%.

TUBERCULOUS PERITONITIS: Tuberculous peritonitis is rare in industrialized countries, but it may occur in developing countries. Many patients with tuberculous peritonitis do not have apparent pulmonary or miliary disease, which suggests that it represents activation of latent tuberculous foci in the peritoneum derived from previous hematogenous dissemination.

PATHOLOGY: Grossly, bacterial peritonitis resembles purulent infection elsewhere. A fibrinopurulent exudate covers the surface of the intestines. When it organizes, fibrinous and fibrous adhesions form between loops of bowel, which then adhere to each other. Such adhesions may eventually be lysed, or they may lead to **volvulus** and **intestinal obstruction**. Bacterial salpingitis, usually due to gonococcus, may lead to pelvic peritonitis and adhesions. This occurrence defines **pelvic inflammatory disease** (see Chapter 24).

Chemical Peritonitis Usually Results from Endogenous Sources

- **Bile peritonitis** occurs when bile enters the peritoneum, usually from a perforated gallbladder but sometimes from needle biopsy of the liver. This abrupt insult may lead to shock.
- **Hydrochloric acid or hemorrhage** from a perforated peptic ulcer of the stomach or duodenum may elicit an inflammatory reaction in the peritoneum.
- In **acute pancreatitis,** activated lipolytic and proteolytic enzymes are released into the peritoneum, where they cause severe peritonitis with fat necrosis. Shock is common and may be lethal unless it is adequately treated.
- **Foreign materials** introduced by surgery (e.g., talc) or by trauma are unusual causes of chemical peritonitis.
- **Leakage of urine** can produce ascites.

NEOPLASMS OF THE PERITONEUM

Mesenteric and Omental Cysts Are Usually of Lymphatic Origin

They may also derive from other embryonic tissues. Usually a slowly enlarging, painless mass is discovered in a child older than 10 years. The cyst may come to medical attention because of rupture, bleeding, torsion or intestinal obstruction. Surgical excision is curative.

Malignant Peritoneal Mesotheliomas Are Rare, Aggressive Tumors

One quarter of mesotheliomas arise in the peritoneum. ***Like pleural mesotheliomas, most of these malignant tumors are associated with exposure to asbestos.*** Pathologic characteristics of peritoneal mesotheliomas are identical to those of their pleural counterparts (see Chapter 18).

Primary Peritoneal Carcinomas Resemble Ovarian Carcinoma

Primary peritoneal carcinomas present as tumor masses involving the omentum and peritoneum. They are morphologically identical to serous carcinomas of the ovary, except that in primary peritoneal carcinomas, the ovaries are normal (see Chapter 24).

The Most Common Malignancies of the Peritoneum Are Metastatic Carcinomas

Ovarian, gastric and pancreatic carcinomas are particularly likely to seed the peritoneum, but any intra-abdominal malignancy can spread to the peritoneum.

The Liver

ANATOMY

The liver arises from the embryonic foregut as an endodermal bud that differentiates into the hepatic diverticulum. Strands of endodermal cells mingle with proliferating mesenchymal cells to form the adult liver, gallbladder and extrahepatic bile ducts.

The liver weighs about 1500 g in an average adult man and is in the right upper quadrant of the abdomen, just below the diaphragm. It has two lobes, a larger **right lobe** and a smaller **left lobe,** which meet at the level of the gallbladder bed. Inferiorly, the right lobe has lesser segments, the **caudate** and **quadrate lobes.** The **gallbladder** lies inferiorly, in a fossa of the right hepatic lobe, and extends a little below the inferior margin of the liver.

The liver has a dual blood supply: (1) the **hepatic artery,** a branch of the celiac axis, and (2) the **hepatic portal vein,** formed when the splenic and superior mesenteric veins join. The **hepatic veins** empty into the inferior vena cava, which is partly surrounded by the posterior surface of the liver. Hepatic lymphatics drain mainly into porta hepatis and celiac lymph nodes.

The right and left hepatic ducts merge to form the **hepatic duct,** which joins the cystic duct from the gallbladder to make the **common bile duct**. The latter meets the pancreatic duct just before emptying into the duodenum. It terminates in the ampulla of Vater, where its lumen is guarded by the sphincter of Oddi.

The Lobule Is the Basic Unit of the Liver

Liver lobules are polyhedral (Figs. 20-1 and 20-2), classically depicted as hexagons. **Portal triads** (or portal tracts) are peripheral, at the angles of the polygon, and contain intrahepatic branches of the (1) **bile ducts,** (2) **hepatic artery** and (3) **portal vein.** Portal tracts are invested by the **limiting plate,** a layer of adjacent hepatocytes. The **central venule** (or, **terminal hepatic venule**) is at the center of the lobule. Radiating from it are **one-cell-thick plates of hepatocytes,** which extend to the edge of the lobule, where they are continuous with plates of other lobules. Between plates of hepatocytes are **hepatic sinusoids,** which are lined by endothelial cells, Kupffer cells and stellate cells.

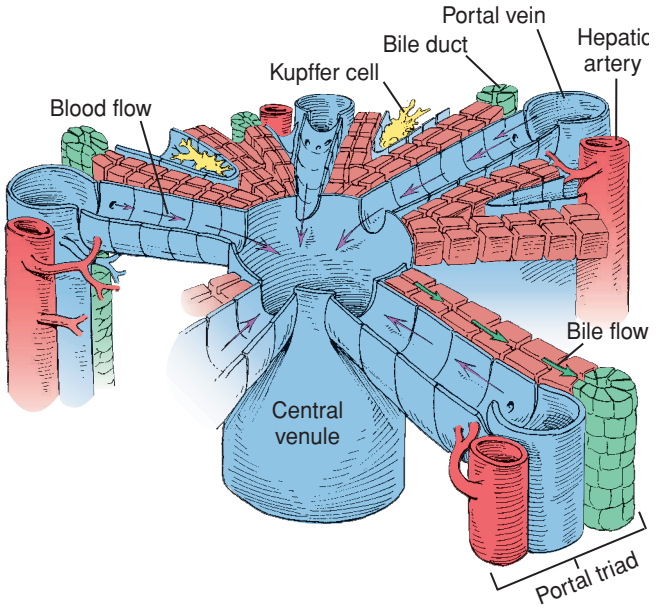

FIGURE 20-1. Microanatomy of the liver. The classic lobule is composed of portal triads, hepatic sinuses, a terminal hepatic venule (central venule) and associated plates of hepatocytes. *Red arrows* indicate the direction of sinusoidal blood flow. *Green arrows* show the direction of bile flow.

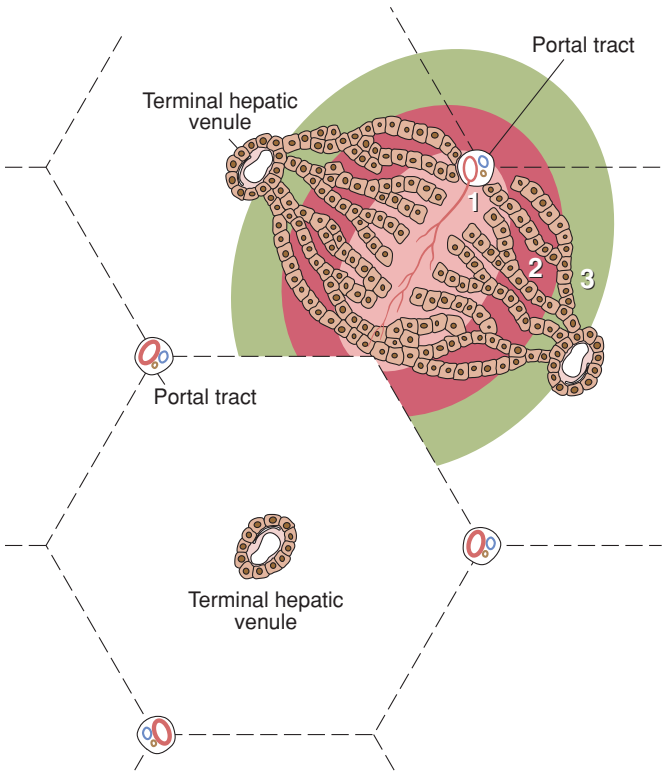

FIGURE 20-2. Morphologic and functional concepts of the liver lobule. In the classic *morphologic* liver lobule, the periphery of the hexagonal lobule is anchored in the portal tracts, and the terminal hepatic venule is in the center. The *functional* liver lobule is an acinus derived from the gradients of oxygen and nutrients in the sinusoidal blood. In this scheme, the portal tract, with the richest content of oxygen and nutrients, is in the center (zone 1). The region most distant from the portal tract (zone 3) is poor in oxygen and nutrients and surrounds the terminal hepatic venule.

The hepatic artery and portal vein enter the liver at the porta hepatis and eventually divide into the small interlobular branches in the portal triads. From there, interlobular vessels distribute blood into hepatic sinusoids, where it flows centripetally toward the central venule. Central venules coalesce into sublobular veins, which eventually merge into the hepatic veins.

Bile is secreted by hepatocytes into **bile canaliculi**. These are formed by apposed lateral surfaces of contiguous hepatocytes. Bile flows in a direction opposite to that of the blood. Contraction of the bile canaliculus by the hepatocyte pericanalicular cytoskeleton propels bile toward the portal tract. From canaliculi, bile flows into canals of Hering, to **bile ductules,** or **cholangioles,** at the border of portal tracts. It then enters a branch of the **intrahepatic bile ducts**. Within each liver lobe, smaller bile ducts progressively merge, eventually forming right and left hepatic ducts.

The Liver Acinus Is the Functional Interpretation of the Lobule

The structural lobule described above is arranged around a central venule and reflects the liver's histologic appearance. ***However, a functional unit can be conceptualized with the portal tract*** at the center (Fig. 20-2). Such a construct reflects the functional gradients within lobules. That is, oxygen, nutrients, etc., delivered by the blood are most concentrated near the portal tracts, then progressively decline as hepatocytes extract these materials from the blood going through the sinusoids toward the central venule. Such a construct allows for concentric functional zones. **Zone 1** is the most highly oxygenated zone, around portal tracts. **Zone 3** surrounds central venules and is oxygen-poor. **Zone 2** is intermediate and midlobular. Ischemic injury usually affects zone 3 first. Differences between hepatocytes are not limited to blood flow. The acinus is also heterogeneous with respect to metabolism, independent of oxygenation. In particular, toxic injury is often prominent in zone 3, which is enriched in hepatocyte enzymes that perform drug detoxification and biotransformation. For convenience, pathologic changes in the liver are usually designated in relation to the classic histologic lobule. For example, centrilobular necrosis describes a lesion around central venules, and periportal fibrosis occurs at the periphery of the classic lobule.

Hepatocytes Carry Out the Major Functions of the Liver

Hepatocytes comprise 60% of liver cells and about 90% of the organ's volume. They are roughly 30 μm across and have three specialized surfaces: **sinusoidal, lateral and canalicular**. Each cell has two sinusoidal surfaces, with numerous slender microvilli. Hepatocyte sinusoidal surfaces are separated from the endothelial cells that line sinusoids by the **space of Disse** (Fig. 20-3). Canalicular surfaces of adjacent hepatocytes form the **bile canaliculus,** which is actually an intercellular space without a separate wall. Along this surface, microvilli extend into the lumen. Tight junctions between adjacent hepatocytes prevent bile leakage from canaliculi. Lateral, or intercellular, surfaces of adjacent hepatocytes are in close contact and contain gap junctions.

Centrally placed, occasionally multiple, hepatocyte nuclei are spherical, with one or more nucleoli. Most are diploid, but tetraploid and octaploid nuclei are common. The cytoplasm is rich in organelles, with prominent rough and smooth endoplasmic reticulum (SER), Golgi complexes,

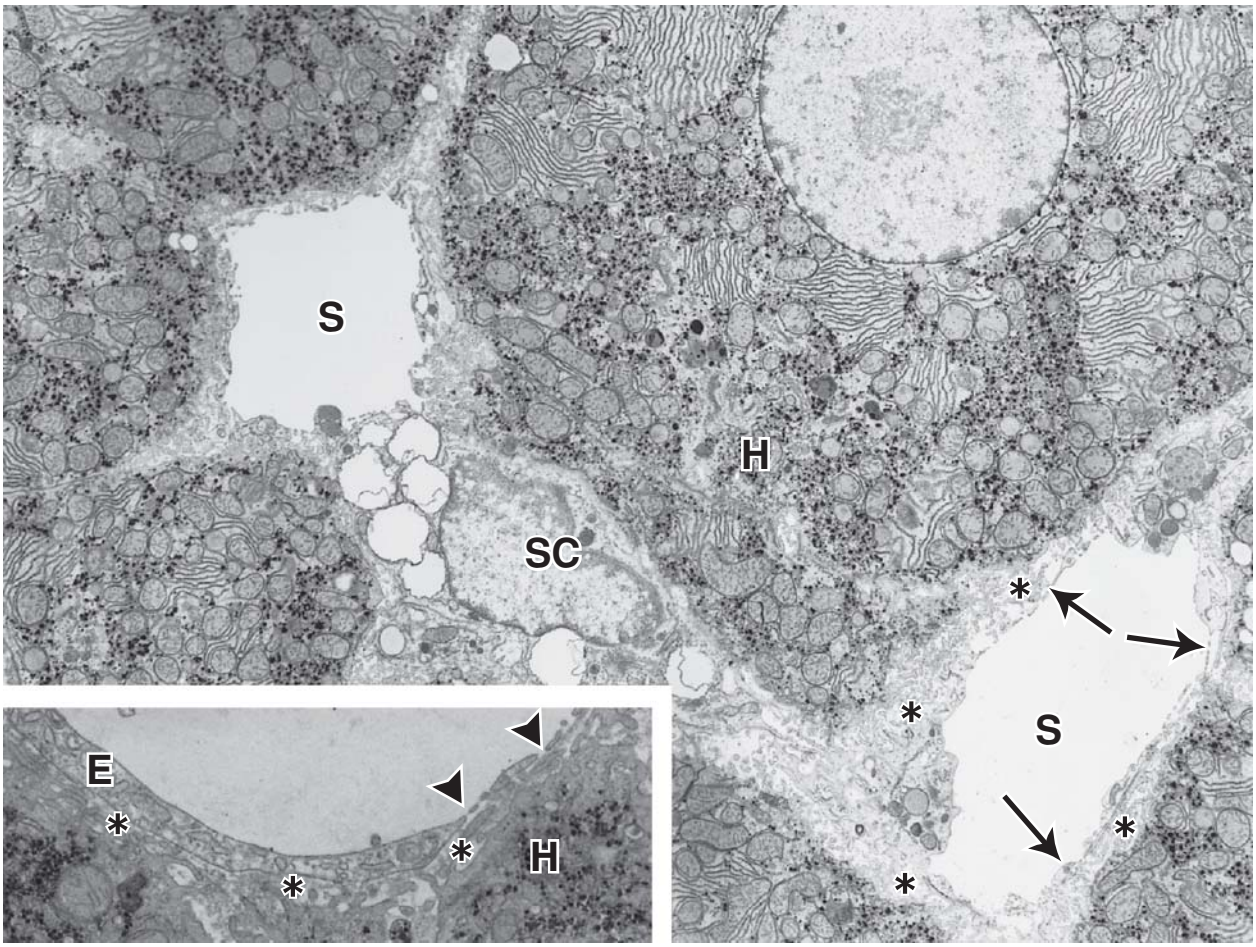

FIGURE 20-3. Hepatic sinusoids and space of Disse. An electron micrograph illustrates the relationship between hepatocytes, sinusoids, the space of Disse and hepatic stellate cells (Ito cells, fat-storing cells). The *arrow* indicates the endothelial cell, and the *asterisk* indicates the space of Disse. H = hepatocyte; S = sinusoid; SC = stellate cell. *Inset.* The relationship between hepatocytes (*H*) and endothelial cells (*E*). The *arrowheads* indicate fenestrae in the endothelial cells; the *asterisks* are in the space of Disse.

mitochondria, lysosomes and peroxisomes. In addition, in the fed state, abundant glycogen and occasional fat droplets are evident.

Blood Traverses the Liver through Hepatic Sinusoids

Sinusoids contain three cell types: endothelial, Kupffer and stellate cells.

ENDOTHELIAL CELLS: Endothelial cells line sinusoids and are penetrated by many holes, or **fenestrae** (Fig. 20-3). Adjacent endothelial cells do not form junctions in the liver, and there are many gaps between them. The result is a sieve-like structure that provides free communication between the sinusoidal lumen and the space of Disse. There is no basement membrane between endothelial cells and hepatocytes, further facilitating access of sinusoidal plasma to hepatocytes.

KUPFFER CELLS: Kupffer cells are macrophages, found in gaps between adjacent endothelial cells or on their surfaces (Fig. 20-1). Because they derive from bone marrow, the Kupffer cells that repopulate transplanted livers are from the recipient, not the donor. Like other macrophages, they protect against infection and circulating toxins (e.g., endotoxin), but with higher efficiency. Activated Kupffer cells also release cytokines, such as TNF-α, interleukins, interferons and TGFs α and β.

STELLATE CELLS: Stellate cells (also known as Ito cells) are occasionally seen beneath endothelial cells in the space of Disse and have specialized storage capacities. They contain fat, vitamin A and other lipid-soluble vitamins. Stellate cells also secrete extracellular matrix components, including collagens, laminin and proteoglycans. In some diseases, they make these species in great excess, leading to hepatic fibrosis and eventually cirrhosis.

The most abundant extracellular matrix component in the space of Disse is fibronectin. Bundles of type I collagen fibers provide a scaffold for liver lobules.

FUNCTIONS OF THE LIVER

Hepatocytes Serve Myriad Functions

Hepatocytes perform metabolic, synthetic, storage, catabolic and excretory functions.

METABOLIC FUNCTIONS: The liver is a center of **glucose homeostasis** and responds rapidly to fluctuations in blood glucose levels. After feeding, excess blood glucose is shunted to the liver to be stored as glycogen. During fasting, blood glucose levels are stabilized by hepatic **glycogenolysis** and **gluconeogenesis**. For the latter, the liver uses amino acids, lactate and glycerol. Amino acid nitrogen is converted to urea. Free fatty acids are taken up by the liver and oxidized to produce energy, or are converted to triglycerides and secreted as **lipoproteins** to be used elsewhere.

SYNTHETIC FUNCTIONS: Most serum proteins are synthesized in the liver. **Albumin** is the main source of plasma oncotic pressure; in chronic liver disease, decreased albumin causes edema and ascites. Blood **clotting factors,** including prothrombin and fibrinogen, are produced by hepatocytes. Severe and often life-threatening bleeding may thus complicate liver failure. Hepatic endothelial cells manufacture **factors V and VIII;** thus, hemophilia can be treated by liver transplantation. **Complement** and other "acute-phase reactants" (e.g., ferritin, C-reactive protein, serum amyloid A) are also secreted by the liver. Numerous specific **binding proteins** (such as those for iron, copper and vitamin A) are also made by the liver.

STORAGE FUNCTIONS: The liver stores glycogen, triglycerides, iron, copper and lipid-soluble vitamins. Severe liver disease can result from excessive storage—for example, abnormal glycogen deposition in type IV glycogenosis, excess iron in hemochromatosis and copper in Wilson disease (WD).

CATABOLIC FUNCTIONS: The liver catabolizes many endogenous substances, such as hormones and serum proteins. As a result, in chronic liver disease, impaired elimination of estrogens causes feminization in men. The liver is also the principal **detoxifier of foreign compounds** such as drugs, industrial chemicals, environmental contaminants and, perhaps, products of intestinal bacterial metabolism.

Ammonia from amino acid metabolism is mainly removed by the liver. Serum ammonia increases in liver failure and is used as a marker for this condition.

EXCRETORY FUNCTIONS: The principal excretory product of the liver is **bile,** an aqueous mixture of conjugated bilirubin, bile acids, phospholipids, cholesterol and electrolytes. Bile is a repository for the products of heme catabolism and is vital for fat absorption in the small intestine. Normal bile production is critical for eliminating environmental toxins, carcinogens and drugs and their metabolites.

Regeneration Is a Unique Characteristic of the Liver

Liver size is normally maintained within narrow limits, relative to body size. If there is substantial loss of liver tissue (e.g., after mechanical, toxic or viral insult), the organ regrows from the undamaged tissue, a process called **liver regeneration**. Hepatocytes, which are normally in a fully differentiated, quiescent state (G_0), reenter the cell cycle for as many synchronized rounds of replication as are needed to recover the organ's original size. Uniquely, the liver maintains its differentiated functions during this process. Little is known about how this process is triggered or how the liver recognizes when it has reattained its normal size and architecture. ***Conditions that interfere with regeneration may cause permanent liver dysfunction and may bring about liver failure.***

Several phases are distinguished in liver regeneration:

- **Priming:** Liver tissue recognizes that damage has occurred and that remaining functional parenchymal cells must transition from their peaceful G_0 state to enter the cell cycle. This process, called *priming,* entails expression of many genes, especially transcription factors. These are required to drive cell cycling (see Chapter 5). Priming requires release of TNF-α, IL-6 and other cytokines.
- **Progression to mitosis:** In the next phase, the cell progresses through G_1 into S phase, where DNA synthesis occurs. This is followed by G_2 and M phases, where cell division occurs. Several growth factors drive this part of the process, including hepatocyte growth factor (HGF/SF), epidermal growth factor (EGF), TGF-α and others. Several growth factors (e.g., HGF, IL-6) promote protection of the liver and survival in various models of hepatic injury. After one or two rounds (depending on need) of mitosis, hepatocytes become quiescent again and resume normal function.

- **Nonparenchymal and progenitor cells:** In the final phase, nonparenchymal cells (sinusoidal endothelium, Kupffer cells, stellate cells and biliary epithelium) replicate. The tissue remodels to recover the original structure of liver cell plates.

Hepatic progenitor cells ("oval cells"), which lie within the terminal branches of bile ductules and canals of Hering, contribute to ductular proliferation after extensive hepatic necrosis. However, the role of these cells in hepatic regeneration is unclear, as is any involvement of bone marrow–derived stem cells (see Chapter 3).

BILIRUBIN METABOLISM AND MECHANISMS OF JAUNDICE

Bilirubin Is the End-Product of Heme Catabolism

About 80% of this heme comes from senescent erythrocytes, removed by mononuclear phagocytes of the spleen, bone marrow and liver from the circulation. The remainder of the heme comes from other sources, including cytochrome P450 isoenzymes, myoglobin and premature breakdown of erythroid progenitors in the bone marrow. Beyond this, no specific physiologic role for bilirubin is known.

Bilirubin dissolves poorly in water but is quite miscible with fat. Thus, in the circulation, it is transported bound to albumin. The albumin in the blood and extracellular space is a large reservoir for binding bilirubin, ensuring a low extracellular concentration of free (unbound) bilirubin. Bilirubin that is not bound to albumin or conjugated to glucuronic acid easily enters the lipid-rich brain. There, it is very toxic, and high concentrations of it in newborns causes irreversible brain injury, **kernicterus**.

Transfer of bilirubin from blood to the bile involves four steps:

1. **Uptake:** The albumin–bilirubin complex is dissociated when it reaches hepatocytes, and the bilirubin is transported across the plasma membrane. Transporter proteins facilitate mostly passive uptake by hepatocytes.
2. **Binding:** Once inside hepatocytes, bilirubin binds to cytosolic proteins, known collectively as **glutathione S-transferases** (also termed *ligandin*).
3. **Conjugation:** Bilirubin is converted to a water-soluble glucuronic acid conjugate for excretion. This is done in the endoplasmic reticulum (ER), where the uridine diphosphate-glucuronyl transferase (UGT) system attaches glucuronic acid to bilirubin. The process yields mostly water-soluble bilirubin diglucuronide and a small amount (<10%) of monoglucuronide.
4. **Excretion:** Conjugated bilirubin diffuses through the cytosol to bile canaliculi and is excreted into the bile by an energy-dependent carrier-mediated process. This is the rate-limiting step in the transhepatic transport of bilirubin.

Conjugated bilirubin enters the small intestine as part of mixed micelles but is not absorbed there. It remains intact until it reaches the distal small bowel and colon, where it is hydrolyzed by bacterial flora into free (unconjugated) bilirubin, which is reduced to a mixture of pyrroles, collectively called **urobilinogen**. Most urobilinogen is excreted in feces, but a small amount is absorbed in the terminal ileum and colon, returned to the liver and reexcreted into the bile. Bile acids are also reabsorbed in the terminal ileum and salvaged by the liver. This recycling process is the **enterohepatic circulation of bile**. Some urobilinogen escapes reabsorption by the liver, reaches the systemic circulation and is excreted in the urine.

FIGURE 20-4. Jaundice. A patient in hepatic failure displays yellow sclera.

- **Hyperbilirubinemia** means increased blood levels of bilirubin (>1.0 mg/dL).
- **Jaundice** or **icterus** is yellow skin and sclerae (Fig. 20-4), the color becoming apparent when circulating bilirubin concentrations exceed 2.5–3.0 mg/dL.
- **Cholestasis** is pathological plugging of dilated bile canaliculi by inspissated bile. Bile pigment, which is normally invisible, is seen in hepatocytes.
- **Cholestatic jaundice** is histologic cholestasis and hyperbilirubinemia. Many conditions are associated with hyperbilirubinemia (Fig. 20-5).

Overproduction of bilirubin, interference with its hepatic uptake or intracellular metabolism and impaired bile excretion and flow may all cause jaundice (Fig. 20-5).

Bilirubin Overproduction Can Lead to Unconjugated Hyperbilirubinemia

Increased production of free bilirubin results from enhanced destruction of erythrocytes (e.g., hemolytic anemia) or ineffective erythropoiesis. Rarely, erythrocyte breakdown in a large hematoma (e.g., after trauma) may also generate excess unconjugated bilirubin.

In adults, even severe hemolytic anemia does not lead to sustained increases in serum bilirubin above 4.0 mg/dL as long as hepatic bilirubin clearance is normal. However, prolonged hemolysis, as in sickle cell anemia, in the context of intrinsic liver disease, such as viral hepatitis, may cause extremely high blood bilirubin levels (up to 100 mg/dL) and pronounced jaundice.

Hyperbilirubinemia from uncomplicated hemolysis is mainly unconjugated bilirubin, whereas parenchymal liver disease causes elevation of both conjugated and unconjugated bilirubin. Unconjugated hyperbilirubinemia is of little clinical significance in adults but can cause kernicterus with catastrophic brain damage in newborns (see Chapter 6). This occurs if bilirubin concentrations exceed 20 mg/dL, but subtle psychomotor retardation may follow considerably lower bilirubin concentrations.

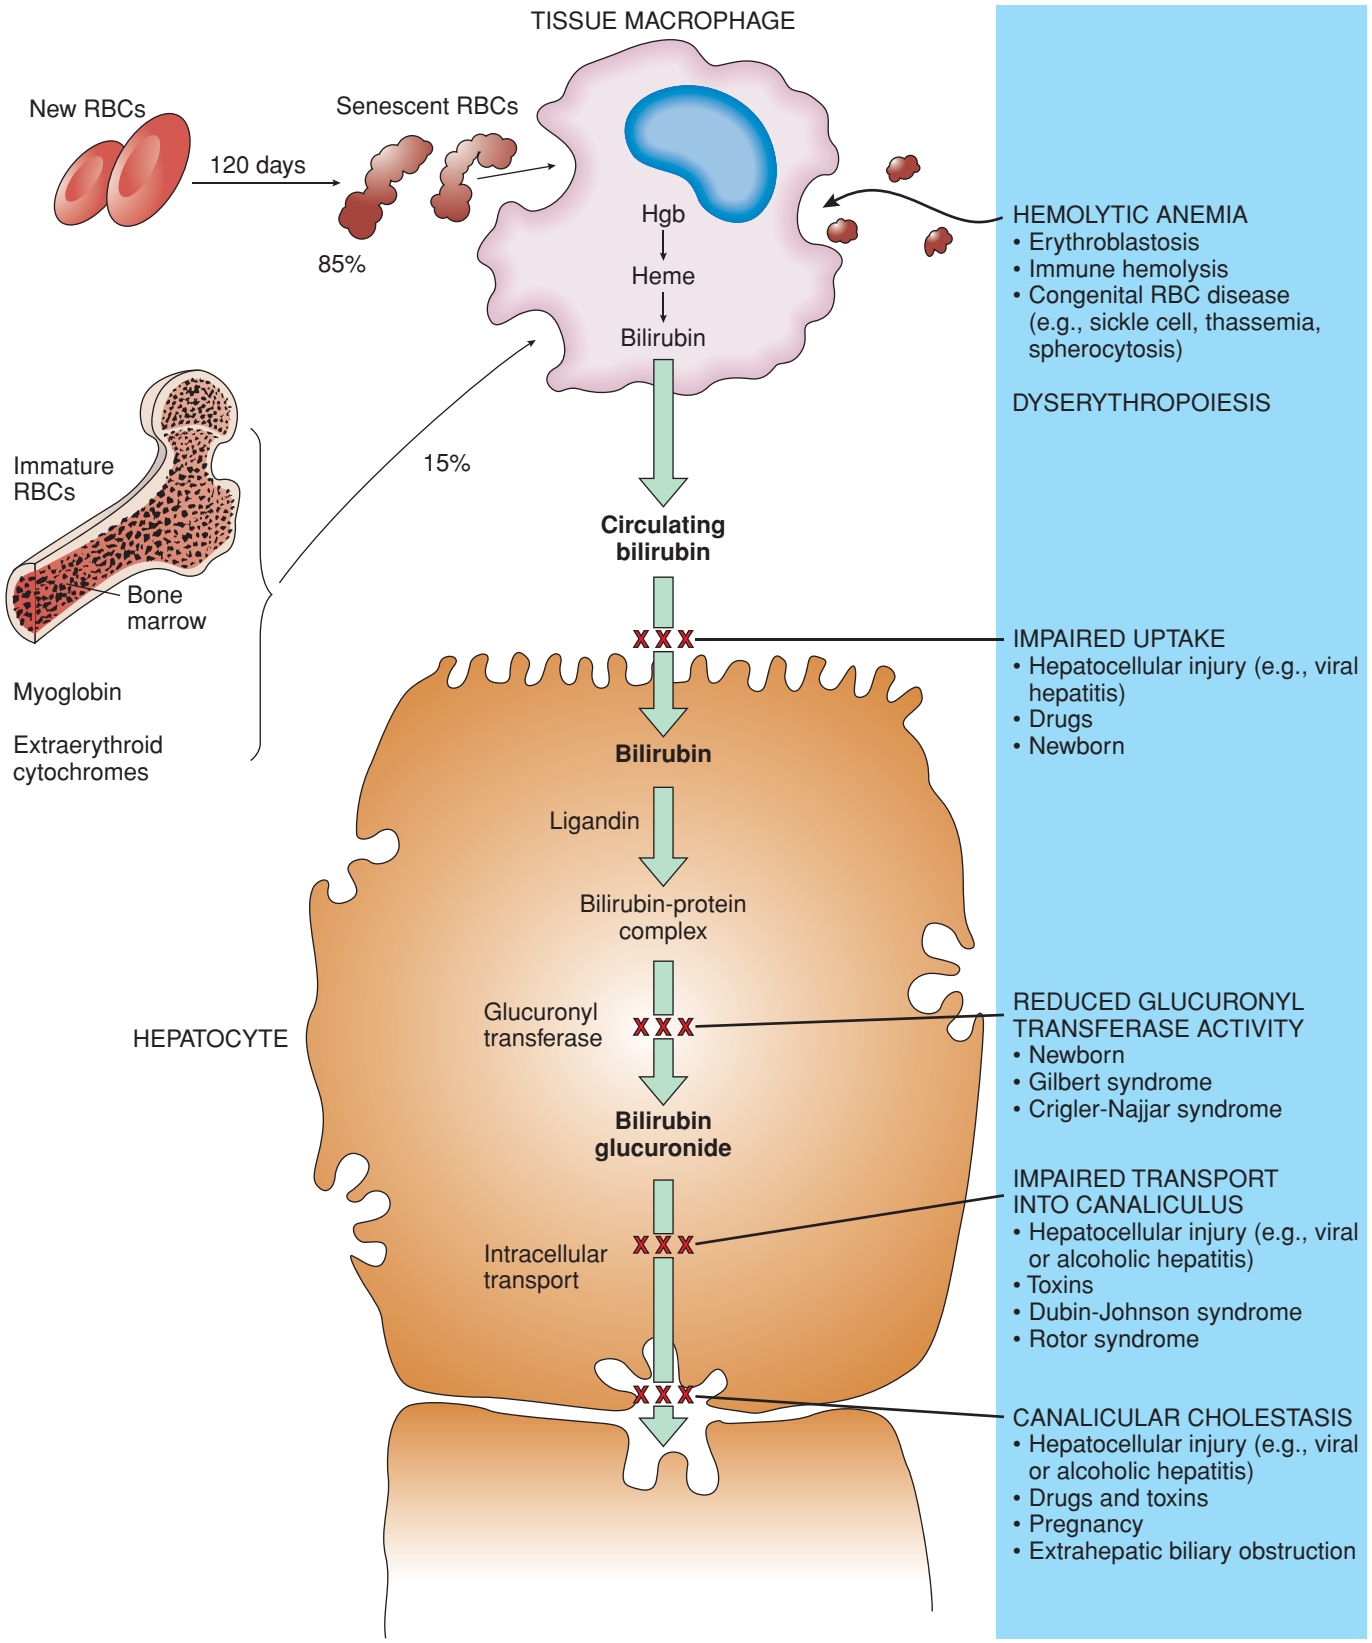

FIGURE 20-5. Mechanisms of hyperbilirubinemia at the level of the hepatocyte. Bilirubin is derived principally from the senescence of circulating red blood cells (RBCs), with a smaller contribution from the degradation of erythropoietic elements in the bone marrow, myoglobin and extraerythroid cytochromes. Hyperbilirubinemia and jaundice result from overproduction of bilirubin (hemolytic anemia), dyserythropoiesis, impaired bilirubin uptake or defects in its hepatic metabolism. The locations of specific blocks in the metabolic pathway of bilirubin in the hepatocyte are illustrated. Hgb = hemoglobin.

In disorders of ineffective erythropoiesis (e.g., megaloblastic or sideroblastic anemias; see Chapter 20), increased bone marrow–derived bilirubin may cause hyperbilirubinemia. In a rare hereditary disease of unknown etiology, "primary shunt hyperbilirubinemia" or "idiopathic dyserythropoietic jaundice," massive overproduction of bone marrow–derived bilirubin is associated with chronic unconjugated hyperbilirubinemia.

Decreased Hepatic Uptake of Bilirubin Is a Common Cause of Jaundice

Generalized liver cell injury (e.g., due to viral hepatitis or certain drugs, such as rifampin or probenecid) may interfere with net uptake of bilirubin by liver cells. This can cause mild unconjugated hyperbilirubinemia.

Decreased Bilirubin Conjugation Occurs in Several Hereditary Syndromes

Crigler-Najjar Syndrome

Crigler-Najjar syndrome type I is a rare, recessively inherited disease due to a complete lack of hepatic UGT activity. Affected patients show chronic, severe, unconjugated hyperbilirubinemia beginning in early childhood.

The appearance of the liver is normal. Crigler-Najjar syndrome type I was invariably lethal before the advent of phototherapy and liver transplantation.

Crigler-Najjar syndrome type II is similar to type I but is less severe and entails only a partial decrease in UGT activity. Almost all patients with type II syndrome develop normally, but some show neurologic changes resembling kernicterus.

Gilbert Syndrome

Gilbert syndrome is an inherited, mild, chronic unconjugated hyperbilirubinemia (<6 mg/dL). Bilirubin clearance is impaired, without functional or structural liver disease. The mode of inheritance is unclear, but autosomal recessive inheritance is most likely. Mutations in the *UGT* gene promotor region lead to reduced transcription of the *UGT* gene and, thus, inadequate synthesis of UGT. In a few patients the *UGT* promotor is normal, and missense mutations in the coding region are responsible for the disorder. Factors that elevate serum bilirubin concentrations in normal persons, such as fasting or an intercurrent illness, produce exaggerated increases in people with Gilbert syndrome. Mild hemolysis, which also tends to increase bilirubin levels, occurs in more than 1/2 of persons with Gilbert syndrome, but the mechanism is unclear.

Gilbert syndrome is exceptionally common, occurring in 5%–10% of the population. It occurs more often in men than in women and is usually recognized after puberty. Differences and the age at onset and patient gender suggest that hormones influence hepatic bilirubin metabolism. Gilbert syndrome is generally without clinical import, except for the possibility that drug metabolism may be altered.

Mutations in the Multidrug Resistance Protein Gene Family Often Alter Transport of Conjugated Bilirubin

Multidrug resistance proteins (MRPs) mediate transmembrane transport of organic ions, including conjugated bilirubin, bile acids and phospholipids. Mutations in genes encoding these proteins, or in other canalicular transporters, impair hepatocellular secretion of bilirubin glucuronides and other organic anions into canaliculi. The spectrum of resultant diseases varies from innocuous to lethal.

Dubin-Johnson Syndrome

This syndrome is caused by mutations in the *ABCC2/MRP2* gene. It is a benign, autosomal recessive disease with chronic conjugated hyperbilirubinemia and conspicuous deposition of melanin-like pigment in the liver.

Dubin-Johnson syndrome can be distinguished from other conditions with conjugated hyperbilirubinemia by testing **urinary coproporphyrin excretion**. There are two forms of human coproporphyrins, **isomer I** and **isomer III**. A shift in the ratio of urinary coproporphyrin isomer I and III from 1:3 (normal) to 4:1 (abnormal) is diagnostic of Dubin-Johnson syndrome.

PATHOLOGY: Liver histology is entirely normal, except for coarse, iron-free, **dark-brown granules** in hepatocytes and Kupffer cells, mainly in the centrilobular zone (Fig. 20-6). By electron microscopy, the pigment is in enlarged lysosomes. As liver cells do not synthesize melanin, the pigment may reflect auto-oxidation of anionic metabolites (e.g., tyrosine, phenylalanine, tryptophan), and possibly of epinephrine. Accumulation of this pigment causes the liver to be grossly pigmented, or "black."

CLINICAL FEATURES: Symptoms are mild: slight intermittent jaundice and vague nonspecific complaints. Dark urine is present in 1/2 of those affected. In women, the disease may be diagnosed when

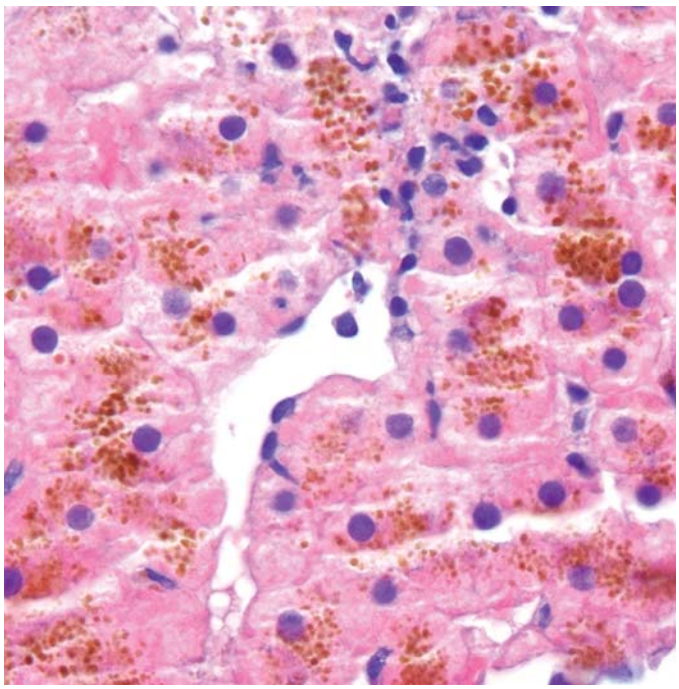

FIGURE 20-6. Dubin-Johnson syndrome. The hepatocytes contain coarse, iron-free, dark-brown granules.

jaundice appears with use of oral contraceptives or during pregnancy. Serum bilirubin is 2–5 mg/dL but may transiently be much higher.

Rotor Syndrome

Rotor syndrome is an autosomal recessive, familial conjugated hyperbilirubinemia, clinically similar to Dubin-Johnson syndrome but without liver pigmentation. Defective hepatic uptake or intracellular binding of organic ions has been blamed. The pattern of urinary coproporphyrins is like that of most hepatobiliary disorders with conjugated hyperbilirubinemia (i.e., increased total urinary coproporphyrins, 65% of which are isomer I). Patients with Rotor syndrome have few symptoms and lead normal lives.

Progressive Familial Intrahepatic Cholestasis

Progressive familial intrahepatic cholestases (PFICs) are a heterogeneous group of rare, inherited, autosomal recessive disorders of infancy or early childhood in which intrahepatic cholestasis progresses relentlessly to cirrhosis. PFIC1, PFIC2 and PFIC3 are due to mutations of different genes. In PFIC1, mutant *ATP8B1* causes deficiency in FIC1 protein. PFIC2 is a defect in a bile salt export pump (BSEP) encoded by the *ABCB11* gene. PFIC3 is caused by multidrug resistant 3 (MDR3) protein deficiency, encoded by the *ABCB4* gene. Both benign recurrent intrahepatic cholestasis and intrahepatic cholestasis of pregnancy (ICP; see below) are milder forms of PFIC that do not progress to cirrhosis.

The first patients with PFIC1 were descendents of an Amish man, Jacob Byler (Byler syndrome), but PFIC is not limited to that ethnic group. There is an associated high incidence of retinitis pigmentosa. The children are often mentally retarded. Most affected children die within the first 2 years of life.

Benign Recurrent Intrahepatic Cholestasis

In benign recurrent intrahepatic cholestasis, self-limited, episodic intrahepatic cholestasis may be preceded by malaise and itching. The occurrence of familial cases suggests a genetic origin. Symptoms tend to last several weeks to several months. Patients usually have 3–5 episodes in their lives, but some may have as many as 10. Recurrences may be separated by weeks to years. Serum bilirubin during the acute episodes ranges from 10 to 20 mg/dL, mostly conjugated.

The liver shows centrilobular cholestasis (bile plugs in bile canaliculi) and a few mononuclear inflammatory cells in portal tracts. All structural and functional alterations disappear during remissions. No permanent sequelae have been reported.

Intrahepatic Cholestasis of Pregnancy

ICP is a rare disease marked by pruritus and cholestasis, usually in the last trimester of each pregnancy. These promptly disappear after delivery. Women with ICP fare well, but fetal morbidity and mortality are increased, as are premature labor, fetal distress and placental insufficiency. Mutations in the ATP-cassette transporter B4 (*ABCB4*) and the multidrug resistance protein-3 (MDR3) have been described in women with ICP. Increased gonadal and placental hormones during pregnancy most likely cause cholestasis in susceptible women. Mothers' livers show mainly centrilobular cholestasis. The diagnosis is generally made by clinical observation and is confirmed by the markedly increased maternal total bile acid levels. Therapy with ursodeoxycholic acid (UDCA) provides some relief of pruritus.

Sepsis Can Cause Jaundice

Severe conjugated hyperbilirubinemia may occur in sepsis involving either gram-positive or gram-negative bacteria. In such situations, serum alkaline phosphatase and cholesterol levels are usually low, suggesting a defect in excretion of conjugated bilirubin. Liver pathology is nonspecific and includes mild canalicular cholestasis and slight fat accumulation. Portal tracts may contain excess inflammatory cells and variable bile ductule proliferation. Occasionally, dilated ductules are filled with inspissated bile.

Neonatal (Physiologic) Jaundice Occurs in Most Newborns

Neonatal hyperbilirubinemia occurs in the absence of any specific disorder. Hepatic clearance of bilirubin in the fetus is minimal; hepatic uptake, conjugation and biliary excretion are all much lower than in children and adults. Liver UGT activity is less than 1% of that in adults, and ligandin levels are low. Fetal bilirubin levels are low because bilirubin crosses the placenta and is conjugated and excreted by the mother's liver.

The livers of newborns thus become responsible for clearing bilirubin before the conjugation and excretion are fully developed. Moreover, increased erythrocyte destruction in the postnatal period adds to the liver's duties in the newborn. ***Thus, 70% of normal infants have transient unconjugated hyperbilirubinemia.*** Such physiologic jaundice is more pronounced in premature infants, because liver clearance of bilirubin is less developed and red blood cell turnover is greater than in term infants. When hepatic bilirubin-conjugating capacity reaches adult levels, about 2 weeks after birth (ligandin takes somewhat longer), serum bilirubin levels rapidly decline to adult values. Absorption of light by unconjugated bilirubin generates water-soluble bilirubin isomers. ***Thus, phototherapy is now routinely used to treat neonatal jaundice.***

Maternal–fetal blood group incompatibilities may lead to **erythroblastosis fetalis** (see Chapter 6), in which striking bilirubin overproduction in the fetus is due to immune-mediated hemolysis. Newborns with erythroblastosis fetalis show increased cord blood bilirubin. However, jaundice becomes severe only after birth, since the mother's liver no longer compensates for the immaturity of the neonatal liver.

Cholestasis Reflects Extra- or Intrahepatic Biliary Obstruction

Functionally, cholestasis represents decreased bile flow through the canaliculus and reduced secretion of water, bilirubin and bile acids by hepatocytes. Clinical diagnosis depends on the accumulation in the blood of materials that are normally transferred to the bile, including bilirubin, cholesterol and bile acids, and elevated blood activities of

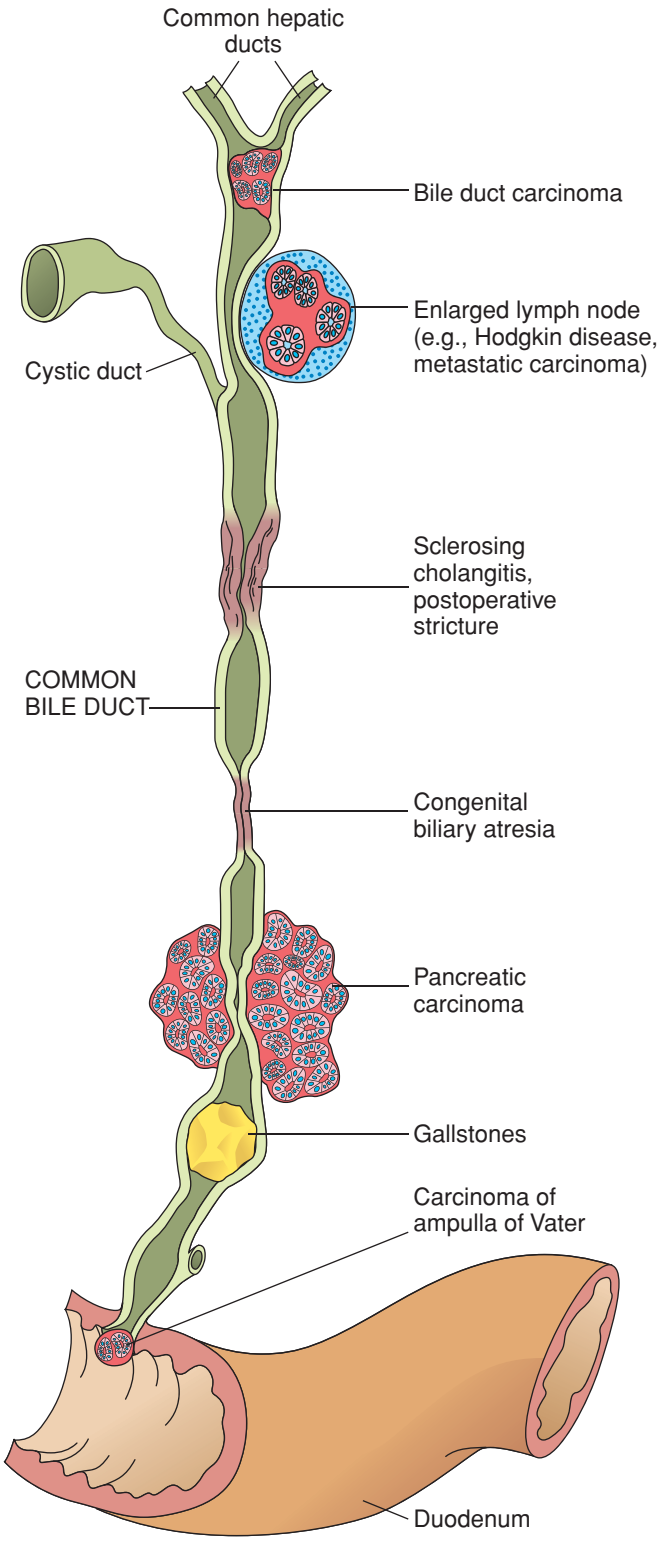

FIGURE 20-7. Major causes of extrahepatic biliary obstruction.

certain enzymes, typically alkaline phosphatase. Cholestasis due to intrinsic liver disease is **intrahepatic cholestasis** (Fig. 20-5), whereas that caused by obstruction of large bile ducts is extrahepatic cholestasis. ***In any event, it reflects a defect in bile transport across the canalicular membrane.***

The inability to excrete bile acids into canaliculi raises serum and hepatocellular bile acid levels. As detergents, bile acids injure cells by both detergent action and direct activation of apoptosis. They are thus potent hepatotoxins, and their accumulation within hepatocytes causes much of the hepatic injury and progression to cirrhosis associated with cholestasis. Elevation of serum bile acids is the likely cause of severe itching **(pruritus)**.

The extrahepatic biliary system may be obstructed by gallstones lodged in the common bile duct, cancers of the bile duct or surrounding tissues (pancreas or ampulla of Vater), external compression by enlarged neoplastic lymph nodes in the porta hepatis (as in lymphoma), benign strictures (postoperative scarring or primary sclerosing cholangitis [PSC]) and congenital extrahepatic biliary atresia (EHBA) (Fig. 20-7).

PATHOPHYSIOLOGY: Bile secretion into canaliculi and passage into the biliary collecting system depend on (1) functional and structural characteristics of canalicular microvilli, (2) permeability of canalicular plasma membranes, (3) intracellular contractile systems around canaliculi (microfilaments, microtubules) and (4) interactions of bile acids with the secretory apparatus.

The biochemical basis of cholestasis is unclear, but several abnormalities in bile formation and movement of bile are described. For extrahepatic biliary obstruction, the effects clearly begin with increased pressure within bile ducts. However, in the early stages, the biochemistry and morphology at the canalicular level resemble those in intrahepatic cholestasis, including initial centrilobular canalicular bile plugs (Fig. 20-8).

The invariable presence of bile constituents in the blood of people with cholestasis implies regurgitation of conjugated bilirubin from hepatocytes into the blood. Hepatic clearance of unconjugated bilirubin in cholestasis is normal. Even if bile duct obstruction is complete, serum bilirubin levels only reach 30–35 mg/dL because renal excretion of bilirubin prevents further accumulation.

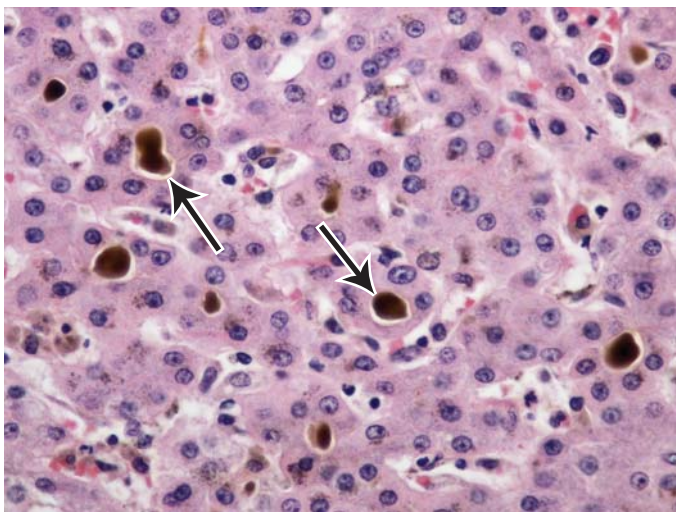

FIGURE 20-8. Bile stasis. The liver from a patient with drug-induced cholestasis shows prominent bile plugs in dilated bile canaliculi (*arrows*). In the absence of inflammation, this lesion may be termed *pure cholestasis*.

In both intrahepatic and extrahepatic cholestasis, bile pigment initially is centrilobular. Fluid secretion into the canalicular bile has two components: one that is dependent on bile acid secretion and the other that is not. Since periportal hepatocytes secrete most of the bile acids, the fluid content in the periportal zone of the canaliculus exceeds that in the central zone, thus keeping bilirubin in solution. In addition, the bile acids themselves act as detergents in the intestine and solubilize aggregates of bilirubin in the periportal areas. As well, the higher activity of microsomal mixed-function oxidases in the central zone predisposes central hepatocytes to injury by a variety of drugs and toxins. Such an effect may favor bile deposition in centrilobular areas in cholestasis.

Several mechanisms of cholestasis have been proposed.

DAMAGE TO CANALICULAR PLASMA MEMBRANES: The canalicular plasma membrane is the site of sodium (and therefore fluid) secretion into the bile. This membrane also participates in bile acid and bilirubin secretion. Fluid secretion is controlled by the Na^+/K^+-ATPase of the canalicular membrane. Alterations in the canalicular membrane by drugs and other agents that can perturb its structure inhibit the Na^+/K^+-ATPase, decrease bile flow or produce morphologic alterations.

ALTERED CONTRACTILE PROPERTIES OF THE CANALICULUS: Bile is propelled along the canaliculus by a peristalsis-like contractile activity of hepatocytes. Agents that interact with the pericanalicular actin microfilaments (e.g., cytochalasin and phalloidin) inhibit this peristalsis and may cause cholestasis.

ALTERATIONS IN CANALICULAR MEMBRANE PERMEABILITY: Agents that cause cholestasis, including estrogens and taurolithocholate, may allow back-diffusion of bile components by making canalicular membranes more permeable, or "leaky."

PATHOLOGY: ***Cholestasis is characterized by the presence of brownish bile pigment within dilated canaliculi and in hepatocytes*** (Figs. 20-8, 20-9 and 20-10). Canaliculi are enlarged. By electron microscopy, the microvilli are blunted and fewer in number or even absent. Bile accumulates in hepatocytes in large, bile-laden lysosomes.

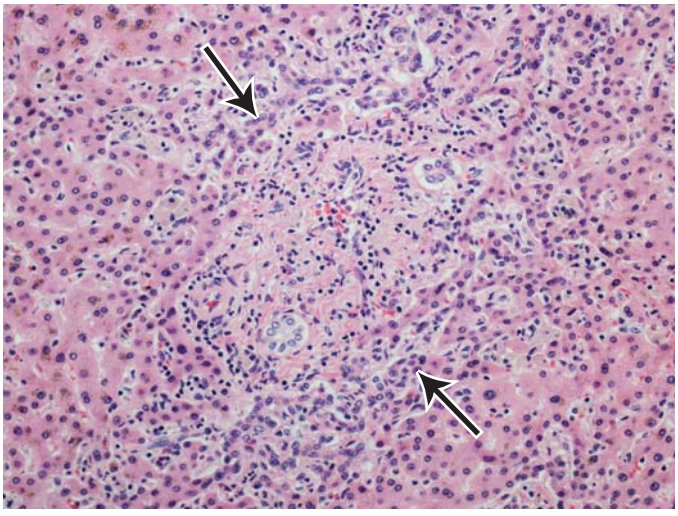

FIGURE 20-9. Extrahepatic biliary obstruction. A portal tract is expanded by ductular reaction (*arrows*) and acute and chronic inflammation.

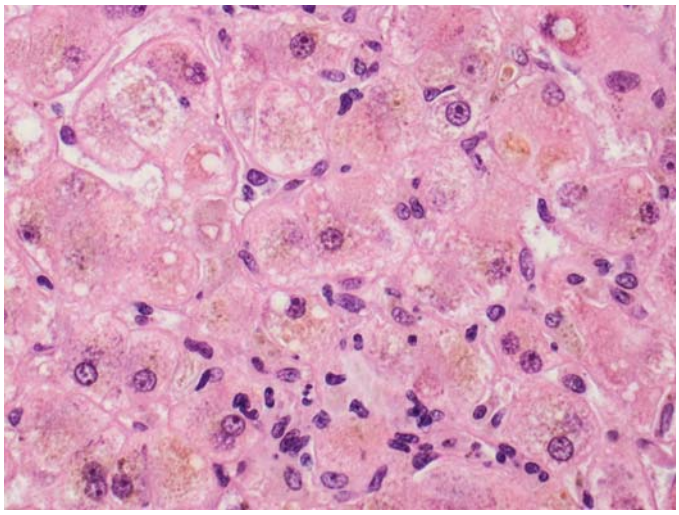

FIGURE 20-10. Cholestasis. Hepatocytes are swollen and bile stained (feathery degeneration).

When cholestasis persists, secondary morphologic abnormalities develop. Scattered necrotic hepatocytes probably reflect the toxicity of excess intracellular bile. Intrasinusoidal macrophages and Kupffer cells contain bile pigment and cellular debris. Whereas early cholestasis is limited almost entirely to the central zone, chronic cholestasis is also marked by bile plugs at the periphery of lobules.

In **extrahepatic biliary obstruction,** the liver is swollen and bile stained. Prolonged obstruction suppresses bile secretion, causing the bile to become almost colorless ("white bile"). The liver, however, remains green. At first, edema in portal tracts accompanies centrilobular cholestasis, progressing to portal mononuclear infiltrates as obstruction persists. Tortuous and distended bile ductules proliferate and attract neutrophils (Fig. 20-9). Damaged

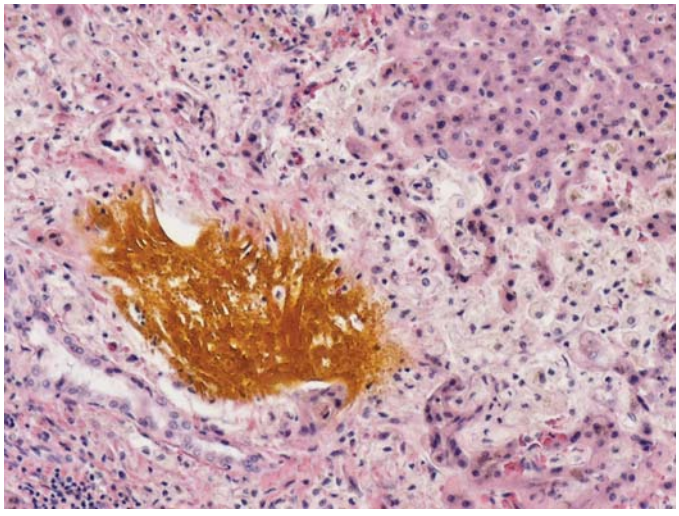

FIGURE 20-11. Bile infarct (bile lake). The liver in a patient with extrahepatic biliary obstruction, showing an area of necrosis and accumulation of extravasated bile.

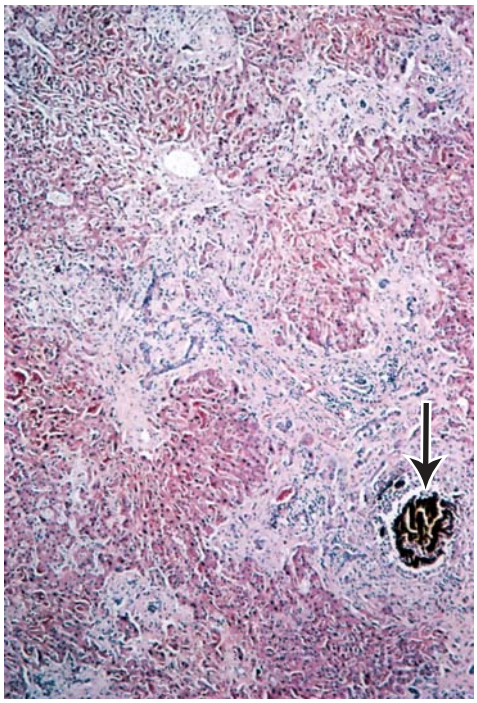

FIGURE 20-12. Secondary biliary cirrhosis. Liver from a patient with a carcinoma of the pancreas that obstructed the common bile duct. Irregular fibrous septa extend from enlarged portal tracts containing a dilated interlobular bile duct that encloses a dense bile concretion (*arrow*). Ductular reaction are seen within the septa.

hepatocytes swollen with bile show (1) hydropic swelling, (2) diffuse impregnation with bile pigment and (3) a reticulated appearance. This triad is **feathery degeneration** (Fig. 20-10). Cholestasis eventually reaches the periphery of the lobule. Dilated bile ducts may rupture, leading to **bile lakes** (Fig. 20-11)—focal, golden-yellow deposits surrounded by degenerating hepatocytes. Infection of obstructed biliary passages often leads to superimposed suppurative cholangitis, intraluminal pus and even intrahepatic abscesses. Within bile ducts and ductules, biliary concretions may be conspicuous.

In time, portal tracts become enlarged and fibrotic (Fig. 20-12). If extrahepatic biliary obstruction is untreated, septa eventually extend between portal tracts of contiguous lobules to form **micronodular cirrhosis** (see below).

CLINICAL FEATURES: Whatever the cause, cholestasis usually presents with jaundice. **Pruritus** (itching) is common and can be severe and intractable. It may be caused by deposition of bile acids in the skin, but other bile components may play a role. Cholesterol accumulates in the skin to form **xanthomas**. **Malabsorption** may develop in cases of protracted cholestasis (see Chapter 13).

CIRRHOSIS

Cirrhosis is destruction of normal liver architecture by fibrous bands around regenerative nodules of hepatocytes. This pattern invariably results from persistent liver cell necrosis. Advanced cases of cirrhosis all tend to have a similar appearance, and the cause often can no longer be ascertained by morphologic examination alone. In earlier stages, on the other hand, features characteristic of an inciting pathogenic insult may be evident. For example, fat and Mallory bodies are typical of alcoholic liver injury, whereas chronic inflammation and periportal necrosis are prominent in chronic hepatitis.

The pathogenesis of cirrhosis involves death and regeneration of hepatocytes, extracellular matrix deposition by activated hepatic stellate cells and resulting alterations in hepatic vascular architecture.

Many terms are applied to the different forms of cirrhosis, rivaling the number of etiologies incriminated in chronic liver disease, but some patterns emerge. At one end of this spectrum, usually early in the evolution of cirrhosis, is the **micronodular** type (Fig. 20-13), characterized by small, uniform nodules separated by thin fibrous septa. At the other end, ordinarily late in the disease, is **macronodular cirrhosis** (Fig. 20-14), with grossly visible, coarse, irregular nodules, mirrored histologically by large nodules that vary in size and shape and are encircled by similarly variably broad bands of connective tissue. ***Between these extremes are many cases with features of both. In practice, the different appearances of cirrhosis are less important than their etiologies.***

Once considered to be irreversible, cirrhotic livers may undergo collagen resorption, hepatic regeneration and remodeling over years to decades—if the underlying cause of cirrhosis is removed. However, even as functional and structural improvement may occur, complete regression is unlikely.

MICRONODULAR CIRRHOSIS: This form of liver disease was previously termed **Laennec cirrhosis,** to honor the early 19th-century French physician who first described it accurately. (He also invented the stethoscope.) Nodules in micronodular cirrhosis are usually less than 3 mm, scarcely larger than a lobule (Fig. 20-13). They show no landmarks of lobular architecture, such as portal tracts or central venules. Connective tissue septa separating nodules are usually thin, but irregular focal collapse of parenchyma may lead to wider septa. In its active stages, mononuclear inflammatory cells and proliferated bile ductules inhabit the septa. ***The prototypical cause of micronodular cirrhosis is alcoholic injury, but other etiologies may also be responsible.***

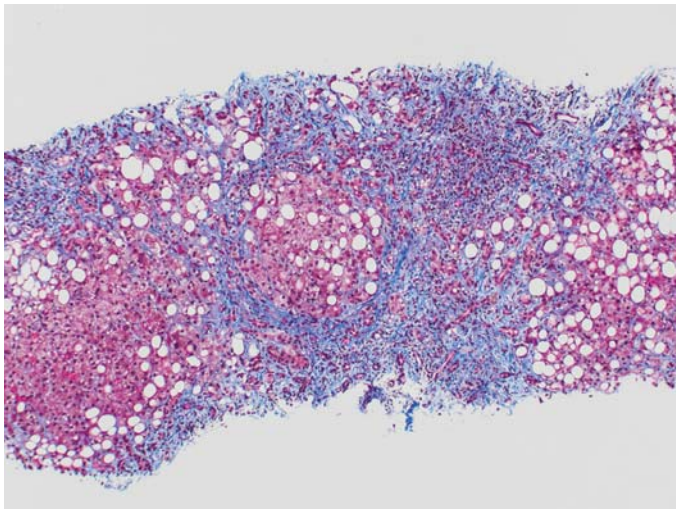

FIGURE 20-13. Micronodular cirrhosis. Cirrhotic liver from a chronic alcoholic. Note the small, regenerative nodules of parenchyma and fatty change.

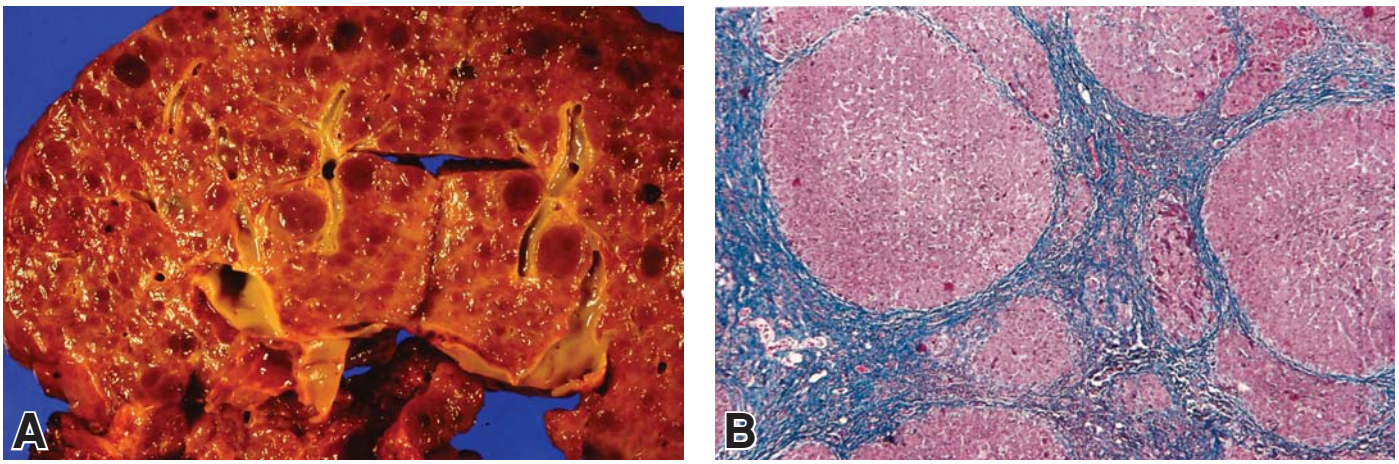

FIGURE 20-14. Macronodular cirrhosis. A. The liver is misshapen, and the cut surface reveals irregular nodules and connective tissue septa of varying width. **B.** Nodules of varying size and irregular fibrous septa.

MACRONODULAR CIRRHOSIS: Macronodular cirrhosis is classically due to chronic hepatitis. Broad connective tissue septa (Fig. 20-14) show elements of preexisting portal tracts, mononuclear inflammatory cells and proliferated bile ductules. Micronodular cirrhosis can become macronodular with continued regeneration and expansion of existing nodules, especially in alcoholics who stop drinking.

The diseases associated with cirrhosis are listed in Table 20-1. They have little in common except that they all entail persistent liver cell necrosis. Most cases of cirrhosis are attributable to alcoholism and chronic viral hepatitis. And for 15% of cases, etiologies remain unknown. These are labeled **cryptogenic cirrhosis**. Nonalcoholic steatohepatitis (NASH) is now felt to account for a significant proportion of cryptogenic cirrhosis.

TABLE 20-1
MAJOR CAUSES OF CIRRHOSIS

Alcoholic Liver Disease	
Nonalcoholic Fatty Liver Disease	
Chronic Hepatitis	
Chronic viral hepatitis	
Autoimmune hepatitis	
Drugs	
Biliary Disease	
Extrahepatic biliary obstruction	
Primary biliary cirrhosis	
Primary sclerosing cholangitis	
Metabolic Disease	
Hemochromatosis	Glycogen storage disease
Wilson disease	Hereditary fructose intolerance
α_1-Antitrypsin deficiency	Hereditary storage diseases
Tyrosinemia	Galactosemia
Cryptogenic	

HEPATIC FAILURE

Hepatic failure is the clinical syndrome that occurs when the liver cannot sustain its vital activities. It may develop acutely, mostly due to viral hepatitis or toxic exposure. Or, chronic liver diseases, such as chronic viral hepatitis or cirrhosis, may lead to insidious onset of hepatic failure. Advances in supportive care have improved survival in acute hepatic failure, but mortality for this condition without liver transplantation exceeds 50%. The consequences of hepatic failure are depicted in Figure 20-15.

Jaundice Reflects Inadequate Clearance of Bilirubin by the Liver

Hyperbilirubinemia in hepatic failure is mostly conjugated, although unconjugated bilirubin levels also tend to increase. On occasion, increased erythrocyte turnover may add to unconjugated hyperbilirubinemia, thus aggravating the jaundice.

The Effect of Liver Failure on the CNS Is Hepatic Encephalopathy

Altered mental status is common in patients with acute liver failure and portal hypertension (see below).

PATHOPHYSIOLOGY: No one factor explains the clinical syndrome of hepatic encephalopathy. Because of hepatocyte dysfunction and/or structural or functional vascular shunts, harmful compounds absorbed from the intestine escape hepatic detoxification. This is particularly evident after surgical construction of a portal–systemic anastomosis (portal vein to inferior vena cava or its equivalent) to relieve portal hypertension (see below). Hence, the term

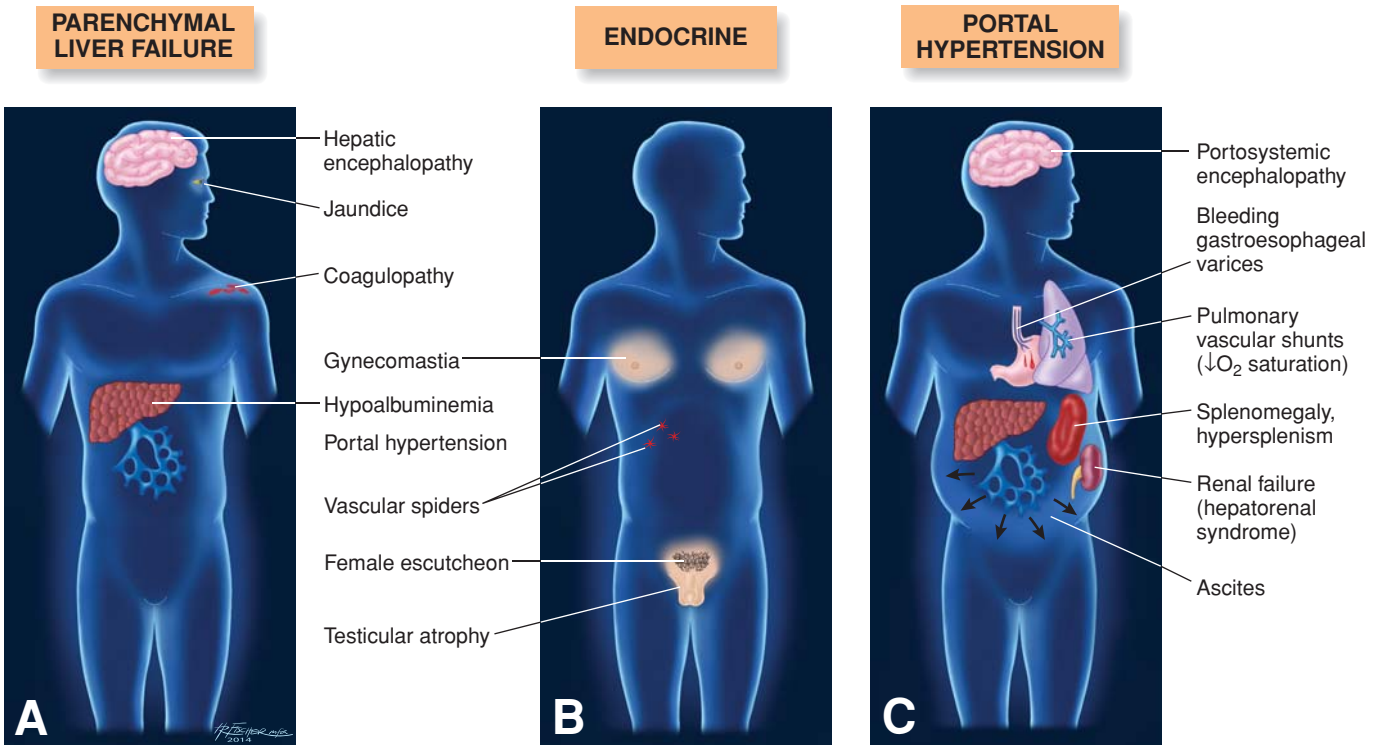

FIGURE 20-15. Complications of cirrhosis and hepatic failure. Clinical features related to **(A) parenchymal liver failure, (B) endocrine disturbances** and **(C) portal hypertension.** There is considerable overlap of these clinical features with regard to their pathogeneses.

portal–systemic encephalopathy is used to describe postshunt encephalopathy.

AMMONIA: Ammonia levels are usually increased in the blood and brain of patients with hepatic encephalopathy. Most of the body's ammonia is derived from ingestion of ammonia in foods, digestion of proteins in the small intestine and bacterial catabolism of dietary protein and urea secreted into the intestine. Ammonia is produced in the small bowel when glutamine is deaminated by glutaminase, an enzyme that is more active in cirrhosis than normally. Ammonia is detoxified by the liver. However, in patients with acute liver failure or cirrhosis, reduced hepatocyte mass or portal–systemic shunts, respectively, an excess of ammonia escapes into the systemic circulation.

Ammonia has several harmful effects. The brain detoxifies ammonia by synthesizing glutamate and glutamine. Excess levels of these molecules may alter neurotransmission and brain osmolality. However, correlation between blood ammonia levels and the severity of hepatic encephalopathy is inexact, thus the neurotoxicity of ammonia remains only partly understood.

γ-AMINOBUTYRIC ACID: Neural inhibition, mediated by the γ-aminobutyric acid (GABA)–benzodiazepine receptor complex, is accentuated in hepatic encephalopathy by increased levels of benzodiazepine-like molecules.

OTHER SUBSTANCES: Other compounds that may contribute to hepatic encephalopathy include **mercaptans** from the breakdown of sulfur-containing amino acids in the colon. A characteristic breath odor of patients with hepatic failure, **fetor hepaticus,** is due to these mercaptans in saliva. Blood levels of aromatic amino acids are increased in hepatic failure. They impair synthesis of normal neurotransmitters such as norepinephrine but increase production of **false neurotransmitters** (e.g., octopamine). Toxicity of **phenols** and **short-chain fatty acids** on the brain has also been postulated. Finally, the blood-brain barrier may be impaired in patients with hepatic failure.

PATHOLOGY: **Cerebral edema** is the major cause of death in most patients with acute hepatic failure. It often coincides with uncal and cerebellar herniation. This edema is a specific lesion associated with hepatic coma, although the precise mechanism is obscure.

In brains of patients who died with chronic liver disease and hepatic coma, the most striking changes are in astrocytes. Termed **Alzheimer type II astrocytes** (see Chapter 28), these cells are swollen, increased in number and size and show nuclear enlargement and nuclear inclusions. Deep layers of the cerebral cortex and subcortical white matter, the basal ganglia and the cerebellum show laminar necrosis and a spongiform appearance.

CLINICAL FEATURES: Hepatic encephalopathy traverses four stages:

- **Stage I:** Sleep disturbance, irritability and personality changes
- **Stage II:** Lethargy and disorientation
- **Stage III:** Deep somnolence
- **Stage IV:** Coma

This sequence may require many months, or it may evolve in days or weeks in cases of acute liver failure. Associated neurologic symptoms include (1) a flapping tremor of the hands, or **asterixis,** and hyperactive reflexes in the early stages; (2) extensor toe responses (Babinski reflex) later; and (3) a decerebrate posture in terminal stages. Intensive supportive measures may suffice early in hepatic encephalopathy, but patients with stages III and IV encephalopathy usually require liver transplantation.

Treatment of hepatic encephalopathy hinges on reversal of the underlying hepatic disease and reduction in ammonia levels. The latter requires purgatives (to rid the bowel of protein, the substrate for ammonia formation), nonabsorbable antibiotics (to reduce the urease-producing bacteria that make ammonia) and correction of other sources of ammonia production, including infections and electrolyte disturbances.

Defects of Coagulation Often Cause Bleeding

In liver failure, impaired synthesis of coagulation factors and thrombocytopenia lead to poor hemostasis. The clotting factors—fibrinogen, prothrombin, and factors V, VII, IX and X—are reduced, reflecting generalized impairment of hepatic protein synthesis.

Thrombocytopenia (<80,000/μL) is common in hepatic failure, as are qualitative defects in platelet function. Hypersplenism, bone marrow depression and platelet loss due to **disseminated intravascular coagulation** (DIC) decrease circulating platelets.

DIC occurs frequently in liver failure. It may be stimulated by liver cell necrosis, activation of factor XII (Hageman factor; see Chapter 4) by endotoxin or inadequate hepatic clearance of activated clotting factors from the circulation.

Hypoalbuminemia Complicates Hepatic Failure

Impaired hepatic albumin synthesis causes hypoalbuminemia. This is an important factor in the pathogenesis of the edema that often complicates chronic liver disease.

Liver Failure Causes Imbalances in Steroid Hormones

Hyperestrogenism in chronic liver failure in men leads to **gynecomastia,** a female body habitus and female distribution of pubic hair (female escutcheon). Vascular effects of hyperestrogenism are common and include **spider angiomas** in the drainage territory of the superior vena cava (upper trunk and face) and **palmar erythema**.

Feminization reflects reduced catabolism of estrogens and weak androgens by a dysfunctional liver. Weak androgens (androstenedione and dehydroepiandrosterone) are converted to estrogens in peripheral tissues, thus increasing circulating estrogen levels. Extrahepatic portal–systemic shunts due to portal hypertension in cirrhosis (see below) permit these hormones to bypass the liver.

Men with alcoholic liver disease are more likely to be feminized than those with liver disease from other causes, and the feminization is usually more severe. Chronic alcoholics also suffer hypogonadism, with testicular atrophy, impotence and loss of libido. Alcoholic women also have gonadal failure, which presents as oligomenorrhea, amenorrhea, infertility, ovarian atrophy and loss of secondary sex characteristics. These effects in both sexes reflect a direct toxic action of alcohol on gonadal function and are independent of chronic liver disease.

PORTAL HYPERTENSION

The superior mesenteric and splenic vein meet to make the hepatic portal vein. This vessel carries the major venous drainage from the gastrointestinal tract, pancreas and spleen to the liver. It accounts for 2/3 of the liver's blood flow but less than 1/2 of its total oxygen supply. The remainder is supplied by the hepatic artery. ***Portal hypertension is either an absolute increase in portal venous pressure, usually above 8 mm Hg, or an increase in the pressure gradient between the portal vein and the hepatic vein of 5 mm Hg or more.*** Obstruction to blood flow somewhere in the portal circuit is responsible. Increased portal pressure causes opening of **portal–systemic collateral channels,** bleeding from gastroesophageal varices, ascites, splenomegaly and renal and pulmonary disease (Fig. 20-15).

Portal hypertension is most accurately assessed by directly measuring hepatic vein pressure: a balloon-tipped catheter is inserted into the internal jugular vein and advanced to a terminal hepatic vein to obtain the **free hepatic vein pressure** (FHVP). The **wedged hepatic vein pressure** (WHVP) is determined after balloon inflation and is an indirect measure of the portal vein pressure. The difference between WHVP and FHVP is the **hepatic vein pressure gradient** (HVPG); that is, WHVP – FHVP = HVPG.

Increased resistance to portal blood outflow is the basis for diagnosing portal hypertension (Fig. 20-16). This increase in resistance can originate in one of three areas:

1. **Sinusoidal (intrahepatic):** Injury to sinusoids leads to sinusoidal, or intrahepatic, portal hypertension. In the Western world, cirrhosis is the most common cause of all forms of portal hypertension. In cirrhosis, fibrosis leads to obstruction of intrahepatic sinusoids. This, in turn, impedes the inflow of portal blood. The result is increased pressure in the portal vein, relative to the hepatic vein. In sinusoidal portal hypertension, the pressure difference between the WHVP and FHVP (HVPG) is usually 5 mm Hg or more.
2. **Presinusoidal:** Resistance to blood flow in the extrahepatic portal vein or intrahepatic portal veins or venules (e.g., thrombotic occlusion) is known as **presinusoidal portal hypertension**. If the point of resistance is within portal venules (i.e., within the liver), the HVPG may be increased. However, if the point of resistance is more distal, allowing for a zone of normal pressure in the portal vein, between the occlusion and the sinusoids, the HVPG can be normal.
3. **Postsinusoidal:** If the point of resistance is in the hepatic veins, venules or cardiac circulation, **postsinusoidal portal hypertension** may result. This can occur if blood flow in the hepatic veins is impeded, as in Budd-Chiari syndrome or congestive heart failure. The HVPG usually is normal in this situation. That is, if the hepatic vein pressure is measured distal to the point of postsinusoidal obstruction, the FHVP will be increased, and the HVPG can be expected to be normal, as the sinusoids are normal and pose no significant resistance to the flow of blood into the liver. However, if high pressure due to outflow resistance is constant, the sinusoids may become progressively injured, leading to eventual elevation in the HVPG.

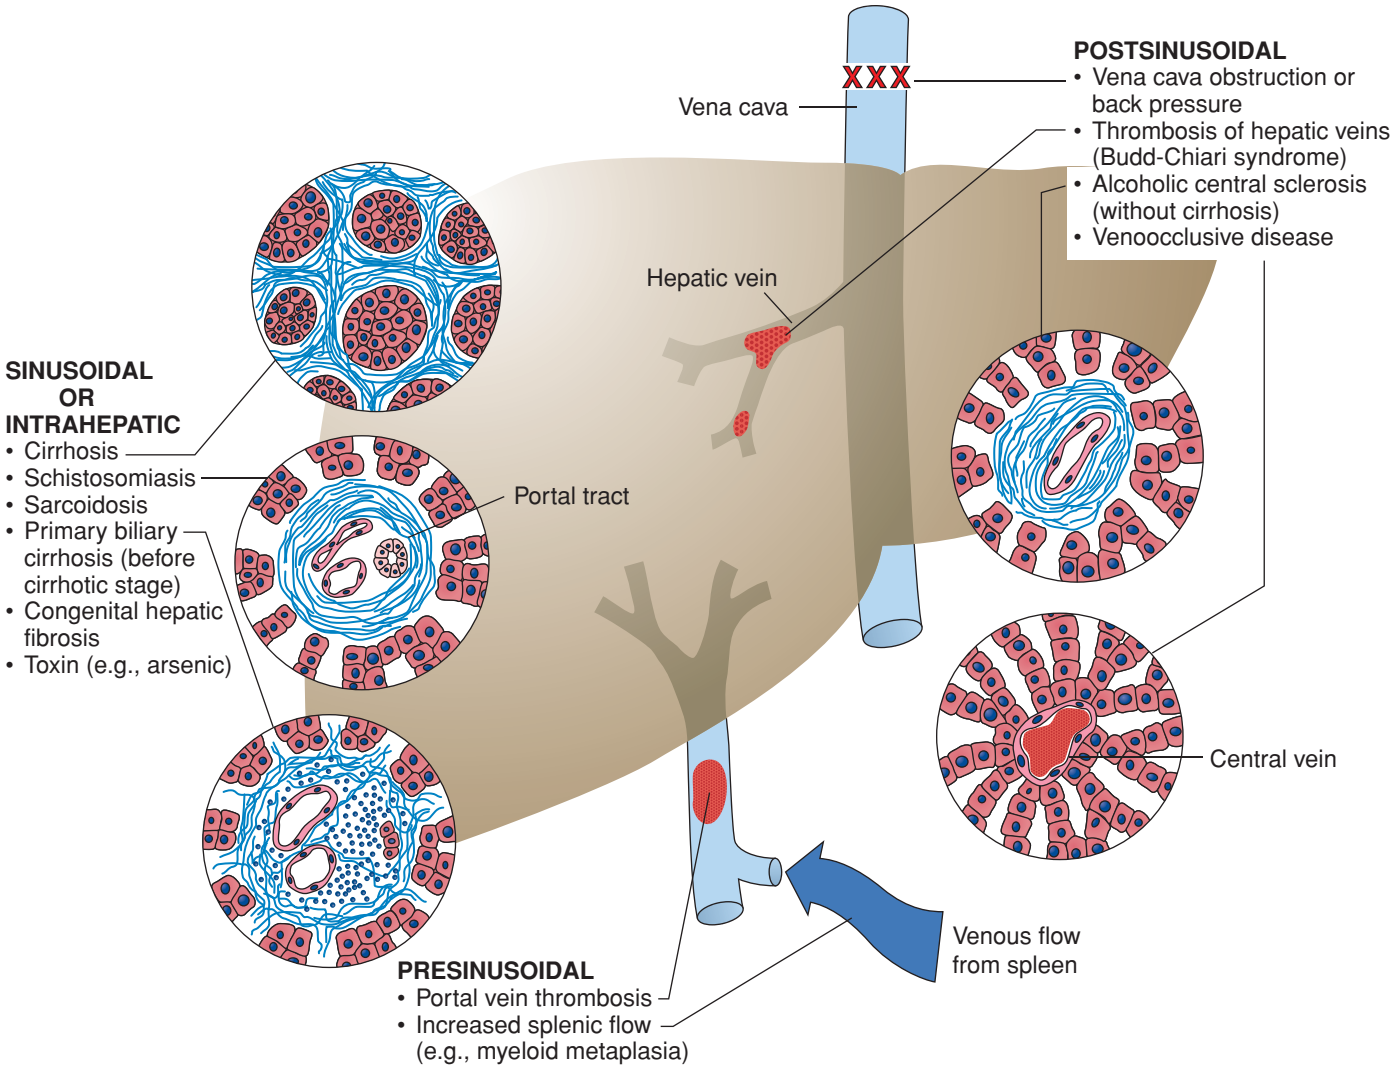

FIGURE 20-16. Causes of portal hypertension.

Intrahepatic Portal Hypertension Is Usually Caused by Cirrhosis

PATHOPHYSIOLOGY: Intrahepatic portal hypertension, such as occurs in cirrhosis, offers the best paradigm for understanding the pathogenesis of portal hypertension. Even before fibrosis distorts sinusoidal architecture, active contraction of vascular smooth muscle and stellate cells initiates resistance to the flow of blood into the liver from the portal vein. The trigger for this is not clear but is probably related to factors that incite inflammation, such as alcoholic hepatitis and viral hepatitis. As fibrosis develops, sinusoids become increasingly disordered. Regenerative nodules in the cirrhotic liver impinge on the hepatic veins, obstructing blood flow beyond the lobules. The small portal veins and venules are trapped, narrowed and often obliterated by scarring of the portal tracts. Blood flow through the hepatic artery is increased and small arteriovenous communications open. In this way, arterial blood flow increases and adds to portal hypertension due to obstruction of blood flow distal to the sinusoid.

In cirrhosis, **endothelial cell dysfunction** occurs in the liver and in the systemic circulation. Hepatic vascular tone increases, and intrahepatic vessels constrict. Impaired endothelial nitric oxide sythetase (eNOS) phosphorylation, reduced nitric oxide (NO) availability due to oxidative stress and excess vasoconstrictive factors (e.g., angiotensinogen, endothelin and eicosanoids) all reduce eNOS activity. This decreases hepatic NO production. Ensuing vasoconstriction increases resistance to portal blood flow into the liver.

Progressive portal hypertension parallels mesenteric arterial vasodilation. That is, to make matters worse, **mesenteric arterial vasodilation** increases blood flow into the portal vein just when portal vein resistance is going up. This vasodilation reflects increased NO caused by greater sheer forces upon the mesenteric vessels, owing to increased resistance to portal blood flow into the liver, increased vascular endothelial growth factor (VEGF) and inflammatory mediators such as TNF-α.

Mesenteric artery vasodilation provokes systemic circulatory dysfunction, systemic arterial vasodilation and reduced effective arterial blood volume.

This decrease in effective arterial blood volume causes the clinical syndrome of advanced portal hypertension: ascites, and **hepatorenal syndrome (HRS)** and **hepatopulmonary syndrome (HPS)**. The increase in portal pressure also opens vascular shunts that decompress the portal circuit. Although ostensibly valuable, these shunts are a mixed blessing, as they may cause such complications as bleeding varices and encephalopathy (see above).

Worldwide, hepatic schistosomiasis is a major cause of intrahepatic portal hypertension (see Chapter 9). Ova released from the intestinal veins traverse the portal system and lodge in intrahepatic portal venules, where they elicit a granulomatous reaction that heals by scarring. Because the obstruction within the liver occurs mainly before portal blood enters the hepatic sinusoids, hepatic schistosomiasis is functionally akin to prehepatic portal hypertension. Liver function is well maintained, but the intrahepatic presinusoidal vascular obstruction leads to severe portal hypertension.

Idiopathic portal hypertension, also called **noncirrhotic portal hypertension, hepatoportal sclerosis or obliterative venopathy,** refers to occasional cases of intrahepatic portal hypertension with splenomegaly in the absence of demonstrable intrahepatic or extrahepatic disease. Known causes of idiopathic portal hypertension are chronic exposure to copper, arsenic and vinyl chloride. In some countries (England, Japan), idiopathic portal hypertension accounts for 15%–35% of all cases that require surgery to decompress the portal circulation.

Intrahepatic portal hypertension can be caused by other conditions that interfere with blood flow through the liver, including cystic disease of the liver (see Chapter 16), partial nodular transformation of the liver in the region of the porta hepatis and nodular regenerative hyperplasia (small regenerative nodules without fibrosis that compress the intervening hepatic parenchyma).

Portal Vein Thrombosis Often Causes Presinusoidal Portal Hypertension

ETIOLOGIC FACTORS: Portal vein thrombosis occurs most often in the setting of cirrhosis. Other causes include tumors, infections, hypercoagulability states, pancreatitis and surgical trauma. Some cases are of unknown etiology. Primary hepatocellular carcinoma (HCC) may invade branches of the portal vein and occlude the main portal vein. When the portal vein is obstructed by a septic thrombus, bacteria may seed the intrahepatic branches of the portal vein (suppurative pylephlebitis) and cause multiple hepatic abscesses.

Portal vein occlusion (Fig. 20-17) may occur in the neonatal period or in early childhood. In some cases, umbilical sepsis is an important cause, but other local and systemic infections may also play a role. Sometimes the thrombosed portal or splenic vein is replaced by a fibrous cord or interlacing vascular channels, a condition termed **cavernous transformation**.

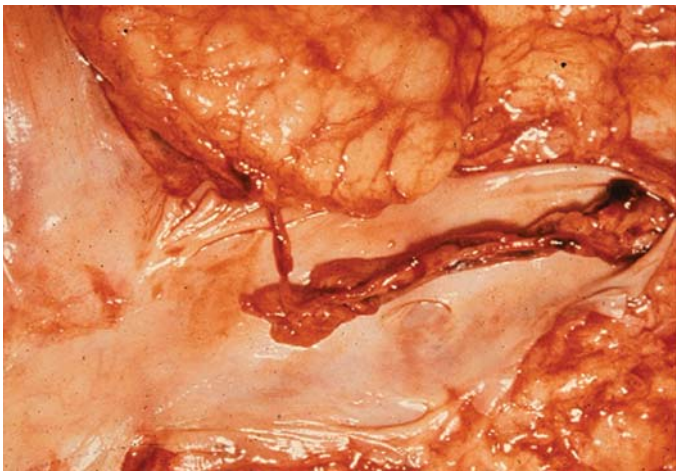

FIGURE 20-17. Portal vein thrombosis.

The liver normally offers little resistance to blood outflow through the sinusoids and so can accommodate substantial increases in blood volume without a secondary increase in pressure. However, increased portal venous blood flow can occasionally lead to prehepatic portal hypertension. Arteriovenous fistulas (abnormal communications between an artery and the portal vein) may cause prehepatic portal hypertension. These generally arise from trauma or rupture of an aneurysm of the splenic or hepatic artery. They may also develop in patients with hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome). Splenomegaly due, for example, to myeloproliferative neoplasms (see Chapter 20) may result in portal hypertension. The splenomegaly that accompanies cirrhosis tends to aggravate portal hypertension.

Postsinusoidal Portal Hypertension Is Obstruction to Blood Flow beyond Liver Lobules

Budd-Chiari Syndrome

Budd-Chiari syndrome is a congestive disease of the liver caused by occlusion of the hepatic veins and their tributaries.

ETIOLOGIC FACTORS: Hepatic vein thrombosis is the main cause of Budd-Chiari syndrome, and it may occur in such diverse diseases as myeloproliferative neoplasms (especially polycythemia vera), hypercoagulable states associated with malignancies, use of oral contraceptives, pregnancy, bacterial infections, paroxysmal nocturnal hemoglobinuria, metastatic and primary tumors in the liver and surgical trauma. In 20% of cases, there is no clear cause. Thrombi form most often in the large hepatic veins, near their exit from the liver, and in the intrahepatic part of the inferior vena cava. In parts of Africa and Asia, membranous webs of unknown cause can compromise the vena cava above the orifices of the hepatic veins and lead to Budd-Chiari syndrome. Increased venous backpressure from severe congestive heart failure, tricuspid stenosis or regurgitation or constrictive pericarditis may mimic the syndrome.

Hepatic veno-occlusive disease is a variant of Budd-Chiari syndrome, caused by hepatic sinusoidal injury

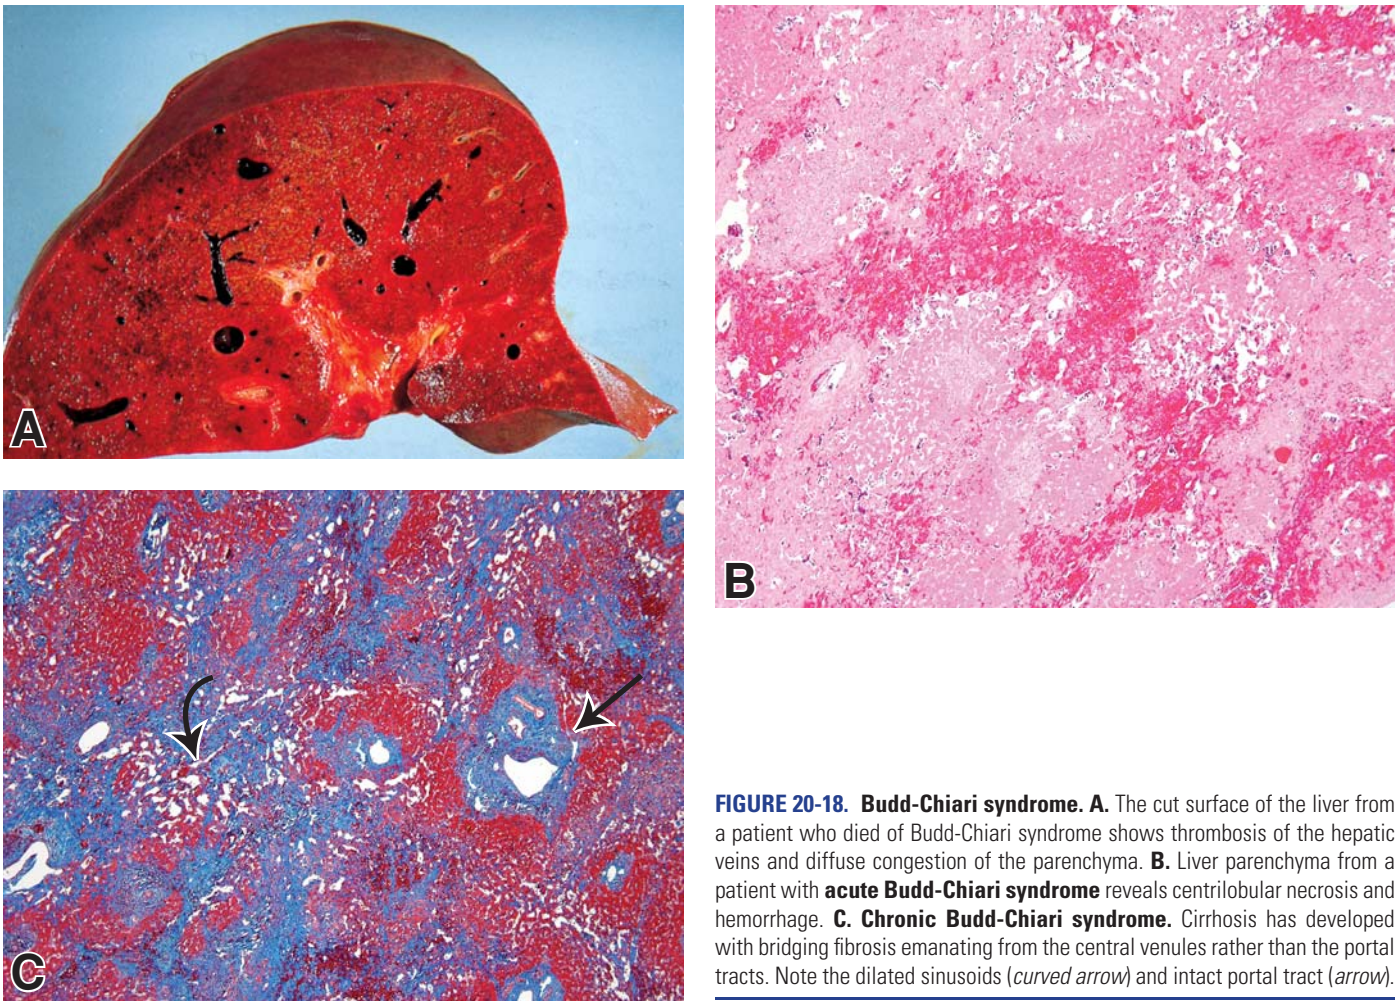

FIGURE 20-18. Budd-Chiari syndrome. A. The cut surface of the liver from a patient who died of Budd-Chiari syndrome shows thrombosis of the hepatic veins and diffuse congestion of the parenchyma. **B.** Liver parenchyma from a patient with **acute Budd-Chiari syndrome** reveals centrilobular necrosis and hemorrhage. **C. Chronic Budd-Chiari syndrome.** Cirrhosis has developed with bridging fibrosis emanating from the central venules rather than the portal tracts. Note the dilated sinusoids (*curved arrow*) and intact portal tract (*arrow*).

resulting in occlusion of the centrilobular hepatic sinusoids, central venules and small branches of the hepatic veins. This disorder is most often traced to ingestion of toxic pyrrolizidine alkaloids in plants of the *Crotalaria* and *Senecio* genera, which are used in "bush teas." It is also seen in patients given certain antineoplastic agents, after hepatic irradiation and after bone marrow transplantation, possibly as a manifestation of graft-versus-host disease.

PATHOLOGY: In the acute stage of **hepatic vein thrombosis,** the liver is swollen and tense. Its cut surface is mottled and oozes blood (Fig. 20-18A). In the chronic stage, the cut surface is paler, and the liver is firm, owing to an increase in connective tissue. The hepatic veins have thrombi in varying stages of evolution, from recent clots to well-organized thrombi that have been rcanalized.

In the acute stage of both Budd-Chiari syndrome and veno-occlusive disease, the sinusoids of the central zone are dilated and packed with erythrocytes (Fig. 20-18B). Liver cell plates are compressed, with hemorrhage and necrosis of centrilobular hepatocytes. In long-standing venous congestion, fibrosis of the central zone may radiate to more peripheral portions of the lobules (Fig. 20-18C). Sinusoids are dilated, and central to midzonal hepatocytes show pressure atrophy. Eventually, **reverse lobulation** occurs, with connective tissue septa linking adjacent central zones to form nodules with a single central portal tract. This fibrosis is usually not severe enough to justify a label of cirrhosis.

CLINICAL FEATURES: Complete thrombosis of the hepatic veins presents as an acute illness with abdominal pain, enlargement of the liver, ascites and mild jaundice. Acute hepatic failure and death often follow quickly. Most often, the obstruction of the hepatic venous circulation is incomplete, and similar symptoms persist for periods from a month to a few years. More than 90% of patients with Budd-Chiari syndrome develop ascites, usually severe, and splenomegaly is common. Typically, serum bilirubin and aminotransferase activities increase only modestly. Most patients eventually die in hepatic failure or from complications of portal hypertension. Liver transplantation may be curative.

Portal Hypertension Affects Many Organ Systems

Esophageal Varices

Esophageal varices are the most important complication of portal hypertension. They arise when collateral portal–systemic vascular channels open to relieve pressure in the portal circuit. One of the most common causes of death in patients with disorders associated with portal hypertension is exsanguinating upper gastrointestinal hemorrhage from **bleeding esophageal varices** (see Chapter 13).

PATHOPHYSIOLOGY: The collaterals of most clinical significance are in the submucosa of the lower esophagus and upper stomach, which communicate between the portal vein and the gastric coronary vein. Normally, these collaterals are closed. However, when the portal circulation sustains increased blood flow and higher pressures that follow, these collaterals open. They are submucosal veins near the esophagogastric junction, and they become dilated and protrude into the lumen. There is no simple correlation between the magnitude of the portal venous pressure and the risk of variceal bleeding, but that risk does rise with increasing size of the varices.

CLINICAL FEATURES: Bleeding esophageal varices portend a poor prognosis: acute mortality may be as high as 40%. In patients with cirrhosis who have survived one episode of variceal bleeding, long-term survival is unlikely because the chances of rebleeding or worsening liver failure are high. By contrast, patients in whom portal hypertension is caused by a presinusoidal block without underlying hepatic dysfunction, as in schistosomiasis, have a much better prognosis than those with cirrhosis. Death from bleeding esophageal varices is usually due to hepatic failure precipitated by stress, ischemic necrosis of the liver and the encephalopathy caused by the nitrogenous load imposed by blood in the intestinal tract. Exsanguination and shock are only infrequently the direct causes of death.

Initial treatment of acute variceal hemorrhage focuses on stopping the bleeding, by endoscopic variceal ligation, injection of varices with a sclerosing agent during endoscopy or direct tamponade with an inflatable balloon. In addition, intravenous administration of a somatostatin analog, octreotide, inhibits splanchnic vasodilation. This, in turn, reduces splanchnic blood flow and portal venous pressure. If these measures fail and varices rebleed, permanent portal circulation decompression may be needed. Angiographically a small stent, or shunt, is placed into the liver to join the portal and systemic circulations (transjugular intrahepatic portal–systemic shunt [TIPS]). This procedure, in addition to surgically constructed portal–systemic shunts, diverts blood from the high-pressure portal circulation to the lower-pressure systemic venous circulation. In some cases, liver transplantation is an alternative to shunt surgery.

Back-pressure in the portal vein also dilates its tributaries, including the inferior hemorrhoidal veins, which become dilated and tortuous **(anorectal varices)**. Collateral veins radiating about the umbilicus produce a pattern known as **caput medusae**.

Splenomegaly

The spleen in portal hypertension enlarges progressively and often causes **hypersplenism,** leading to decreased life spans and consequent reduced levels in the circulation of all formed elements of the blood (pancytopenia). Hypersplenism is attributed to a prolonged transit time through the hyperplastic spleen.

The spleen is firm and weighs up to 1000 g (normal, <180 g). Its cut surface is uniformly deep red, with inapparent white pulp. Sinusoids are dilated and lined by hyperplastic endothelium and macrophages. Their walls are thickened by fibrous tissue. Focal hemorrhages cause fibrotic, iron-laden nodules known as **Gamna-Gandy bodies**.

Ascites

Ascites is accumulation of fluid in the peritoneal cavity. It often accompanies portal hypertension, and the amount of fluid may be so great (often many liters) that it distends the abdomen and interferes with breathing. The onset of ascites in cirrhosis is associated with a poor prognosis.

PATHOPHYSIOLOGY: Reduced effective arterial blood volume and mean arterial pressure lead to predictable homeostatic responses. Early in portal hypertension, heart rate and cardiac output increase, thus preserving arterial pressure. However, as peripheral arterial vasodilation worsens, circulatory dysfunction worsens; cardiac output cannot keep pace with homeostatic demand, and endogenous vasoactive mechanisms become engaged. To preserve arterial pressure, the activities of the renin–angiotensin system and sympathetic nervous system increase. These effects raise renal sodium and water resorption. Vasodilation also activates antidiuretic hormone secretion, promoting to additional water retention and dilutional hyponatremia.

Increased liver sinusoidal pressure results in hydrostatic movement of fluid and lymph from the sinusoids into the space of Disse. This compounds the effects of greater sodium and water retention. These fluids spill into the peritoneal cavity as ascites. Decreased albumin synthesis lowers intravascular oncotic pressure and facilitates movement of fluid into the peritoneal space.

Accumulation of fibrous tissue makes the sinusoidal endothelium less and less permeable. Decreased permeability lowers the amounts of protein and albumin that spill into the ascites fluid. This effect increases the serum:ascites albumin gradient (SAAG). A SAAG exceeding 1.1 is associated with ascites due to portal hypertension from cirrhosis.

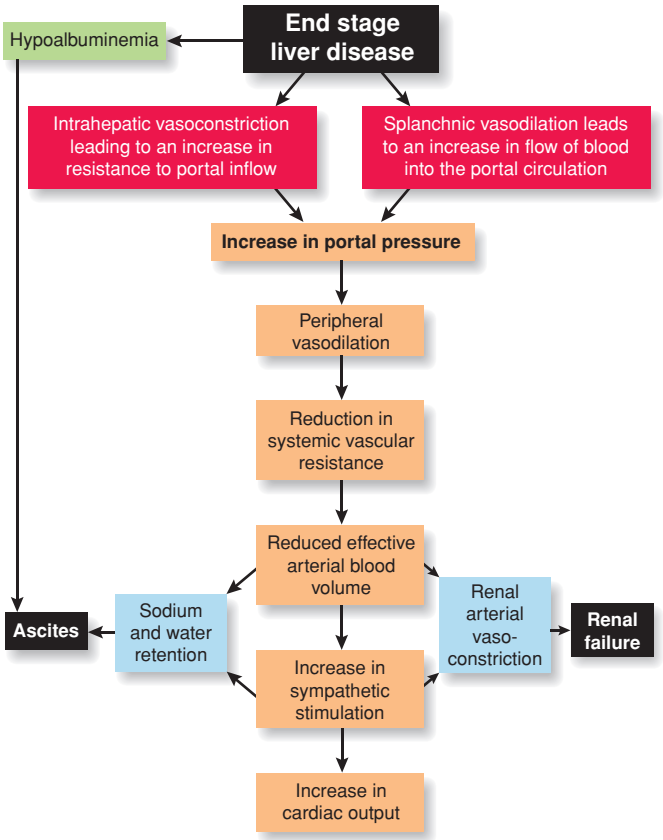
The pathogenesis of ascites is illustrated in Figure 20-19.

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis (SBP) is an important complication in patients with both cirrhosis and ascites.

ETIOLOGIC FACTORS: SBP is due to translocation of intestinal bacteria into the systemic circulation, with secondary infection of ascitic fluid. The most common bacteria are the gram negatives of the gut (*E. coli, Klebsiella*); *Strep. pneumoniae* is also a common cause of SBP. Patients with low complement levels in ascitic fluid, reflected as low protein levels (<1 g/dL), are at particular risk for SBP.

CLINICAL FEATURES: Patients with SBP typically present with ascites and abdominal pain, or other signs of infection such as fever or leukocytosis. Up to 20% of patients are asymptomatic. A finding of



End stage liver disease
Hypoalbuminemia
Intrahepatic vasoconstriction leading to an increase in resistance to portal inflow
Splanchnic vasodilation leads to an increase in flow of blood into the portal circulation
Increase in portal pressure
Peripheral vasodilation
Reduction in systemic vascular resistance
Reduced effective arterial blood volume
Ascites
Sodium and water retention
Renal arterial vaso-constriction
Renal failure
Increase in sympathetic stimulation
Increase in cardiac output

FIGURE 20-19. Pathogenesis of ascites.

more than 250 neutrophils/μL in ascitic fluid establishes the diagnosis of SBP. ***Without appropriate therapy, SBP mortality exceeds 80%.*** Even if it is treated with resolution of the acute infection, an episode of SBP is associated with a 70% 1-year mortality. Therefore, SBP is often an indication for liver transplantation.

Hepatorenal Syndrome

HRS is characterized by renal hypoperfusion, with oliguria, azotemia and increased plasma creatinine. It usually occurs in the setting of cirrhosis and indicates a poor prognosis. Oddly, the kidneys can still function normally, as kidneys from patients who died with HRS function well when transplanted into recipients with chronic renal failure. Conversely, in patients with HRS, liver transplantation can restore renal function.

PATHOPHYSIOLOGY: In the early stages of portal hypertension, glomerular filtration pressure is protected from systemic arteriolar vasodilation by intrarenal prostaglandins. As vasodilation worsens, these intrarenal factors become ineffective; renal vasoconstriction intensifies and glomerular perfusion and filtration decline. Eventually, this leads to clinically evident renal dysfunction, or HRS. A diagnosis of HRS also requires that serum creatinine exceeds 1.5 mg/dL and does not improve after diuretic withdrawal and volume expansion.

There are two types of HRS. Type I HRS is rapidly and inexorably progressive. Liver transplantation is the only definitive therapy. Type II HRS progresses more slowly and usually occurs in the setting of severe ascites unresponsive to conventional therapies with salt restriction and diuretics. This form of HRS may be mitigated by volume expansion or diuretic withdrawal. However, type II ultimately progresses to type I HRS if portal hypertension is not reversed.

Pulmonary Complications of Portal Hypertension

Cirrhosis and portal hypertension can lead to hepatopulmonary syndrome (HPS), **portopulmonary hypertension** (PPHTN) and **hepatic hydrothorax**. Directly or indirectly, these are due to the circulatory and vascular disturbances of advanced liver disease.

Up to 1/3 of patients with cirrhosis show signs of HPS, which results from shunts in the pulmonary vascular bed due to portal hypertension. These patients present with progressive shortness of breath, although chest radiography and pulmonary hemodynamics are typically normal. Treatment with supplemental oxygen may be useful, but liver transplantation is the only effective therapy because it reverses the intrapulmonary shunting. HPS is associated with reduced survival, particularly if arterial oxygen is less than 50 mm Hg.

PPHTN is increased pulmonary vascular resistance in the setting of portal hypertension. Usually, it is associated with increased mean pulmonary arterial pressure, to more than 25 mm Hg, and occurs in 2% of those with portal hypertension. The pathophysiology of the disorder is unclear. It may reflect aspects of the hyperdynamic circulation of portal hypertension: shear stress, endothelial injury, vasoconstriction and liberation of vasoactive factors. Proliferative pulmonary arteriopathy develops. PPHTN is inexorably progressive and usually does not reverse following liver transplantation. In fact, severe PPHTN it is a risk factor for intraoperative death due to acute heart failure and represents a contraindication to liver transplantation.

Hepatic hydrothorax is a pleural effusion attributed to portal hypertension. Most such effusions occur in the right chest and are caused by ascitic fluid moving through the diaphragm into the pleural space. Thus, the fluid has the same composition and protein content as ascites and, like ascites, is prone to spontaneous infection.

VIRAL HEPATITIS

Viral hepatitis is infection of hepatocytes that causes liver necrosis and inflammation. It was known as "epidemic jaundice" for millennia. Worldwide, more than 500 million people are infected with hepatotropic viruses and are at great risk for HCC. Many viruses and other infectious agents can produce hepatitis and jaundice (Table 20-2), but in the industrialized world, more than 95% of cases of viral hepatitis are caused by hepatitis A, B, C, D and E viruses (HAV, HBV, etc.). HGV is 25% homologous with HCV but does not lead to acute or chronic hepatitis.

The following discussion emphasizes the illnesses commonly termed **viral hepatitis**. The reader is referred to Chapter 9 for consideration of the other agents.

TABLE 20-2
INFECTIOUS AGENTS THAT CAUSE HEPATITIS

Hepatitis A virus (HAV)	Herpes simplex virus
Hepatitis B virus (HBV)+/– HDV	Cytomegalovirus
Hepatitis C virus (HCV)	Enteroviruses other than HAV
Hepatitis E virus (HEV)	
Yellow fever virus	Leptospires (leptospirosis)
Epstein-Barr virus (infectious mononucleosis)	*Entamoeba histolytica* (amebic hepatitis)
Lassa, Marburg and Ebola viruses	

Hepatitis A Virus Is the Most Common Cause of Acute Hepatitis

Hepatitis A virus (HAV) is a small RNA-containing enterovirus of the picornavirus family (which includes polio virus) (Fig. 20-20). It mainly replicates in hepatocytes, but gastrointestinal epithelial cells may also be infected. Infectious virus progeny are shed into the bile and present in the feces. HAV is not directly cytopathic, and hepatic injury has been attributed to the immunologic reaction against virally infected hepatocytes.

EPIDEMIOLOGY: The only reservoir for HAV is acutely infected people, so transmission is mostly from person to person by the fecal–oral route. Epidemics of hepatitis A occur in crowded and unsanitary conditions, such as exist in warfare, or by fecal contamination of water and food. Edible shellfish in contaminated waters concentrate the virus and may transmit infection if they are not adequately cooked.

In industrialized countries, which have low rates of infection, most cases of hepatitis A are seen in older children and adults. By contrast, in less developed regions, where the disease is endemic, most of the population is infected before 10 years of age.

In the United States, about 10% of the population younger than 20 years show serologic evidence of previous HAV infection, indicating that ***most HAV infections are anicteric***. Hepatitis A is common in day care centers and among international travelers and men who have sex with men. However, no source is identified in about 1/2 of cases. Hepatitis A vaccination confers long-term protection from the disease. Universal vaccination programs have significantly reduced the incidence of acute hepatitis A in the United States.

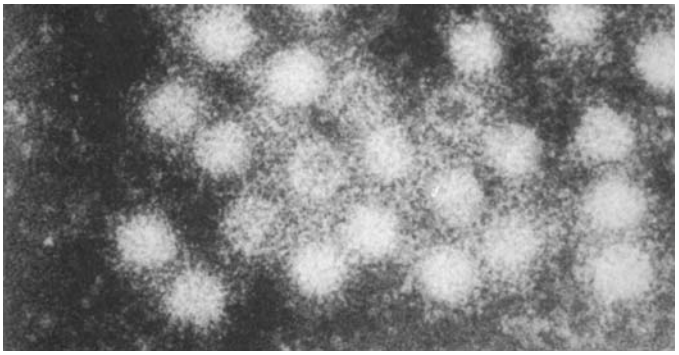


FIGURE 20-20. Electron micrograph of hepatitis A virus (HAV). A fecal extract was treated with convalescent serum containing anti-HAV.

CLINICAL FEATURES: After an incubation period of 3–6 weeks (mean, about 4 weeks), HAV-infected patients develop nonspecific symptoms, including fever, malaise and anorexia. Concomitantly, liver injury is evidenced by a rise in serum aminotransferases (Fig. 20-21). Aminotransferase levels begin to decline, usually 5–10 days later. Jaundice may then appear. It remains evident for an average of 10 days but may persist for more than a month. Aminotransferase levels generally return to normal by the time jaundice has disappeared. ***Hepatitis A never becomes chronic. There is no carrier state, and infection provides lifelong immunity.*** Fulminant hepatitis is rarely seen, and virtually all patients recover without sequelae.

HAV is detectable in the liver about 2 weeks after infection, peaks in another 2 weeks and disappears shortly thereafter (Fig. 20-21). Fecal shedding of HAV follows its appearance in the liver by about a week and is brief. The period of viremia is also short, occurring early in the disease.

IgM anti-HAV is the first detectable immune response to HAV. It appears in the blood during the acute illness. IgM titers begin to decline within a few weeks and are undetectable by 3–5 months. IgG anti-HAV appears as patients recover and persists for life. Serum IgM anti-HAV in a patient with acute hepatitis confirms HAV as the cause.

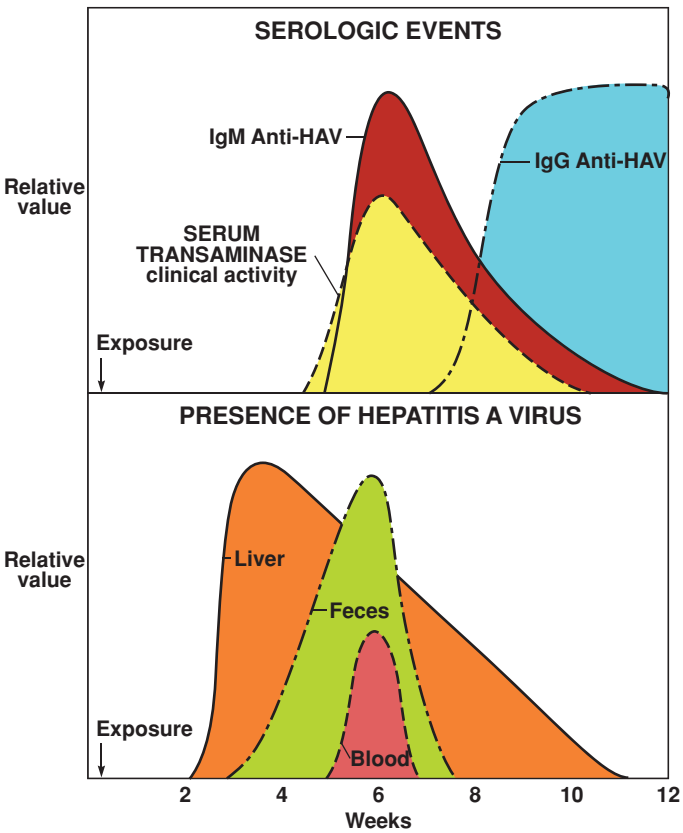

FIGURE 20-21. Typical serologic events associated with hepatitis A (HAV).

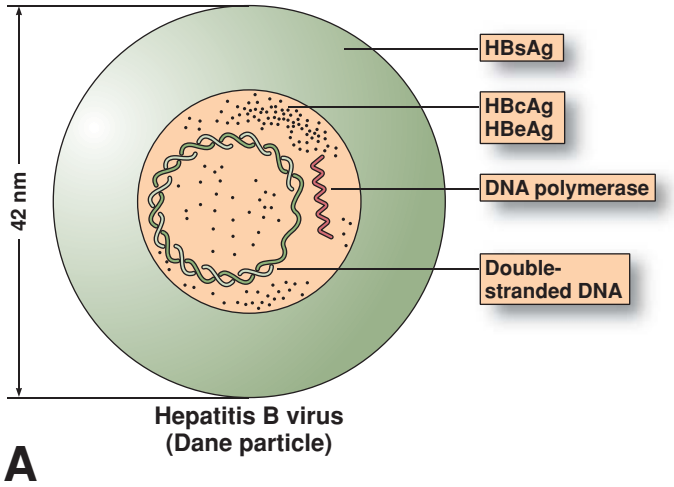
Hepatitis B Is a Major Cause of Acute and Chronic Liver Disease

ETIOLOGIC AGENT: Hepatitis B virus (HBV) is a hepatotropic DNA virus of the **hepadnavirus** group, whose genomes are among the smallest of all known viruses. The HBV genome is circular and predominantly double-stranded DNA with the entire genome, plus a shorter complementary strand that varies from 50% to 85% of the length of the longer strand (Fig. 20-22). The viral particle is a 42-nm sphere (*Dane particle*) that contains the viral DNA. The HBV genome has four genes:

- **Core (*C*) gene:** The core of the virus contains the **core antigen (HBcAg)** and the **e antigen (HBeAg),** both of which are products of the *C* gene. The *C* gene includes two consecutive open reading frames: the precore and core regions. Transcription of the core frame alone yields HBcAg. HBeAg is derived from the translation product of the entire *C* gene by proteolysis.
- **Surface gene:** The outer viral coat contains **hepatitis B surface antigen (HBsAg)**. HBsAg is synthesized by infected hepatocytes independently of the viral core, and vast amounts are secreted into the blood. Electron microscopy of centrifuged serum identifies two distinct HBsAg particles (Fig. 20-22): a 22-nm sphere and a tubular structure 22 nm in diameter and 40–400 nm in length. These particles are immunogenic but not infectious.
- **Polymerase gene:** The *P* gene encodes viral DNA polymerase.
- ***X* gene:** The small X protein activates viral transcription and probably plays a role in HBV-related hepatocarcinogenesis associated with chronic HBV infection.



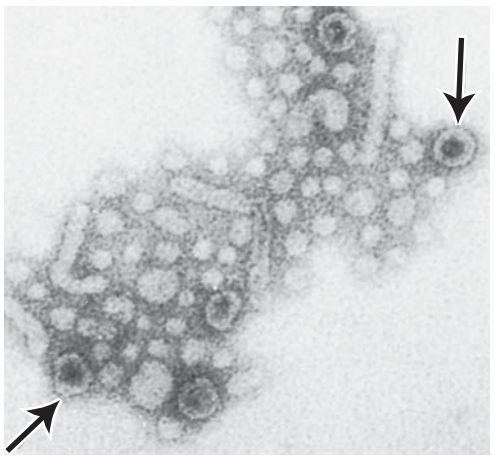


FIGURE 20-22. Hepatitis B virus (HBV). A. Schematic representation of HBV and serum particles associated with HBV infection. (Antigens [Ag] for hepatitis B are indicated by their letters: c = core, e, and s = surface.) **B.** Electron micrograph of particles from centrifuged serum in a case of hepatitis B. Rod-like and spherical particles containing HBsAg are evident. The complete virion, composed of the viral core and its surrounding envelope, is represented by Dane particles (*arrows*).

HBV attaches to host hepatocytes and then enters the cell, where it uncoats. Its genome then goes into the nucleus, where it is converted into a covalently closed circular DNA (cccDNA) that is the template for transcription of viral mRNA. Persistence of cccDNA prevents HBV clearance from the host, even with potent antiviral pharmacotherapy.

There are six distinct HBV serotypes (A through F). Mutations are common, both in unmolested infection and under the influence of pharmacotherapy. ***Precore mutant HBV DNA-containing viruses do not express HBeAg,*** and their function is unclear. Antiviral treatment selects for HBV mutants at high (50%) rates after years of therapy. Newer nucleoside and nucleotide analogs cause lower rates of HBV mutation.

EPIDEMIOLOGY: It is estimated that there are more than 350 million chronic carriers of HBV in the world, constituting an enormous reservoir of infection (Fig. 20-23). Depending on the rate of primary infection with HBV, carrier rates of chronic infection vary from 0.3% (United States, Western Europe) to 20% (Southeast Asia, sub-Saharan Africa, Oceania and the Pacific and Amazon basins). In endemic areas, high carrier rates are sustained by vertical transmission from carrier mothers to newborns.

In the United States, between 500,000 and 1.5 million people are chronically infected HBV carriers. Between 200,000 and 300,000 new cases of HBV occur annually. The use of a protective vaccine lowered the incidence of HBV in the United States from 10.7/100,000 in 1983 to 1.6/100,000 in 2006. Only 1/4 of new cases present with jaundice. Fulminant hepatitis B causes 250–300 deaths annually in the United States. Posttransfusion hepatitis, once common, is now a memory due to routine blood screening for HBsAg.

The incidence of HBV chronicity is inversely proportional to the age at viral acquisition. In countries with high endemicity, the high chronicity rate is due to vertical transmission and unsafe injection practices. In areas with lower rates of infection, HBV transmission is most frequently horizontal. No more than 10% of people infected with HBV as adults become carriers, but neonatal hepatitis B generally leads to persistent infection. Males become carriers more often than females. In the United States, chronic HBV carriers are common among male homosexuals and IV drug users.

Humans are the only significant reservoir of HBV. Unlike hepatitis A, HBV is not transmitted by the fecal–oral route, nor does it contaminate food and water supplies. ***HBsAg is found in most secretions, but infectious virus is only present***

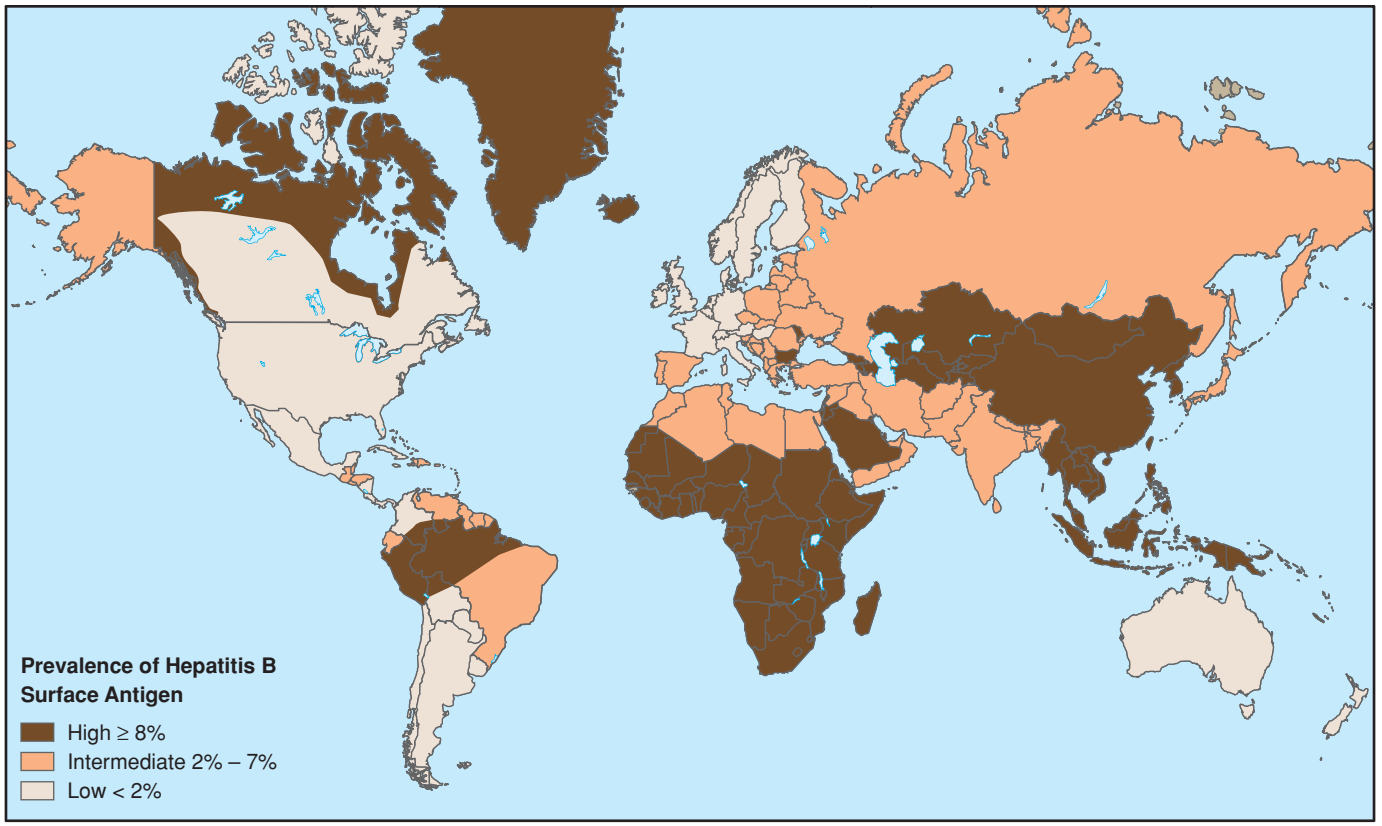

FIGURE 20-23. Geographic prevalence of hepatitis B infection.

in blood, saliva and semen. Most cases of hepatitis B are now transmitted by intimate contact. Such contact transmission largely involves direct transfer of virus through breaks in the skin or mucous membranes. Anal sexual contact is thus an important mode of transmission.

Synthetic hepatitis B vaccines, containing recombinant HBsAg or its immunogenic epitopes, are highly effective and confer lifelong immunity. In some regions where hepatitis B is endemic, vaccination has significantly reduced the prevalence of the disease. In the United States, it is now routine to administer the vaccine. Vaccination of infants is common in most nations (currently 177 of 193 countries).

PATHOPHYSIOLOGY: HBV is not directly cytopathic, as asymptomatic chronic carriers of the virus have a large load of infectious virus in the liver for years without functional or biochemical evidence of liver cell injury. Cytotoxic ($CD8^+$) T lymphocytes (CTLs) that target multiple HBV epitopes cause most of the destruction of hepatocytes and consequent clinical liver disease. Target viral antigens are expressed on the surface of infected hepatocytes, where they are recognized by $CD8^+$ cells. These CTLs, in turn, kill infected hepatocytes.

The infectivity of blood from patients with chronic hepatitis B declines with the duration of the disease. This is largely due to decreased episomal (extrachromosomal) replication of infectious virions. The intact viral genome does not integrate into host DNA. However, genomic fragments are progressively integrated, after which they produce several viral antigens, contributing to viral persistence.

CLINICAL FEATURES: Hepatitis B may follow three courses (Fig. 20-24):

- Acute hepatitis
- Fulminant hepatitis
- Chronic hepatitis

ACUTE HEPATITIS B: Most adult patients have acute, self-limited hepatitis B, similar to that produced by HAV, usually followed by complete recovery and lifelong immunity. Symptoms of hepatitis B are largely similar to those of hepatitis A, but acute hepatitis B tends to be somewhat more severe, and its incubation period is much longer. Typically, symptoms appear 2–3 months after exposure, but incubation periods may vary from under 6 weeks to 6 months. As in hepatitis A, many cases, including virtually all infections in infants and children, are anicteric and thus not clinically apparent.

HBsAg is the first marker to appear in the serum of patients with acute hepatitis B. It appears 1–8 weeks after exposure (Fig. 20-24) and disappears from the blood during convalescence in those patients who recover rapidly. Simultaneously with, or shortly after, HBsAg disappears, serum antibody to HBsAg (anti-HBs) is detectable. Its appearance heralds complete recovery, and it provides lifelong immunity.

HBcAg (core antigen) is not seen in blood of persons with acute hepatitis B, but antibody to HBcAg (anti-HBc) appears shortly after HBsAg. Antibody to HBcAg is a marker of a prior HBV infection but does not clear the virus or protect from reinfection.

HBeAg circulates before the onset of clinical disease and after the appearance of HBsAg. It generally disappears within

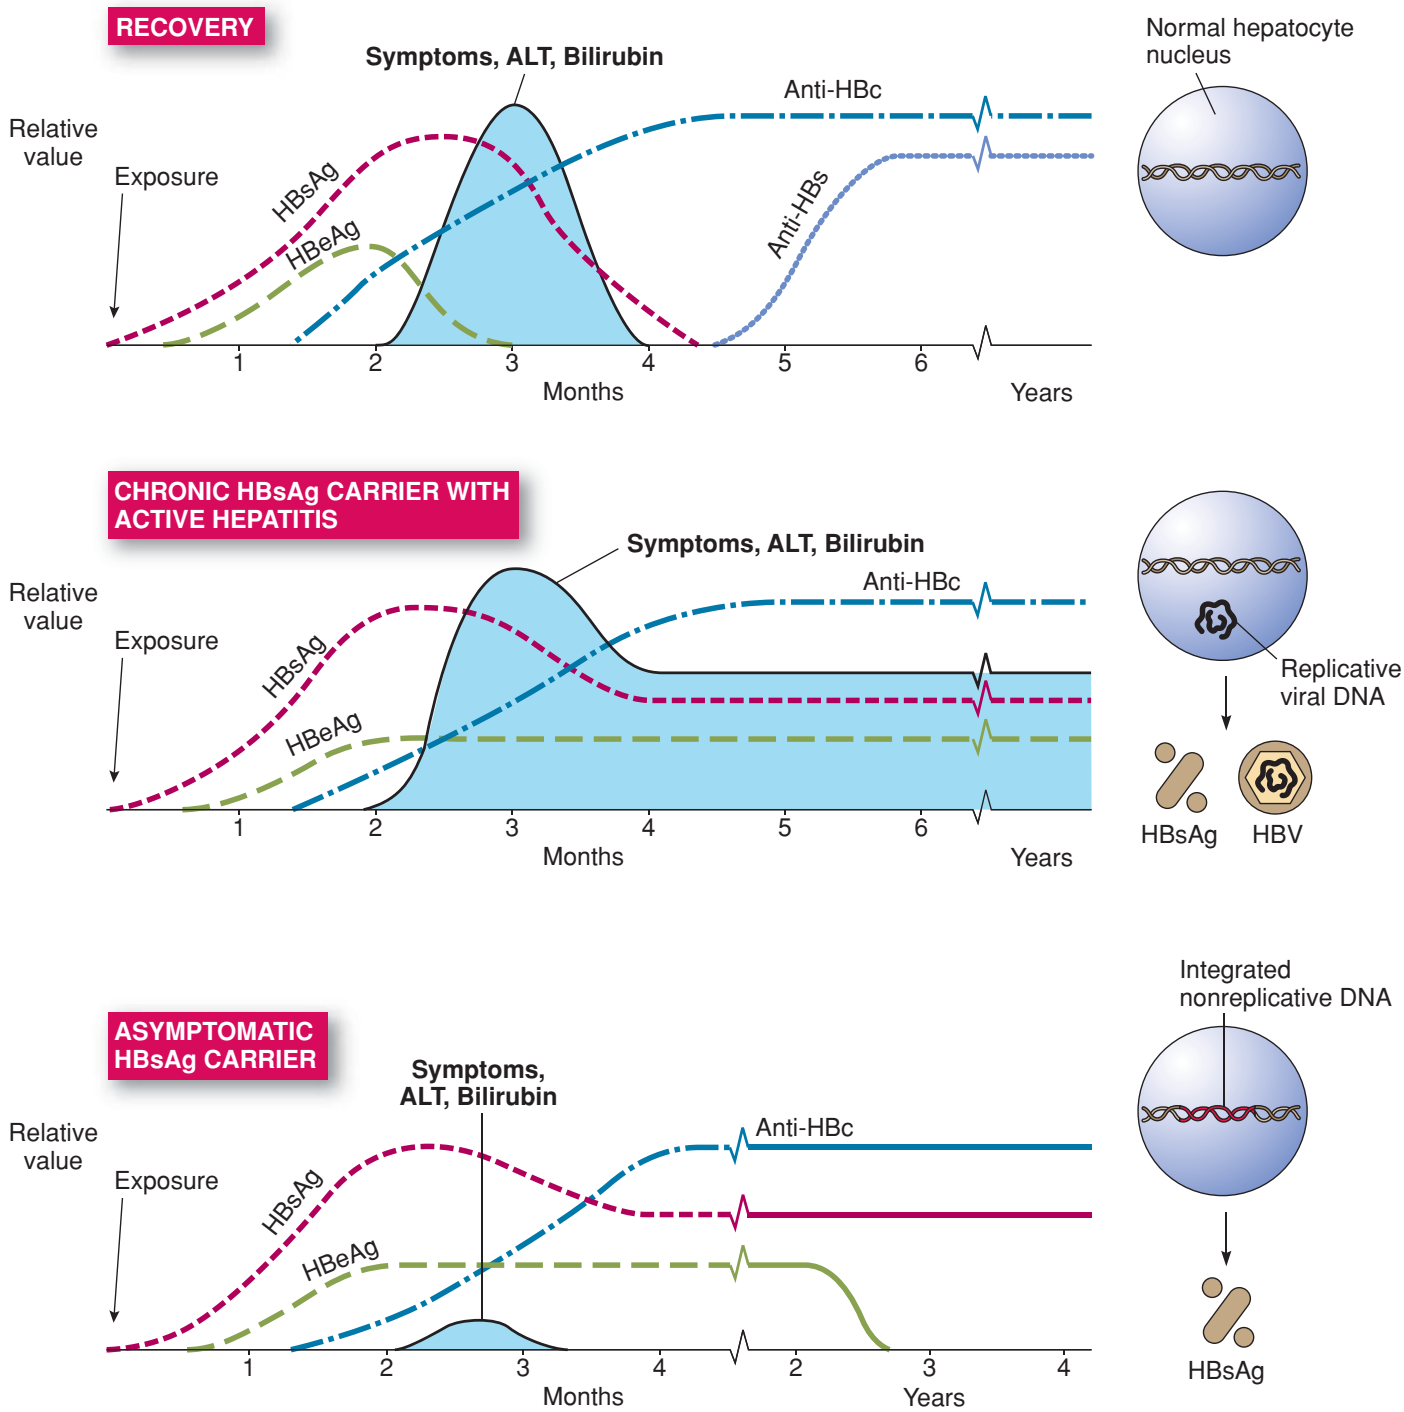

FIGURE 20-24. Typical serologic events in three distinct outcomes of hepatitis B. Top panel. In most cases, the appearance of antibody to hepatitis B surface antigen (HBsAg; anti-HBs) ensures complete recovery. Viral DNA disappears from the nucleus of the hepatocyte. **Middle panel.** In about 10% of cases of hepatitis B, HBs antigenemia is sustained for longer than 6 months, owing to the absence of anti-HBs. Patients in whom viral replication remains active, as evidenced by sustained high levels of HBeAg in the blood, develop active hepatitis. In such cases, the viral genome persists in the nucleus but is not integrated into host DNA. **Lower panel.** Patients in whom active viral replication ceases or is attenuated, as reflected in the disappearance of HBeAg from the blood, become asymptomatic carriers. In these individuals, fragments of the hepatitis B virus (HBV) genome are integrated into the host DNA, but episomal DNA is absent.

about 2 weeks, whereas HBsAg is still present. Serum HBeAg correlates with a period of intense viral replication and, hence, maximal infectivity of the patient. Anti-HBe antibody appears shortly after the antigen disappears and is detectable up to 2 or more years after the hepatitis resolves. A minor subset of patients who seroconvert to anti-HBe antibody and lose serum HBeAg have persistent HBV replication. HBV viruses in these cases are replication competent but do not produce HBeAg because of mutations in the HBV genome.

FULMINANT HEPATITIS B: More often than hepatitis A, but still only rarely, acute hepatitis B can be a fulminant disease, with massive liver cell necrosis, hepatic failure and high mortality. Nucleoside and nucleotide analogs have improved outcomes for patients with fulminant hepatitis B compared to historical controls. Patients with fulminant acute hepatitis B can decompensate rapidly. Death is primarily caused by cerebral edema, cardiopulmonary collapse or sepsis. Liver transplantation, when available, gives excellent patient survival.

CHRONIC HEPATITIS B: Chronic hepatitis is characterized by continued necrosis and inflammation in the liver for more than 6 months. People with chronic HBV infection are at increased risk for cirrhosis and HCC. Men are more susceptible than women. Other risk factors include age greater than 40 years, high levels of HBV viremia, viral genotypes C and F or a precore promoter mutation.

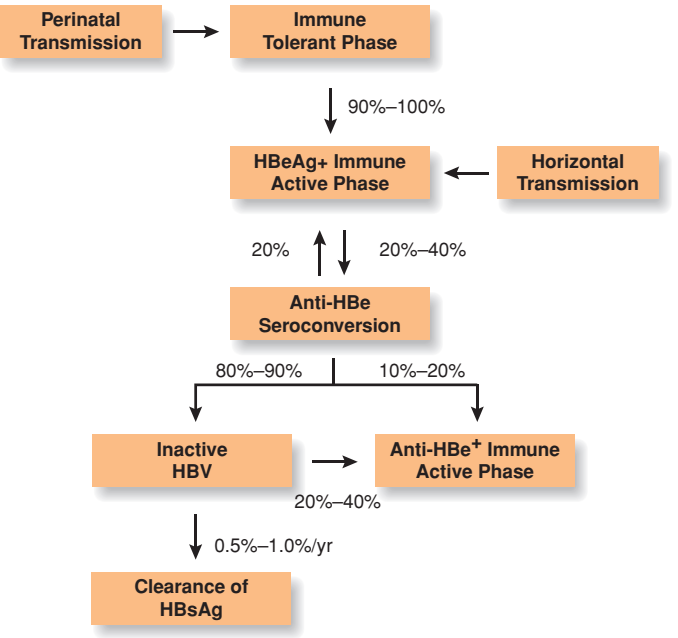

FIGURE 20-25. Outcomes of infection with the hepatitis B virus (HBV).

PATHOPHYSIOLOGY: Three phases of chronic hepatitis B are recognized: (1) immune tolerant phase, (2) immune active phase and (3) inactive phase. A fourth phase, recovery, is not yet generally accepted. People chronically infected with HBV often progress temporally through these phases but can also revert backward.

1. **Immune tolerant phase:** Patients in this phase are HBeAg positive, with very high HBV DNA levels (>20,000 IU/mL). There is little significant hepatocellular inflammation or necrosis: serum aminotransferase levels are normal. This phase may last for decades and is common among those who acquired HBV by vertical transmission. Since HBV DNA integrates into cellular DNA, even patients in this phase are at increased risk for HCC.
2. **Immune active phase:** This phase is characterized by HBV viremia and liver cell necrosis (i.e., elevated serum aminotransferases). Portal-based inflammatory infiltrates and hepatocyte necrosis are seen. Patients with detectable HBe tend to have greater viremia than those who are HBe negative/anti-HBe positive. Significant liver injury, cirrhosis and HCC tend to develop in this phase. Antiviral therapy is often initiated in the immune active phase.
3. **Inactive phase:** In the inactive phase, anti-HBe antibody circulates and HBeAg does not, serum aminotransferases are normal and blood HBV DNA is low (<2000 IU/mL). These people are "asymptomatic carriers" and are at very low risk of progression to cirrhosis or HCC. However, these people may revert to immune active disease and thus require long-term follow-up.

In some chronic HBV carriers, HBsAg–anti-HBs complexes circulate in the blood. Thus, these patients produce antibody but do not clear the virus antigen from the circulation. Such circulating immune complexes may lead to **extrahepatic** complications, including a serum sickness–like syndrome (fever, rash, urticaria, acute arthritis), polyarteritis, glomerulonephritis and cryoglobulinemia. In fact, 1/3 to 1/2 of patients with polyarteritis nodosa are HBV carriers. Chronic hepatitis B is associated with a significant risk of liver cancer (see below). ***The possible outcomes of infection with HBV are summarized in Figures 20-24 and 20-25.***

Hepatitis D Virus Is a Defective RNA Virus

Assembly of hepatitis D virus (HDV) in the liver requires HBsAg to be present. Therefore, infection with HDV is limited to people who are also infected with HBV. The two infections may be simultaneous (coinfection), or HDV infection may follow HBV infection (superinfection). HDV and HBsAg are cleared together, and the clinical course is usually similar to that for the usual acute hepatitis B. However, in some patients, coinfection with HDV leads to severe, fulminant and often fatal hepatitis, particularly in intravenous drug abusers. ***Superinfection of an HBV carrier with HDV typically increases the severity of an existing chronic hepatitis.*** In fact, 70%–80% of HBsAg carriers superinfected with HDV develop chronic hepatitis. Since the discovery of HDV in 1979, recognition of its natural history has led to a significant drop in HDV transmission. The virus remains a clinical problem especially in developing nations endemic for HBV.

Hepatitis C Virus Commonly Causes Chronic Hepatitis and Cirrhosis

Hepatitis C virus (HCV) is an enveloped flavivirus. Its single-stranded RNA genome of 9600 bases encodes one

transcript. This mRNA is translated into a polyprotein of about 3000 amino acids, which is cleaved into three structural proteins (one core and two envelope proteins) and six nonstructural proteins. Short untranslated regions at the end of the genome are required for replication.

The virus is genetically unstable, which leads to the existence of multiple genotypes and subtypes. Six different but related HCV genotypes are known. Types 1, 2 and 3 are most common (about 75% in the United States and Western Europe). Genotypes 2 and 3 respond better to antiviral therapy than does type 1. In an individual patient, many mutant HCVs arise, which likely accounts for several features of infection, including (1) the inability of anti-HCV antibodies to clear the infection, (2) persistent and relapsing infection in the chronic hepatitis phase and (3) lack of progress in developing a vaccine.

EPIDEMIOLOGY: The prevalence of HCV ranges from under 1% in Canada and Scandinavia to 1.8% in the United States to as high as 22% in Egypt. It is estimated that some 170 million people (3% overall prevalence) are infected worldwide. HCV accounts for the majority of patients waiting for liver transplants.

HCV infection is transmitted by contact with infected blood through direct percutaneous exposure to blood or unsafe injection practices. Less efficient transmission occurs via smaller percutaneous exposures (needlestick injuries) or mucosal routes such as vertical and sexual transmission. Intravenous drug abuse (especially with unsafe injection practices), high-risk sexual behavior (particularly male homosexuals) and alcoholism place individuals at high risk for contracting infection with HCV. Screening of the blood supply for anti-HCV antibodies has virtually eliminated transfusions as a source of HCV infection. Transmission from infected mothers to newborn babies is infrequent (2.7%–8.4%) but is four to five times more common in women coinfected with HIV. In a minority of cases, there are no known risk factors. The incidence of new cases of acute HCV infection in the United States has fallen from 230,000 annually in the 1980s to 16,000 now, a drop of 93%. Much of this decrease probably reflects declining use of injectable illicit drugs. Mortality due to hepatitis C is increasing, as people infected long ago are aging. This aging population will likely be increasingly susceptible to decompensated cirrhosis and HCC over the next 20 years.

PATHOPHYSIOLOGY: HCV is not directly cytopathic, and many chronic HCV carriers have no liver cell injury. Despite active humoral and cellular immune responses against all viral proteins, most patients have persistent viremia. ***Liver cell injury probably reflects CTL killing of virus-infected hepatocytes.*** HCV persistence is not well understood. The high level of virus genome mutation (see above) and defects in HCV-specific cellular immunity probably contribute.

CLINICAL FEATURES: The incubation period of hepatitis C is similar to that of hepatitis B. Serum aminotransferases (Fig. 20-26) usually rise in 4–12 weeks after exposure (range, 2–26 weeks). Within 1–3 weeks of infection, HCV RNA circulates in the blood. Anti-HCV antibodies usually appear 7–8 weeks after infection and persist during the chronic phase. Acute hepatitis C is quite mild, or asymptomatic, in most people: only 10%–20% develop jaundice. About 20% of HCV patients spontaneously clear the virus. Persistent viremia is milder in patients who develop jaundice and greater in those who acquire HCV via IV drug use. Fulminant hepatitis, if it occurs at all, is rare.

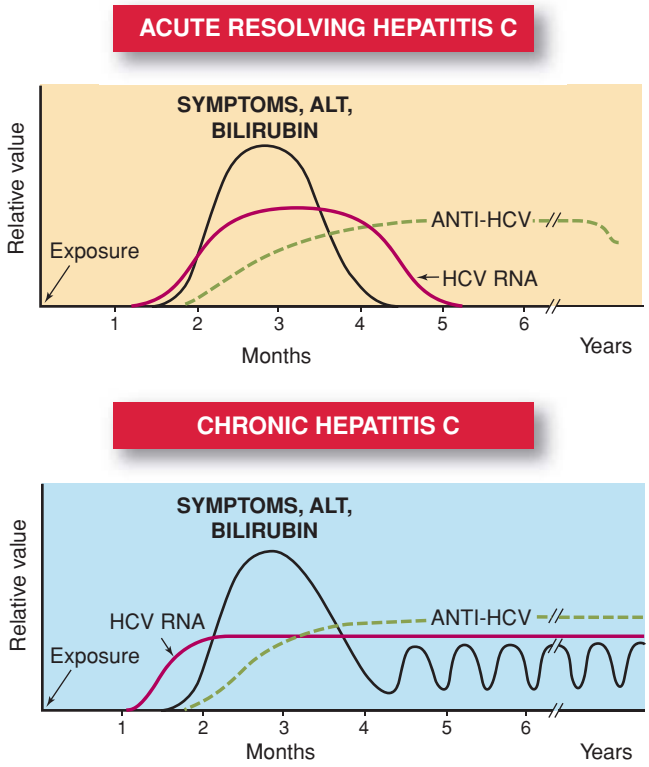

FIGURE 20-26. Clinical course of hepatitis C virus (HCV). Typical serologic events in two distinct outcomes. **Top panel.** About 20% of the patients with acute hepatitis C have a self-limited infection that resolves in a few months. Anti-HCV appears at the end of the clinical course and persists. **Bottom panel.** The remaining patients with hepatitis C develop chronic illness, with exacerbations and remissions of clinical symptoms. The development of anti-HCV does not affect the clinical outcome. Chronic hepatitis often eventuates in cirrhosis. ALT = alanine aminotransferase.

The most important consequences of HCV infection relate to chronic disease. Despite complete recovery from clinical and biochemical acute liver disease, 85% of patients develop chronic disease (Fig. 20-27). Cirrhosis develops in 15%–20% of people chronically infected with HCV for 10–30 years. The risk of cirrhosis is greater in men, older people, alcoholics and those who are also infected with HIV or HBV. Even in the absence of elevated aminotransferases or significant risk factors for progression, patients can present with significant fibrosis and even cirrhosis. Liver biopsy is vital to estimating the risk of clinical progression.

Chronic hepatitis is mild in most patients for at least 10 years and often for 20 or more years. Some 20% of patients with chronic hepatitis C eventually develop cirrhosis. ***Of patients with cirrhosis, up to 5% per year develop HCC.***

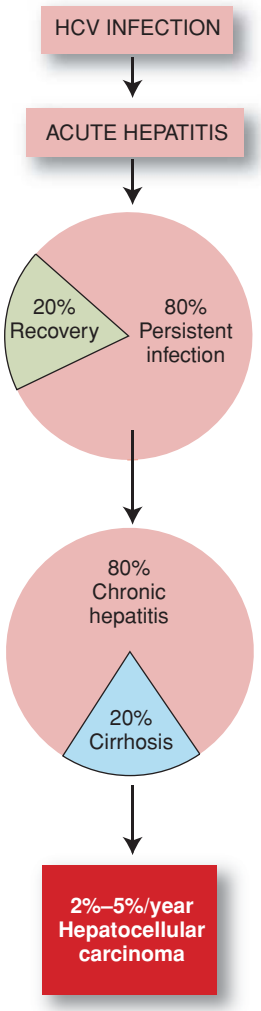

FIGURE 20-27. Outcomes of infection with the hepatitis C virus (HCV).

Liver disease in patients with chronic HCV infection tends to be more severe in the face of concurrent hepatitis B, alcoholic liver disease, hemochromatosis or α_1-antitrypsin (α_1-AT) deficiency. About 25% of patients with advanced alcoholic liver disease have antibodies to HCV, although rates vary in different locales. The relationship is unexplained, and some cases classified as alcoholic cirrhosis may really be due to HCV.

Extrahepatic manifestations of hepatitis C are common and include mixed cryoglobulinemia (see Chapter 20), a systemic vasculitis due to deposition of circulating immune complexes in the microvasculature. The skin (leukocytoclastic vasculitis), salivary glands (sicca syndrome), nervous system (mononeuritis multiplex) and kidney (membranoproliferative glomerulonephritis) may be affected. Non-Hodgkin B-cell lymphomas are more common in patients with chronic hepatitis C.

Since it is largely asymptomatic, acute HCV rarely comes to medical attention. For patients who are treated for acute HCV, success rates are higher than in chronic cases. Chronic hepatitis C is generally treated with a combination of injected interferon-α and oral ribavirin. With genotype 1, 40%–50% of patients eliminate circulating HCV genomes; 75%–80% with genotypes 2 or 3 do the same. Newer therapies including protease and polymerase inhibitors offer even greater promise of effective control of HCV. A sustained virologic response (i.e., no detectable HCV RNA) is associated with a conspicuous decrease in the risk of HCC.

Table 20-3 compares the major features of the common forms of viral hepatitis.

TABLE 20-3
COMPARATIVE FEATURES OF THE COMMON FORMS OF VIRAL HEPATITIS

	Hepatitis A	Hepatitis B	Hepatitis C
Genome	RNA	DNA	RNA
Incubation period	3–6 weeks	6 weeks–6 months	7–8 weeks
Transmission	Oral	Parenteral	Parenteral
Blood	No	Yes	Yes
Feces	Yes	No	No
Vertical	No	Yes	5%
Fulminant	Very rare	Yes	Rare hepatic necrosis
Chronic hepatitis	No	10%	80%
Carrier state	No	Yes	Yes
Liver cancer	No	Yes	Yes

Hepatitis E Virus Is a Major Cause of Epidemic Hepatitis

Hepatitis E is a self-limited, acute, icteric disease similar to hepatitis A. Hepatitis E virus (HEV) is an enteric RNA virus of the Hepeviridae family, four genotypes of which are now known. It accounts for more than 1/2 of cases of acute viral hepatitis in young to middle-aged people in the poorer regions of the world. Large outbreaks have been reported in India, Nepal, Burma, Pakistan, the former Soviet Union, Africa and Mexico. Most of these epidemics have followed heavy rains in areas with inadequate sewage disposal. HEV infection may be transmitted via several routes: waterborne, zoonotic (especially eating raw or undercooked meat of infected wild animals such as pig, boar or deer) and parenteral and vertical transmission. HEV closely resembles a swine virus, suggesting that the latter may represent a reservoir of infection.

The incubation period for HEV is 35–40 days. Jaundice, hepatomegaly, fever and arthralgias are common and usually resolve within 6 weeks, with 1%–12% mortality. Like hepatitis A, clinical illness from hepatitis E is far more common in adults than in children; in the latter, infection may often be subclinical. The disease is very dangerous in pregnant women, in whom mortality may reach 20%–40%. Chronic disease and carrier states are unknown in immunocompetent patients, but immunocompromised people may develop chronic hepatitis E. A successful vaccine against HEV infection has been developed and tested in Nepal but is not yet licensed in the United States.

Other Human Hepatitis Viruses Remain Conjectural

Hepatitis F virus was a hypothetical virus linked to hepatitis, but reports of it in the 1990s were never substantiated. It was consequently disregarded as a cause of viral hepatitis.

Hepatitis G virus (HGV), now more commonly referred as GB virus C (GBV-C), is a lymphotropic flavivirus discovered in 1995 in relation to HCV infection. HGV infection by itself does not cause any known disease; however, several studies found an association between persistent GBV-C infection and improved survival in HIV-positive patients. GBV-C infection may alter T-cell function by modulating chemokine and cytokine release and by reducing T-cell activation, proliferation and apoptosis.

PATHOLOGY OF VIRAL HEPATITIS

All Forms of Acute Viral Hepatitis Are Pathologically Similar

PATHOLOGY: The hallmark of acute viral hepatitis is liver cell death (Fig. 20-28). Within the hepatic lobule, scattered single cell necrosis or death of small clusters of hepatocytes is seen. A few apoptotic liver cells appear as small, deeply eosinophilic bodies **(acidophilic bodies),** sometimes with pyknotic nuclei. Acidophilic bodies are characteristic of viral hepatitis but are also seen in many other liver diseases. In acute viral hepatitis, many liver cells show varying degrees of hydropic swelling and differences in size, shape and staining properties. Concomitantly, regenerative liver cells may have larger nuclei and basophilic cytoplasm. Resulting irregular liver cell plates are described as **lobular disarray**.

Mononuclear cells, mostly lymphocytes, infiltrate lobules diffusely, surround individual necrotic liver cells and accumulate in areas of focal necrosis. Macrophages may be prominent, whereas eosinophils and polymorphonuclear leukocytes are not uncommon. Characteristically, lymphocytes infiltrate between the wall of the central vein and the liver cell plates, an appearance termed **central phlebitis.** Swelling and proliferation of the endothelium of central veins **(endophlebitis)** may develop. Kupffer cells are enlarged, project into sinusoid lumens and contain lipofuscin pigment and phagocytosed debris. Cholestasis is common. If severe, it is called **cholestatic hepatitis,** in which many liver cells are arrayed around dilated bile canaliculi, giving an acinar or glandular appearance. Lumens of dilated canaliculi may contain large bile plugs.

Mononuclear inflammatory cells accumulate within portal tracts. Lymphocytes in portal tracts may form follicles, particularly in hepatitis C. The limiting plate of hepatocytes around the portal tracts is usually intact. These changes are gradually reversed during recovery, and normal hepatic architecture is completely restored.

Confluent Hepatic Necrosis Affects Whole Regions of the Lobule

Confluent hepatic necrosis reflects particularly severe forms of acute viral hepatitis, characterized by death of many hepatocytes in a geographical distribution. In extreme cases, almost all liver cells in a lobule die **(massive hepatic necrosis)**. The most common viral cause is acute hepatitis B; only rarely does confluent hepatic necrosis result from infection with other hepatotropic viruses. The lesions are not unique to viral hepatitis but may also occur after exposure to hepatotoxic chemicals and in autoimmune hepatitis (see below). Unlike most common forms of acute viral hepatitis, in which liver cell necrosis appears to be random and patchy, confluent hepatic necrosis typically affects whole regions of lobules. The lesions of confluent hepatic necrosis, in order of increasing severity, are bridging necrosis, submassive necrosis and massive necrosis.

BRIDGING NECROSIS: At the milder end of the spectrum of lesions that make up confluent hepatic necrosis are bands of necrosis (bridging necrosis) between adjacent portal tracts, between adjacent central veins and from portal tracts to central veins (Fig. 20-29). Adjacent plates of

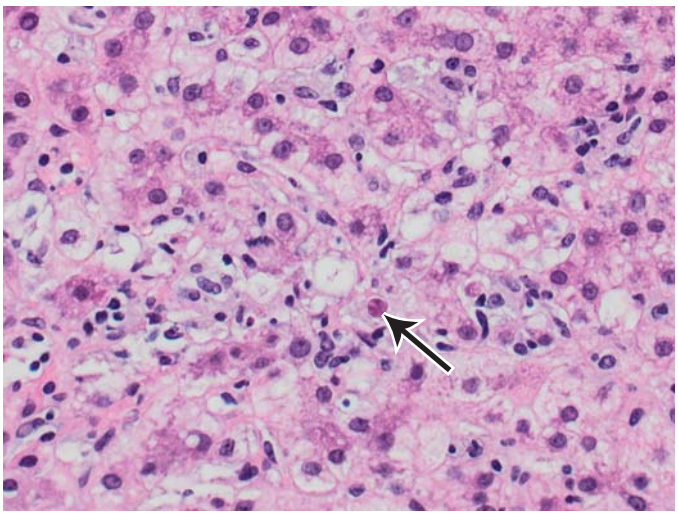

FIGURE 20-28. Acute viral hepatitis. Disarray of liver cell plates, swollen (ballooned) hepatocytes and an infiltrate of lymphocytes and scattered mononuclear inflammatory cells. The remnants of apoptotic hepatocytes have been extruded into the sinusoids, where they appear as acidophilic bodies (*arrow*).

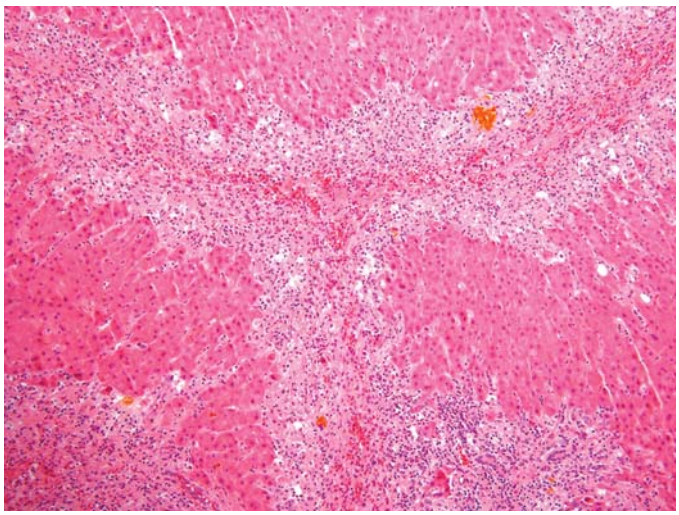

FIGURE 20-29. Confluent hepatic necrosis. Hemorrhagic zones of necrosis bridge adjacent central veins and portal tracts (bridging necrosis).

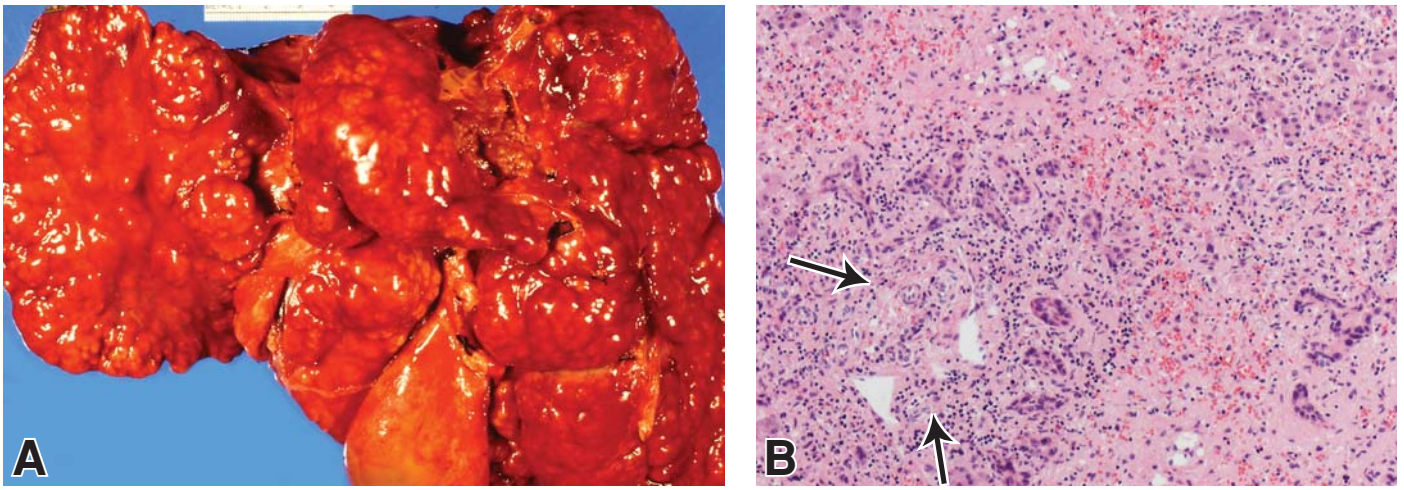

FIGURE 20-30. Massive hepatic necrosis. A. The liver is soft and reduced in size and shows a mottled, yellowish surface ("acute yellow atrophy"). **B.** Complete loss of the hepatocytes. The framework of the lobule has collapsed. The portal tracts (*arrows*) are expanded and contain ductular reaction.

hepatocytes die, causing collapse of the collagenous stroma to form bands of connective tissue. These are best seen with a reticulin stain. If such bands encircle an area of liver cells, they may impart a nodular appearance, as in cirrhosis.

SUBMASSIVE HEPATIC NECROSIS: This form of acute hepatitis defines an even more severe injury in which entire lobules or groups of adjacent lobules die. Clinically, these patients manifest severe hepatitis, which may rapidly proceed to hepatic failure, in which case the disease is classed clinically as **fulminant hepatitis**.

MASSIVE HEPATIC NECROSIS (ACUTE YELLOW ATROPHY): Massive hepatic necrosis, the most feared form of acute viral hepatitis, is fortunately rare. It is almost invariably fatal. Grossly, the liver is shrunken to as little as 500 g (1/3 of normal weight). The capsule is wrinkled, with mottled, soft and flabby red-tan parenchyma. Virtually all hepatocytes are dead (Fig. 20-30), and only the collagenous frameworks remain as epitaphs of liver lobules that collapsed and perished. Macrophages, erythrocytes and necrotic debris fill sinusoids. For unknown reasons, the massive necrosis does not elicit a vigorous inflammatory response in either the parenchyma or portal tracts. Liver transplantation is a mainstay of therapy.

Chronic Hepatitis May Complicate Hepatitis B and C, Metabolic Diseases and Immune Disorders

The morphologic spectrum of chronic hepatitis ranges from mild portal inflammation with little or no liver cell necrosis (Fig. 20-31) to widespread inflammation, necrosis and fibrosis eventuating in cirrhosis (Fig. 20-32).

PORTAL TRACT LESIONS: In chronic hepatitis, portal tracts are variably infiltrated by lymphocytes, plasma cells and macrophages (Figs. 20-31 and 20-32). These expanded portal tracts often show mild to severe proliferation of bile ductules, which is a nonspecific response to chronic liver injury. In the case of chronic hepatitis C, lymphoid aggregates or follicles with reactive centers are often present.

PIECEMEAL NECROSIS: Piecemeal necrosis is focal inflammatory destruction of the limiting plate of hepatocytes. A periportal chronic inflammatory infiltrate creates an irregular border between portal tracts and the lobular parenchyma (Fig. 20-32A).

INTRALOBULAR LESIONS: Focal necrosis and parenchymal inflammation typify chronic hepatitis. Scattered acidophilic bodies and enlarged Kupffer cells are common (Fig. 20-28). In chronic hepatitis B, scattered hepatocytes may show large granular cytoplasm with abundant HBsAg **(ground-glass hepatocytes)** (Fig. 20-33).

PERIPORTAL FIBROSIS: Progressive loss of periportal hepatocytes by piecemeal necrosis leads to deposition of collagen, giving portal tracts a stellate (star-shaped) appearance. In time, fibrosis may join adjacent portal tracts or approach the central vein, ultimately developing into cirrhosis (Fig. 20-32B).

AUTOIMMUNE HEPATITIS

Autoimmune hepatitis is a severe type of chronic hepatitis associated with circulating autoantibodies and elevated serum immunoglobulins. The disorder may appear at any

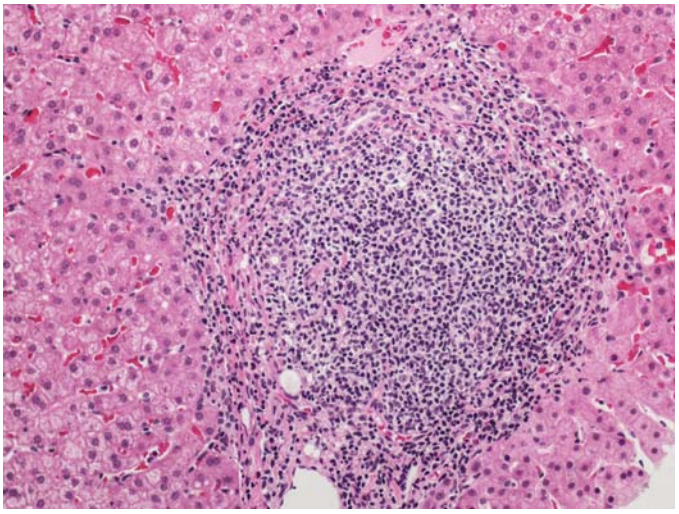

FIGURE 20-31. Mild chronic hepatitis. A portal tract infiltrated by mononuclear inflammatory cells. The lobular parenchyma is intact. Nonzonal or periportal mild fatty change often accompanies hepatitis C.

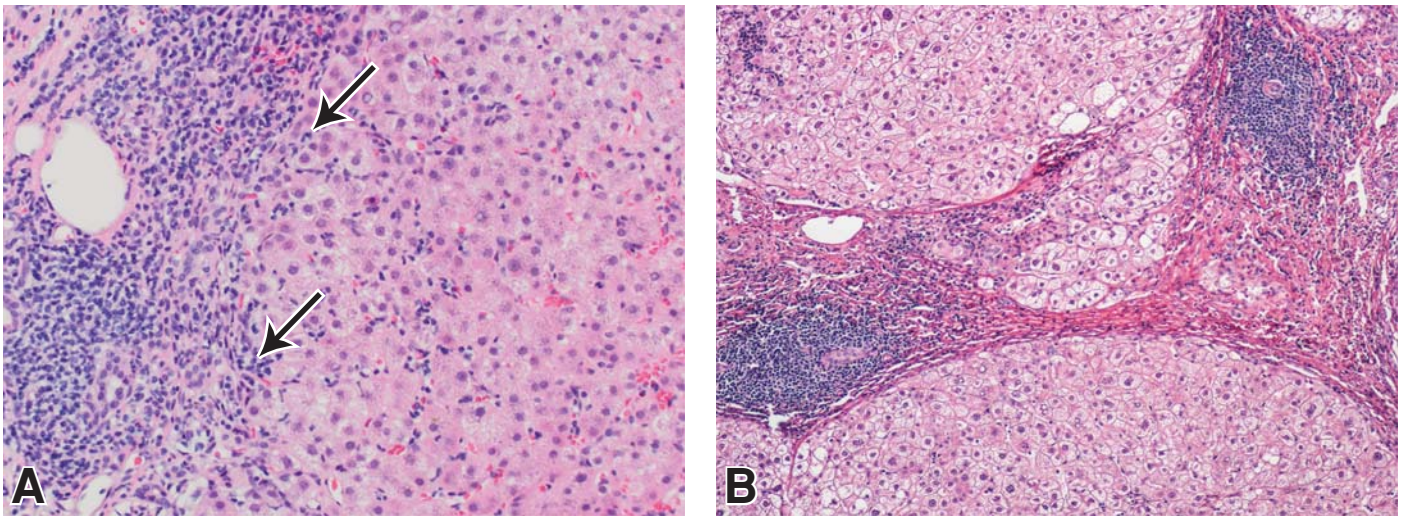

FIGURE 20-32. Severe chronic hepatitis. A. Mononuclear inflammatory infiltration in an expanded portal tract (*left*). Interface hepatitis is penetration of inflammation to the limiting plate and surrounds groups of hepatocytes at the border of the portal tract (*arrows*). **B. Chronic hepatitis with cirrhosis.** A liver from a patient with long-standing chronic hepatitis C shows lymphocytic aggregates, bridging fibrosis and nodular transformation.

age; 70% of cases occur in women. In the United States, autoimmune hepatitis affects up to 200,000 people and accounts for 6% of liver transplants.

PATHOPHYSIOLOGY: There are two types of autoimmune hepatitis:

- **Type I** disease is more common (80% of cases). It features antinuclear and anti–smooth muscle antibodies. Some 70% of cases occur in women younger than 40 years, among whom 1/3 have other autoimmune diseases, including thyroiditis, rheumatoid arthritis and ulcerative colitis. Of those patients with type I autoimmune hepatitis, 1/4 present with cirrhosis, indicating that the disease usually has a prolonged asymptomatic course. There are antibodies against many cytosolic enzymes, but the hepatocyte membrane asialoglycoprotein receptor is the main candidate target for antibody-dependent cell-mediated cytotoxicity (ADCC). The HLA-*DRB1* gene confers particular susceptibility to type I autoimmune hepatitis. Some patients may present with a poorly characterized "overlap syndrome" with mixed clinical and histologic features of autoimmune hepatitis and either primary biliary cirrhosis (PBC) or PSC.
- **Type II** autoimmune hepatitis occurs mainly in children who are 2–14 years old. Antibodies against liver and kidney microsomes (anti-LKM) are characteristic. However, the key autoantigen is a P450-type drug-metabolizing enzyme (CYP 2D6). These patients often have other autoimmune diseases (i.e., type I diabetes and thyroiditis). Genetic determinants of type II disease are not defined.

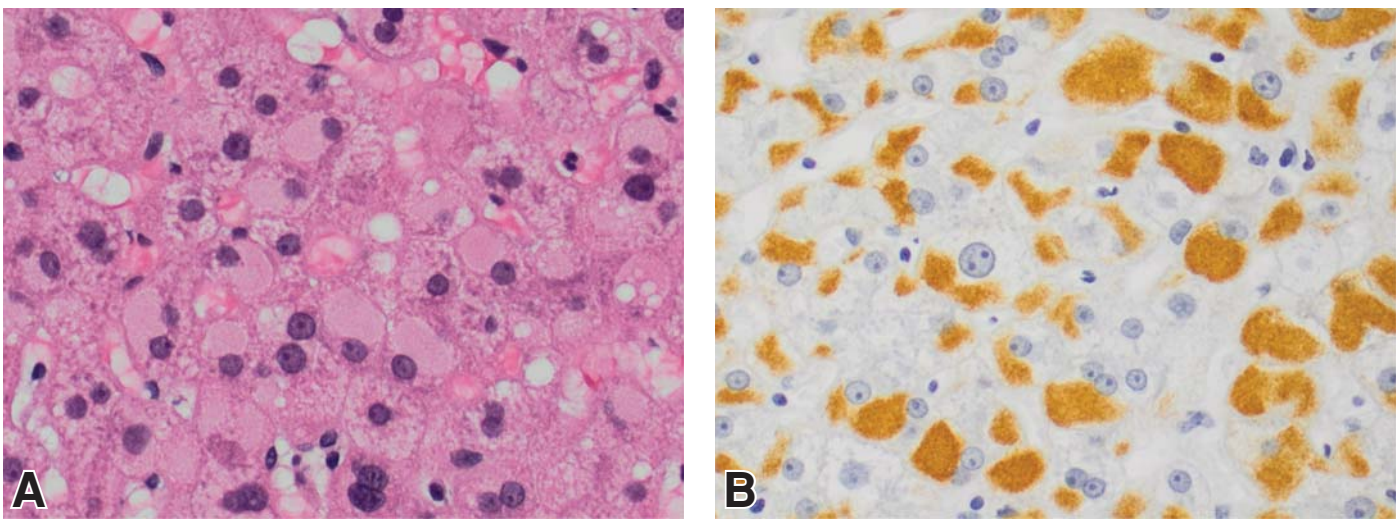

FIGURE 20-33. "Ground-glass" hepatocytes. A. Liver from a patient with chronic hepatitis B shows scattered hepatocytes (*arrow*) with an abundant granular cytoplasm containing hepatitis B surface antigen (HBsAg). **B.** The same specimen has been stained for HBsAg by the immunoperoxidase method. The abundant cytoplasmic HBsAg appears brown.

PATHOLOGY: Autoimmune hepatitis basically resembles acute and chronic viral hepatitis histologically, but lobular inflammation and necrosis are more pronounced. The inflammatory infiltrate is rich in plasma cells, an important diagnostic feature. Confluent hepatic necrosis may be seen in severe acute cases.

CLINICAL FEATURES: Autoimmune hepatitis can arise insidiously, with fatigue and mild right upper quadrant discomfort. Often, there is a personal or family history of autoimmunity. With time, aminotransferase levels rise markedly and may exceed 1000 IU/mL. Marked hyperglobulinemia is common. In severe cases, jaundice, hepatic synthetic dysfunction and even liver failure ensue, but it rarely presents as fulminant disese. Untreated, autoimmune hepatitis often progresses to cirrhosis.

Autoimmune hepatitis usually responds to combinations of corticosteroids and immunosuppressants such as azathioprine. Patients whose disease progresses to cirrhosis may receive liver transplants. Autoimmune hepatitis recurs in up to 20% of patients after liver transplantation.

ALCOHOLIC LIVER DISEASE

The harmful effects of excess alcohol (ethanol, ethyl alcohol) consumption have been recognized almost since the dawn of recorded history. The prophet Isaiah warned, "Woe to him that is mighty to drink wine." Ethanol is now seen as a hepatotoxin that acts both directly and indirectly.

EPIDEMIOLOGY: ***Alcoholic cirrhosis is most common in countries where people consume the most alcohol,*** regardless of the specific alcoholic beverage (e.g., wine in France, beer in Australia, spirits in Scandinavia). Only a minority of chronic alcoholics develop cirrhosis, but there is a dose-response relationship between lifetime dose of alcohol (duration of exposure and daily amount of alcohol consumed) and the appearance of cirrhosis.

About 10% of men and 5% of women in the United States abuse alcohol. In some other countries, this figure is much higher. ***Some 15% of alcoholics develop cirrhosis; many of them die in hepatic failure or from extrahepatic complications of cirrhosis.*** In many urban areas of the United States with high alcoholism rates, cirrhosis of the liver is the third or fourth leading cause of death in men younger than 45 years.

The amount of alcohol required to produce chronic liver disease depends on body size, age, gender and ethnicity, but the lower range seems to be about 20 g/day (about 2 ounces of 86 proof [43%] whiskey, two glasses of wine or two 12-ounce bottles of beer daily) for women and 40 g/day in men. In general, more than 10 years of alcohol use at this level is needed to produce cirrhosis, although a few cirrhotic patients give shorter histories of heavy alcohol use.

Women are more predisposed to the harmful effects of alcohol, for unknown reasons. However, women metabolize alcohol differently and have lower body masses.

The epidemiology of alcoholic liver disease is complicated by its association with the hepatotropic viruses. HBV seropositivity is two- to fourfold more common in alcoholics than in control populations. The prevalence of anti-HCV antibodies is up to 10% among alcoholics and is even higher among alcoholics with chronic liver disease. As noted above, people who abuse alcohol and also have hepatitis C are more likely to develop liver disease than their counterparts not so infected.

Ethanol Is Mainly Metabolized in the Liver

Ethanol is rapidly absorbed from the stomach and eventually distributed in body water space. Between 5% and 10% is excreted unchanged, mostly in the urine and expired breath. The remaining 90% is metabolized by the liver to acetaldehyde and acetate, largely by cytosolic **alcohol dehydrogenase (ADH)**. The mixed-function oxidases in the **microsomal ethanol-oxidizing system** in the SER are a minor metabolic pathway for alcohol. Clearance of alcohol from the body, unlike most drugs, is linear—that is, a fixed quantity is metabolized per unit time. Roughly, for the average man, 7–10 g of alcohol is eliminated per hour. However, since the microsomal pathway (see above) is upregulated in chronic alcoholics, they metabolize ethanol more rapidly, as long as they do not suffer from active liver disease.

Alcohol Consumption Causes a Spectrum of Liver Diseases

Alcoholic liver disease spans three major morphologic and clinical entities: **fatty liver, acute alcoholic hepatitis** and **cirrhosis**. These lesions usually occur in sequence, but they may coexist in any combination and may actually be independent entities.

Fatty Liver

MOLECULAR PATHOGENESIS: Virtually all chronic alcoholics, regardless of their pattern of drinking, accumulate fat in hepatocytes **(steatosis)**. The relative contributions of different metabolic pathways to steatosis may depend on the amount of alcohol consumed, dietary lipid content, body stores of fat, hormonal status and other variables. ***Still, accumulation of fat clearly depends on alcohol intake, as it is fully and rapidly reversible if alcohol ingestion stops.***

Dietary fat, as chylomicrons and free fatty acids, is transported to the liver, where it is taken up by hepatocytes. Triglycerides are then hydrolyzed to free fatty acids. These, in turn, undergo β-oxidation in mitochondria or are converted by the ER to triglycerides. These newly synthesized triglycerides are secreted as lipoproteins or are retained for storage.

Most of the fat deposited in the liver after chronic alcohol consumption is from the diet. Ethanol increases lipolysis and thus delivery of free fatty acids to the liver. Within hepatocytes, ethanol (1) increases fatty acid synthesis, (2) decreases mitochondrial oxidation of fatty acids, (3) raises triglyceride production and (4) impairs release of lipoproteins. Collectively, these metabolic consequences produce a fatty liver.

PATHOLOGY: In the setting of high alcohol intake, the liver becomes yellow and enlarged, sometimes to as much as three times its normal weight. This increased weight does not only reflect fat accumulation; protein and water content also increase. The extent of visible fat accumulation varies from minute droplets scattered in the cytoplasm of a few hepatocytes to distention of

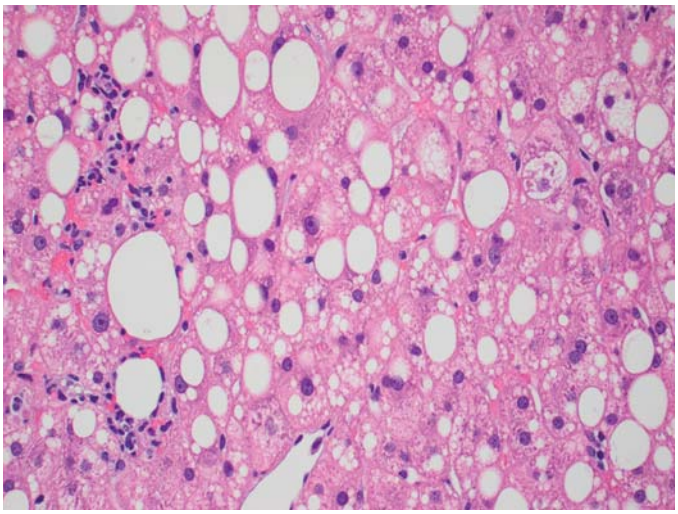

FIGURE 20-34. Alcoholic fatty liver. The cytoplasm of almost all of the hepatocytes distended by fat that displaces the nucleus to the periphery.

the entire cytoplasm of most cells by coalesced droplets (Fig. 20-34). In the latter case, liver cells may be barely recognizable as such and resemble adipocytes, with their cytoplasm distended by a clear area and their nuclei flattened and displaced to the periphery of the cell.

Ultrastructurally, hepatocytes in alcohol-induced fatty livers reflect the cytotoxicity of ethanol rather than an effect of fat. Mitochondria are enlarged, with occasional bizarre giant forms. The SER is hyperplastic, resembling that produced by other inducers of microsomal drug-metabolizing enzymes (see Chapter 1).

Chronic ethanol ingestion elicits pronounced hepatic functional alterations. Liver mitochondria show decreased rates of substrate oxidation (e.g., of fatty acids) and impaired ATP formation. SER hyperplasia is accompanied by increased activity of the cytochrome P450–dependent mixed-function oxidases. Not only is the microsomal ethanol-oxidizing system induced, but metabolism of a variety of drugs is also enhanced. ***This increased microsomal function also augments metabolism of hepatic toxins, thus exaggerating the danger of agents such as acetaminophen, in which it is the drug's metabolic products that are most toxic.*** Whereas chronic alcohol consumption promotes microsomal functions, acute alcohol ingestion inhibits mixed-function oxidases and acutely reduces the rate of clearance of drugs from the body.

CLINICAL FEATURES: Patients with uncomplicated alcoholic fatty liver have surprisingly few symptoms of liver disease. Despite the striking morphologic change in the liver, alcoholic fatty liver is fully reversible and does not by itself progress to more severe disease. The best treatment for fatty liver due to alcohol is abstinence. Fatty liver, although characteristic of alcoholism, is not limited to it. Fatty liver may also be seen in nonalcoholic fatty liver disease (NAFLD; see below), hepatitis C, after certain drugs and in many other conditions.

Alcoholic Hepatitis

Alcoholic hepatitis is characterized by (1) hepatocyte necrosis, mainly in the central zone; (2) cytoplasmic hyaline inclusions within hepatocytes (Mallory bodies); (3) an acute inflammatory infiltrate in the lobule and (4) perivenular fibrosis (Fig. 20-35). **The pathogenesis of alcoholic hepatitis is a mystery.** Alcoholics may have mild fatty liver for many years and, without any change in drinking habits, suddenly develop acute alcoholic hepatitis. It may be that long-standing, subclinical alcoholic hepatitis precedes clinically overt hepatitis. Nevertheless, the often explosive presentation of alcoholic hepatitis suggests that some environmental or physiologic cofactor is involved, although none has been identified.

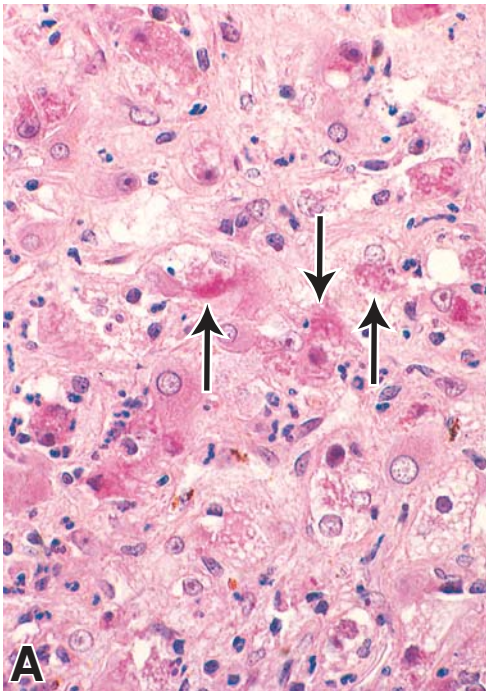
PATHOLOGY: Typically, hepatic architecture is intact. Hepatocytes show variable hydropic swelling, giving them a heterogeneous appearance. Isolated necrotic liver cells or clusters of them have pyknotic nuclei and show karyorrhexis. Scattered hepatocytes contain **Mallory bodies (alcoholic hyaline)** (Fig. 20-35). These cytoplasmic inclusions are more common in visibly damaged, swollen hepatocytes and appear as irregular skeins of eosinophilic material or as solid eosinophilic masses, often perinuclearly. They are aggregates of intermediate (cytokeratin) filaments (Fig. 20-35C). The damaged, ballooned hepatocytes, particularly those with Mallory bodies, are surrounded by neutrophils. A more diffuse, intralobular inflammatory infiltrate is also present. Mallory bodies are characteristic of, but not specific for, alcoholic liver disease, as they may also be present in NASH, chronic cholestatic syndromes, WD and HCC. Mild to severe cholestasis is seen in up to 1/3 of cases. Alcoholic hepatitis is usually superimposed on an existing fatty liver, but there is no evidence that fat accumulation predisposes or contributes to development of alcoholic hepatitis.

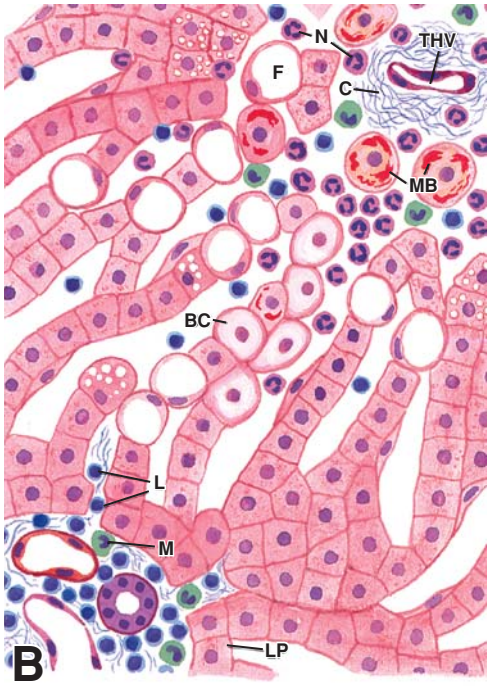
Collagen deposition is always seen in alcoholic hepatitis, especially around central veins (terminal hepatic venules). Chronic alcohol exposure activates hepatic stellate cells to deposit intrasinusoidal collagen. In severe cases, venules and perivenular sinusoids are obliterated and surrounded by dense fibrous tissue to yield **central hyaline sclerosis** (Figs. 20-35 and 20-36). This condition is often associated with noncirrhotic portal hypertension.

Portal tracts in alcoholic hepatitis are highly variable. Some are virtually normal, whereas others are enlarged, with a mononuclear infiltrate and proliferated bile ductules. The altered portal tracts often show spurs of fibrous tissue that penetrate the lobules.

CLINICAL FEATURES: Patients with alcoholic hepatitis have malaise and anorexia, fever, right upper quadrant abdominal pain and jaundice. Leukocytosis is common. Serum aminotransferases, particularly AST, are moderately elevated but not as high as in viral hepatitis: AST usually remains under 400. The AST:ALT ratio is typically 2:1. Serum alkaline phosphatase is usually increased. In severe cases, a prolonged prothrombin time often portends an ominous prognosis.

The outlook in patients with alcoholic hepatitis reflects the severity of liver cell injury. In some patients, the disease progresses rapidly to hepatic failure and death. Mortality in the acute stage of alcoholic hepatitis is about 10%. Most of those who abstain from alcohol after recovery from acute alcoholic hepatitis recover. However, of those who continue to drink, up to 70% ultimately develop cirrhosis.





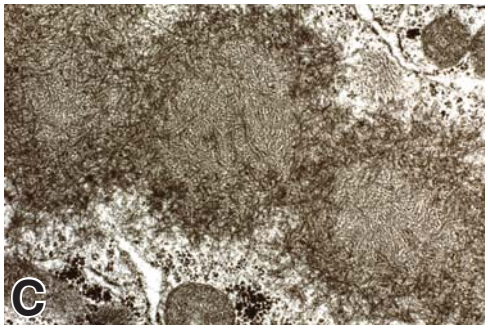


FIGURE 20-35. Alcoholic hepatitis. A. Necrosis and degeneration of hepatocytes, Mallory-Denk bodies (eosinophilic inclusions) in the cytoplasm of injured hepatocytes (*arrows*) and infiltration by neutrophils. **B. Schematic representation of the major pathologic features of alcoholic hepatitis.** The lesions are predominantly centrilobular and include necrosis and loss of hepatocytes, ballooned cells (*BC*) and Mallory-Denk bodies (*MB*) in the cytoplasm of damaged hepatocytes. The inflammatory infiltrate consists predominantly of neutrophils (*N*), although a few lymphocytes (*L*) and macrophages (*M*) are also present. The central venule, or terminal hepatic venule (*THV*), is encased in connective tissue (*C*) (central hyaline sclerosis; also see Fig. 14–36). Fat-laden hepatocytes (*F*) are evident in the lobule. The portal tract displays moderate chronic inflammation, and the limiting plate (*LP*) is focally breached. **C. Ultrastructure of Mallory-Denk bodies.** Dense, interwoven bundles of cytokeratin filaments are in the cytoplasm of hepatocytes.

There is no specific treatment for acute alcoholic hepatitis. Corticosteroids improve short-term mortality and thus are often given if there is no infection or renal failure. Nutritional therapy can be beneficial.

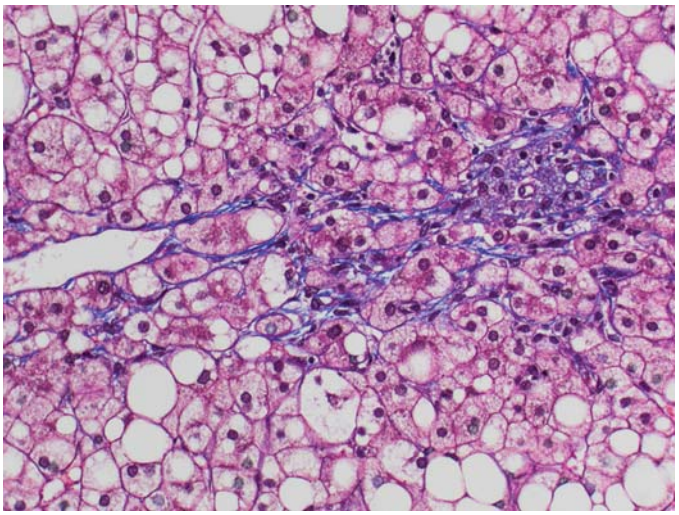

FIGURE 20-36. Pericellular fibrosis in nonalcoholic steatohepatitis (NASH). This trichrome stained liver from a patient with NASH shows pericellular fibrosis around the central venule (*blue*). Note the macrovesicular fat. This lesion mimics that seen in alcoholic liver disease.

Alcoholic Cirrhosis

In about 15% of alcoholics, hepatocellular necrosis, fibrosis and regeneration eventually lead to formation of fibrous septa around hepatocellular nodules (Fig. 20-13). The other lesions of alcoholic liver disease—fatty liver and acute or persistent alcoholic hepatitis—are often seen in conjunction with cirrhosis. Some assert that progression to alcoholic cirrhosis requires at least subclinical alcoholic hepatitis. Activated hepatic stellate cells, which produce perisinusoidal collagen, probably contribute to the development of cirrhosis. The prognosis in cases of established alcoholic cirrhosis is much better in those who abstain from alcohol. Nevertheless, many patients progress to end-stage liver disease, and alcoholic liver disease is a common indication for liver transplantation.

NONALCOHOLIC FATTY LIVER DISEASE

NAFLD is so named because of its close resemblance to alcoholic liver disease. It represents diverse liver injuries

from simple steatosis, with or without associated hepatitis (NASH) to bridging fibrosis and cirrhosis. Risk factors for NAFLD include obesity, type 2 diabetes mellitus, hyperlipidemia and metabolic syndrome (see Chapter 22). About 1/2 of people with both severe obesity and diabetes have NASH, of whom up to 1/5 develop cirrhosis.

NAFLD overlaps alcoholic liver disease histologically, with steatosis, lobular and portal inflammation, hepatocyte necrosis, Mallory-Denk bodies and fibrosis. As in alcoholic liver disease, centrilobular fibrosis is common (Fig. 20-36). If cirrhosis develops, steatosis often disappears. ***Thus, NAFLD is the likely cause of many cases of so-called cryptogenic cirrhosis.***

PATHOPHYSIOLOGY: The pathogenesis of NAFLD and NASH may overlap that of alcoholic hepatitis. Insulin resistance is associated with increased hepatic mitochondrial oxidation of free fatty acids, increased oxidative stress and lipid peroxidation, and it appears to be the strongest risk factor for NAFLD and NASH. Progression to cirrhosis in NAFLD is often insidious, and many patients remain asymptomatic, with only moderate increases in serum liver enzyme activities.

NAFLD is considered the hepatic manifestation of the metabolic syndrome, which consists of abdominal obesity, dyslipidemia, insulin resistance and hypertension (see Chapter 13). Weight reduction, including that via bariatric surgery, tends to improve NAFLD and NASH, but no definitive treatment is yet available.

PRIMARY BILIARY CIRRHOSIS

PBC is an immune-mediated, chronic, progressive cholestatic disease in which intrahepatic bile ducts are destroyed **(nonsuppurative destructive cholangitis)**. Loss of bile ducts leads to impaired bile secretion, cholestasis and hepatic damage. PBC occurs mainly in middle-aged women (10:1 female predominance). The term *cirrhosis* in this context is somewhat misleading, as it is actually a late complication of the disease.

PBC accounts for up to 2% of deaths from cirrhosis. Cases are sporadic, although the prevalence of PBC in families of patients with PBC is considerably higher than that in the general population, suggesting a hereditary predisposition.

MOLECULAR PATHOGENESIS: PBC is associated with many immune abnormalities and thus is widely held to be an autoimmune disease. Most (85%) patients have at least one other autoimmune disease (chronic thyroiditis, rheumatoid arthritis, scleroderma, Sjögren syndrome, systemic lupus erythematosus), and almost 1/2 (40%) have two or more such diseases.

The *DRB1*008* family of major histocompatibility complex–encoded genes is associated with PBC, whereas the disease is less common in people carrying *DRB1*11* and *DRB1*13.* Polymorphisms of key immune regulatory genes, such as those encoding TNF-α and the CTL antigen 4 (CTLA4), are reported in patients with several autoimmune diseases, including PBC. Increased X chromosome monosomy may explain the strong female predominance of PBC.

PATHOPHYSIOLOGY: Humoral and cellular immunity are both impaired. Serum immunoglobulin levels are increased, especially IgM. ***More than 95% of patients have circulating antimitochondrial antibodies (AMAs), a finding of which is commonly used to diagnose PBC.*** Autoantibodies bind epitopes associated with the mitochondrial pyruvate dehydrogenase complex. Despite their specificity, AMAs do not affect mitochondrial function and play no known role in the pathogenesis or progression of the disease. Other circulating autoantibodies are antinuclear, antithyroid, antiplatelet, antiacetylcholine receptor and antiribonucleoprotein antibodies. The complement system is also chronically activated.

The cells surrounding and infiltrating the sites of bile duct damage are mostly suppressor/cytotoxic ($CD8^+$) lymphocytes, suggesting that they mediate the destruction of the ductal epithelium.

PATHOLOGY: Pathologic stages of PBC are portal stage, periportal stage, septal stage and biliary cirrhosis.

- ***STAGE 1: FLORID DUCT LESION OR PORTAL STAGE:*** Early PBC features a unique lesion, a **chronic destructive cholangitis** involving small and medium-sized intrahepatic bile ducts. Injury to the ducts is segmental and thus appears focal in tissue sections. Lymphocytes, plasma cells and macrophages surround the ducts, disrupting the basement membrane (Fig. 20-37). Bile duct epithelium is irregular and hyperplastic, with stratification and occasional papillary ingrowths of epithelial cells. Epithelioid granulomas often occur in portal tracts and may impinge on the bile ducts.
- ***STAGE 2: PERIPORTAL STAGE:*** Bile ducts are reduced in number and ductular proliferation is evident in periportal areas. Inflammation is less than in stage 1.
- ***STAGE 3: SEPTAL STAGE:*** As a result of the destructive inflammation in stages 1 and 2 PBC, small bile ducts virtually disappear. Scarring of medium-sized bile ducts is

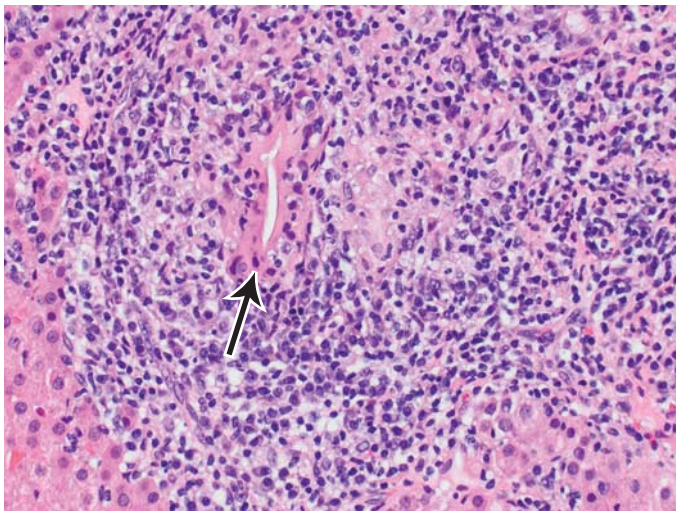

FIGURE 20-37. Florid duct lesion in primary biliary cirrhosis (PBC), stage I. A portal tract expanded by an inflammatory infiltrate consisting of lymphocytes, plasma cells, eosinophils and macrophages. Florid duct lesion represents a damaged bile duct (*arrow*) by the inflammation.

common. Collagenous septa extend from the portal tracts into the lobular parenchyma and begin to encircle some lobules.

- ***STAGE 4: CIRRHOSIS:*** The end stage of PBC is cirrhosis, with a dark-green bile-stained nodular liver with mainly portal-to-portal bridging fibrous septa. This fibrosis gives a "jigsaw puzzle" appearance to the cirrhotic nodules. Small bile ducts are scarce, and medium-sized ducts are conspicuously fewer in number. There is little inflammation within either the fibrous septa or the parenchymal nodules.

CLINICAL FEATURES: ***Some 90%–95% of those afflicted with PBC are women, usually those who are 30–65 years old.*** Fatigue and pruritus are the most common initial symptoms, but many patients have no symptoms during the early stage of PBC. Some remain asymptomatic and appear to have an excellent prognosis; others ultimately develop advanced cirrhosis and its complications. The diagnosis of PBC is confirmed when a patient meets two of three criteria: (1) AMA titer of 1:40 or higher; (2) biochemical cholestasis, as indicated by elevated serum alkaline phosphatase for at least 6 months and (3) typical liver histology. The unusual diagnosis of so-called AMA-negative PBC rests on characteristic histologic and clinical findings (criteria 2 and 3).

Early in PBC, serum alkaline phosphatase is usually high, but bilirubin is normal or slightly elevated. The patient may complain of severe pruritus. As the disease advances, serum bilirubin progressively increases in most patients. Serum AST and ALT are only moderately elevated. Blood cholesterol levels increase strikingly, and an abnormal lipoprotein (lipoprotein-X) appears, a finding in many forms of chronic cholestasis. Cholesterol-laden macrophages accumulate in subcutaneous tissues, where they form localized lesions termed **xanthomas**. Impaired bile excretion into the intestine often leads to severe **steatorrhea** due to fat malabsorption. Associated malabsorption of vitamin D and calcium leads to **osteomalacia** and **osteoporosis,** two important complications of PBC. About 1/3 of patients develop gallstones. Those patients who eventually develop cirrhosis die of liver failure or complications of portal hypertension.

PBC is treated with UDCA, which increases transplant-free survival and leads to biochemical remission in about 40% of patients. The course of PBC is usually indolent and may be as long as 20–30 years. Liver transplantation is highly effective in end-stage PBC.

PRIMARY SCLEROSING CHOLANGITIS

PSC is a chronic cholestatic liver disease of unknown etiology, in which inflammation and fibrosis narrow and then obstruct intrahepatic and extrahepatic bile ducts. It usually occurs in men (70%), with a mean age of 40 years. PSC prevalence is 14 cases per 100,000 population. Progressive biliary obstruction typically leads to persistent obstructive jaundice, recurrent cholangitis and eventually to secondary biliary cirrhosis.

PATHOPHYSIOLOGY: ***The cause of PSC is unknown, but 2/3 of patients also have ulcerative colitis.*** A few cases have been described in patients with Crohn disease of the colon. Associations with retroperitoneal fibrosis, lymphoma and the fibrosing variant of chronic thyroiditis (Riedel struma) are also reported. In 1/4 of cases, no other disease is present. Increased colonic permeability to bacteria has been suggested as a factor, but this possibility remains speculative.

Genetic and immunologic factors are implicated in the pathogenesis of PSC. PSC can occur in families, sometimes associated with certain HLA haplotypes, including HLA B8. Hypergammaglobulinemia is common, as are circulating immune complexes and antineutrophil cytoplasmic antibodies (perinuclear or P-ANCAs), and complement activation by the classic pathway. Portal tracts contain an increased number of T cells.

PATHOLOGY: The pathology of PSC liver disease has four stages:

- ***STAGE 1: PORTAL STAGE:*** At first, there is periductal inflammation and "concentric, onion skin" fibrosis in the portal tracts (Fig. 20-38A).

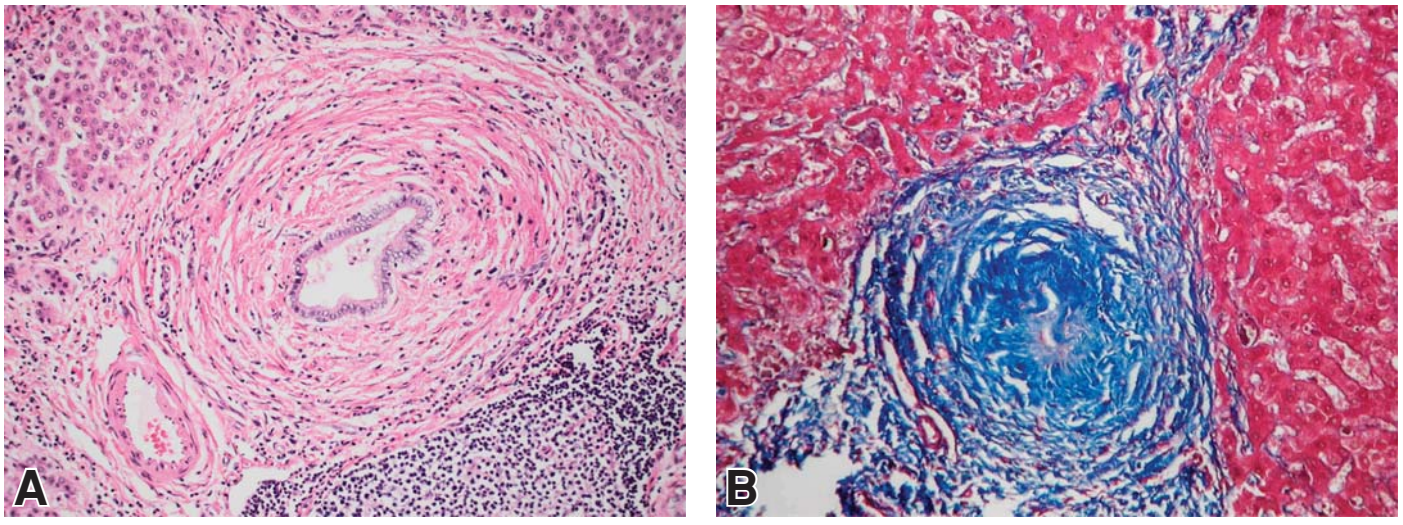

FIGURE 20-38. Primary sclerosing cholangitis (PSC). A. An inflammed portal tract with a dilated bile duct and "onion skin" periductal fibrosis. **B.** A bile duct scar represents a destroyed bile duct in PSC (trichrome stain).

- ***STAGE 2: PERIPORTAL STAGE:*** Many bile ducts become obliterated (Fig. 20-38B), portal fibrosis with fibrous septa extends into the parenchyma.
- ***STAGE 3: SEPTAL STAGE:*** Bridging fibrosis.
- ***STAGE 4: CIRRHOSIS:*** Secondary biliary cirrhosis eventuates (Fig. 20-38B).

Similar inflammatory and fibrotic changes may be seen in large intrahepatic and extrahepatic bile ducts, and these changes can obstruct both. The disease tends to be segmental; thus, the intrahepatic biliary tree shows a characteristic beaded appearance with contrast radiography. The same inflammatory process affects the gallbladder wall. Some patients with typical clinical features of PSC have normal-appearing bile ducts on cholangiography, in which case the condition is termed *small duct PSC.*

CLINICAL FEATURES: The median survival in symptomatic patients with PSC is 8–9 years. Asymptomatic patients have a better prognosis. Clinical presentations vary from asymptomatic elevations in cholestatic liver tests to symptoms of biliary obstruction, recurrent cholangitis and evidence of end-stage liver disease. Infection may lead to abscess formation. ***Cholangiocarcinoma develops in up to 20% of patients with PSC.*** Liver transplantation may be curative; however, PSC often recurs in the transplanted liver.

IRON OVERLOAD SYNDROMES

In several conditions, excessive iron accumulates in the body (siderosis). There are two major groups of iron overload syndromes, divided on the basis of etiology. **Hereditary hemochromatosis (HH)** is caused by a common genetic alteration in control of intestinal iron absorption. **Secondary iron overload** complicates certain hematologic disorders. It entails parenteral iron overload, in which the iron accrues due to multiple blood transfusions or parenteral administration of iron itself, or is caused by huge dietary intake of iron. Secondary iron overload alone rarely causes liver disease.

Body Iron Stores Are Tightly Regulated

An understanding of normal iron metabolism is central to an appreciation of the pathophysiology of diseases of iron overload, such as HH. The normal total body content of iron is 3–4 g. Most of this (about 2.5 g) is bound up in hemoglobin. Iron normally enters the body by being absorbed through the duodenal mucosa. There is no mechanism for iron excretion: men and postmenopausal women eliminate 1–2 mg daily in desquamated cells. Therefore, keeping body iron within acceptable limits requires strict control of intestinal iron uptake (Fig. 20-39).

Several principal proteins control this process:

- **Hepcidin:** This 25 amino acid peptide is manufactured and exported by the liver and is the key to iron regulation. Hepcidin blocks transit of iron through enterocytes to the blood and inhibits its secretion from stores in hepatocytes and macrophages. It does this by binding the main iron export channel in these cells, **ferroportin,** and promoting its degradation.

  Control of hepcidin levels is thus central to iron homeostasis. Hepcidin synthesis is stimulated when body iron stores are sufficient and is downregulated when the body needs more iron. Upregulation of hepcidin requires several important proteins. This group of proteins—transferrin receptor 2 (TfR2), hemojuvelin and HFE—are all necessary to stimulate hepcidin production. Interestingly, hepcidin is also an acute phase reactant and is upregulated by the pro-inflammatory cytokine, IL-6 (see below). Other factors, such as bone morphogenesis proteins, increase hepcidin levels in ways that are not

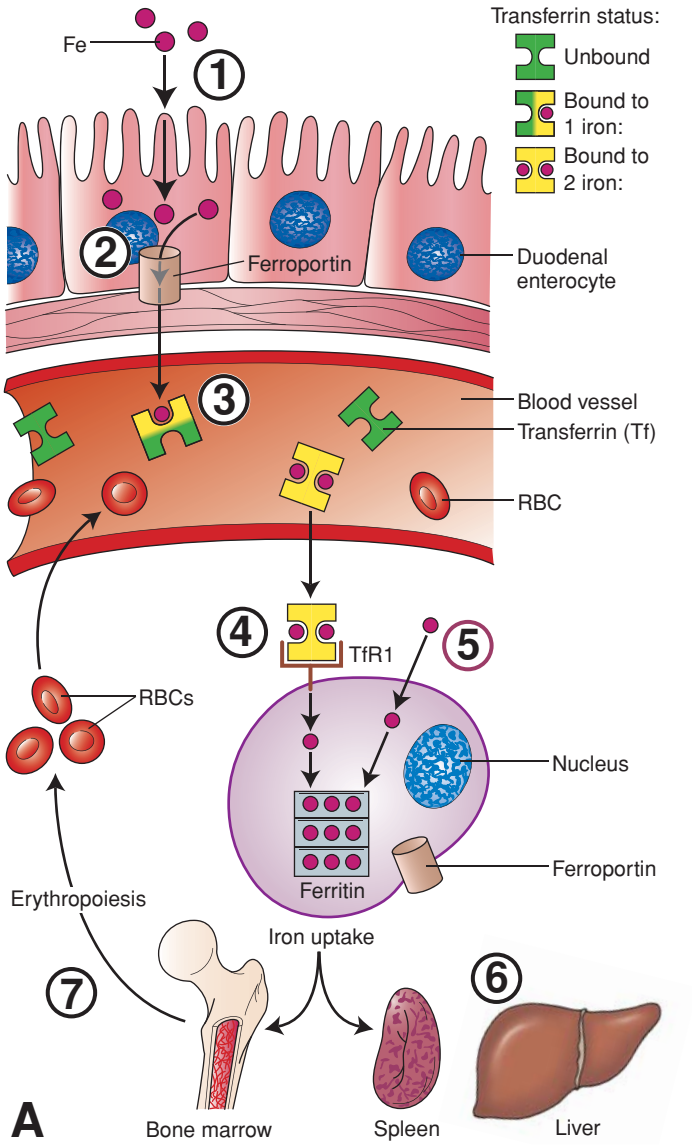

FIGURE 20-39. Normal iron metabolism and the role of hepcidin in its regulation. A. Iron absorption and utilization. 1. Iron enters duodenal enterocytes. These cells have a specific transporter that mediates iron entry. 2. Iron traverses enterocytes on its way to the circulation. Once in enterocyte cytosol, iron is exported by a specific channel, ferroportin, which mediates iron export in enterocytes and other cells. 3. Having traversed the enterocytes, Fe^{3+} binds to Tf, the principal means by which iron circulates. (Some free iron, i.e., iron not bound to Tf, circulates in normal circumstances.) 4. Tf is recognized by a receptor (TfR1) on cells that are engaged in iron uptake. It is stored bound to ferritin. 5. A small amount of iron enters cells as free iron, unbound to Tf. It, too, is stored as ferritin. 6. Excess iron supplies are stored in macrophages and hepatocytes. 7. Cells in the bone marrow incorporate iron into hemoglobin for use in erythrocytes. (*continued*)

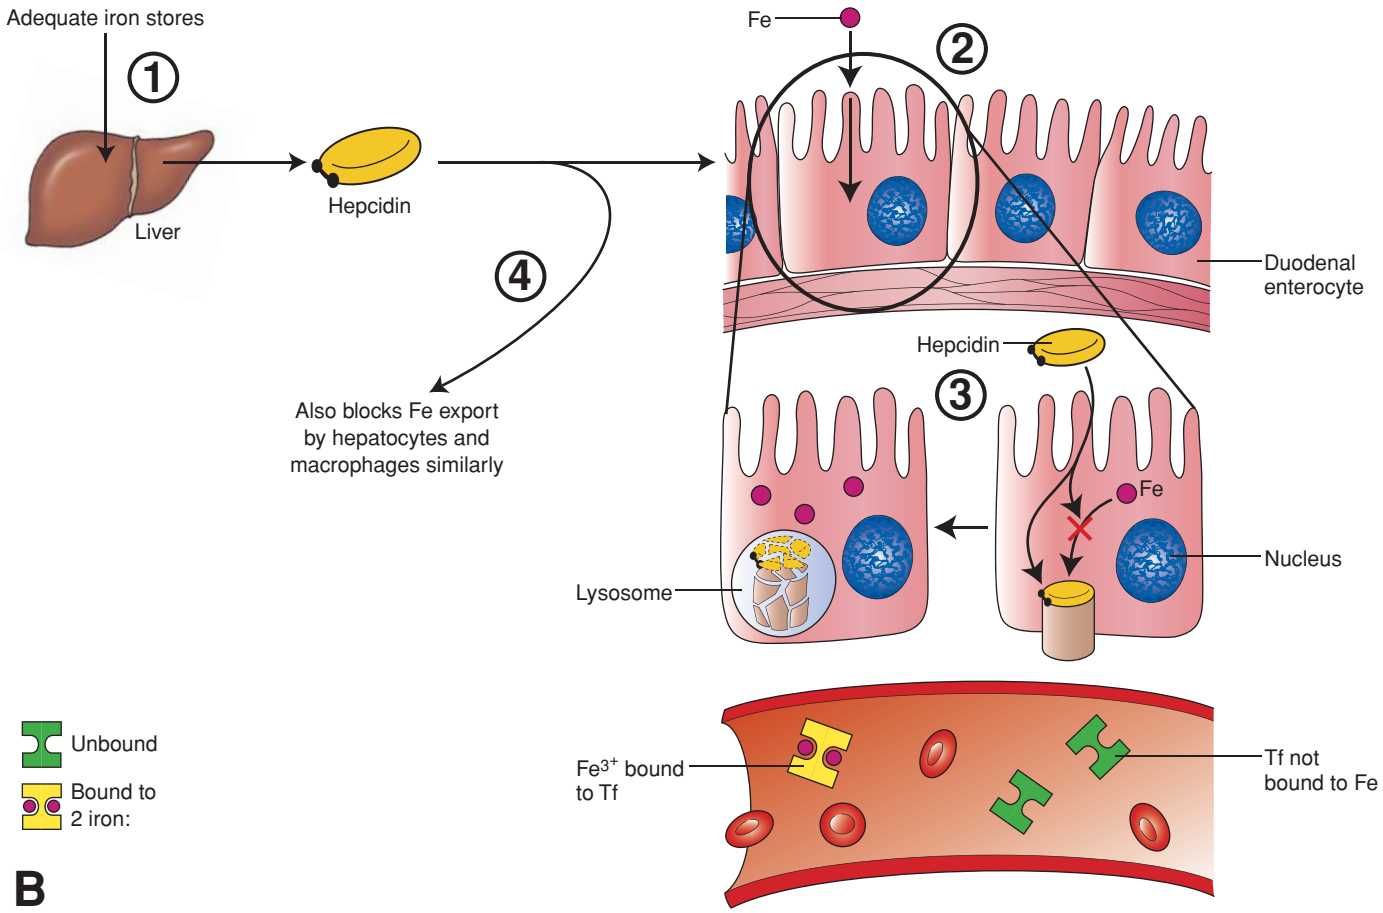

FIGURE 20-39. (*Continued*) **B.** Hepcidin regulation of iron uptake. 1. Hepcidin is produced by hepatocytes and exported into the circulation. 2. The duodenum, the principal portal of iron entry into the body, is a key site of hepcidin action. 3. If hepcidin is present, it binds ferroportin. This has two consequences. First, iron is denied access to ferroportin and thus cannot be exported. Second, hepcidin binding causes the hepcidin–ferroportin complex to be internalized and degraded. 4. The sequence is illustrated here for enterocytes but applies comparably to the other cells that store and export iron, such as macrophages and hepatocytes.

well understood. In addition, hepcidin, as a small peptide, passes through glomeruli. It is degraded in proximal tubules. As a consequence, in renal failure, hepcidin is not eliminated efficiently and its levels are generally elevated.

- **Ferroportin:** This protein is the obligatory iron channel in cells. It is required for cells (mainly enterocytes, hepatocytes and macrophages) to export iron or to transport it through the cell. Hepcidin inhibits ferroportin function by displacing iron from it, then causing the hepcidin–ferroportin complex to be internalized and degraded.
- **Transferrin (Tf):** There is more than one form of this molecule. However, the principal form of the Tf molecule is the main iron carrier in the blood. One Tf molecule binds two Fe^{3+} ions. Tf also mediates iron uptake by cells via its main receptor (TfR1). Normal plasma iron ranges from 80 to 100 mg/dL, and Tf is ordinarily about 33% saturated. A small amount of free iron—not bound by Tf—also circulates normally. In times of huge iron excess, free iron may be the predominant form of iron in the blood.
- **Ferritin:** This multimeric protein is responsible for storing iron within cells and is present in every cell type. It binds the ferric (Fe^{3+}) form of iron to form a complex called **hemosiderin,** and in so doing prevents the stored iron from generating free radical species via the Fenton reaction (see Chapter 1). Every ferritin complex (molecular size, 450 kDa) can store up to 4500 Fe^{3+} ions. Blood ferritin levels generally reflect the status of the body's iron stores: low serum ferritin generally reflects iron deficiency. High ferritin levels occur when the body has large amounts of stored iron or, as well, during acute inflammatory reactions.

Iron Entry into Cells

Under normal circumstances, the main iron portal of entry into enterocytes is a cell membrane channel referred to as divalent metal transporter 1 (DMT-1). Other cells generally admit iron via a different receptor-mediated pathway: Tf-bound iron is recognized by TfR1 and internalized. Free iron (not bound by Tf) enters cells differently, via poorly understood mechanisms. It is this pathway, by which unbound iron enters cells, that allows intracellular iron accumulation when regulatory mechanisms malfunction (see below). Generally, iron is stored in macrophages and hepatocytes bound to **ferritin**.

Hereditary Hemochromatosis Is a Systemic Disease Caused by Excessive Iron Absorption

Toxic iron accumulation in HH is harmful to parenchymal cells, particularly of the liver, heart and pancreas. Up to 20–40 g of iron may accumulate, only within body storage

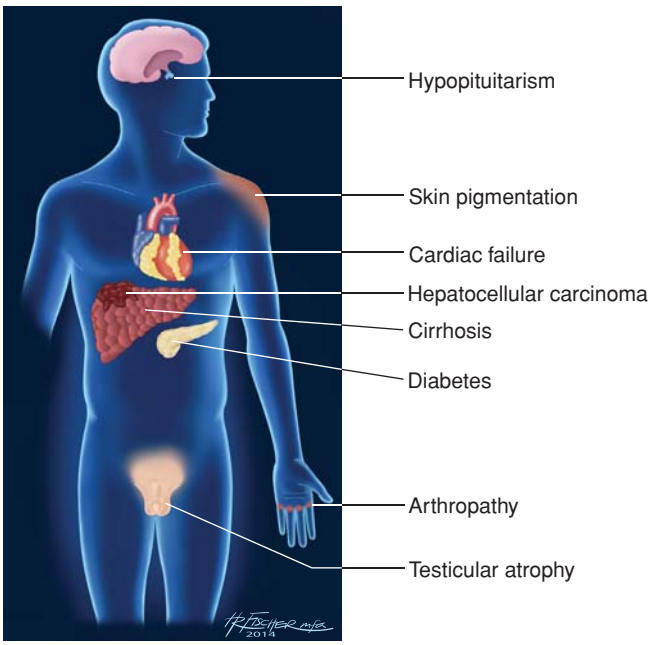

FIGURE 20-40. Complications of hemochromatosis.

compartments. ***The clinical hallmarks of advanced HH are cirrhosis, diabetes, skin pigmentation and cardiac failure*** (Fig. 20-40). HH is the most common inherited metabolic disorder in whites. It manifests most often in patients 40–60 years of age. Men are affected 10 times as often as women, probably because women lose iron by menstruation. However, postmenopausal women may also develop HH. As maximum daily iron absorption is about 4 mg, hemochromatosis develops over years.

Iron Metabolism in Hereditary Hemochromatosis

MOLECULAR PATHOGENESIS: There are several different known forms of HH. In most, it is the *HFE* gene, on the short arm of chromosome 6, that is mutated. Mutations in other genes that control iron metabolism less commonly lead to iron overload and syndromes like hemochromatosis. A particular mutation (C282Y), when present in both alleles of the *HFE* gene, is responsible for HH in 90% of patients. A less common HFE mutation is H63D. Among Europeans, 10% are heterozygous for C282Y, and 1 of 200–400 is homozygous. Oddly, some homozygotes do not develop HH or iron overload, and clinically apparent hemochromatosis only occurs 1 in 400 of the general population. Rarer forms of hemochromatosis are caused by mutations in other genes that control hepcidin expression, such as TfR2 and hemojuvelin. Rarely, the hepcidin gene itself (*HAMP*) is mutated.

PATHOPHYSIOLOGY: At the center of HH is hepcidin. Mutations that decrease hepcidin production mimic a situation in which there is insufficient iron. Iron uptake by enterocytes thus increases (Fig. 20-41). As well, iron transit through enterocytes, and iron export from macrophages and hepatocytes, into the circulation is increased because hepcidin is not present to mediate downregulation of the ferroportin exporter. The exporter thus operates unchecked.

The combination of enhanced iron absorption through the gut and increased export from storage sites overwhelms the Tf system and results in very high circulating free iron levels. Massive influx of iron into many cells ensues. In hepatocytes, this flood of free iron exceeds even the accelerated iron export (see above) that occurs in the absence of hepcidin-mediated inhibition of ferroportin. Hepatocytes thus accumulate iron.

As noted in Chapter 1, iron is a key factor in cell injury mediated by reactive oxygen species (ROS). Excess cellular iron probably renders HH patients more susceptible to oxidative injury. Serum iron levels in HH patients exceed twice the normal, with 100% saturation of Tf. Blood ferritin, which parallels the amount of stored iron, is greatly increased.

The causes of iron overload are summarized in Table 20-4.

PATHOLOGY: In HH, large amounts of iron accumulate in parenchymal cells of a variety of organs and tissues.

LIVER: The liver is always affected in HH and has more than 0.5 g iron per 100 g wet weight in the late stages. It is enlarged and red-brown with micronodular cirrhosis. Hepatocytes and bile duct epithelium are filled with iron granules (Fig. 20-42). Excess cellular iron is mostly stored in lysosomes as ferric iron. Late in the disease, iron is conspicuous in Kupffer cells due to phagocytosis of necrotic hepatocytes. Within the fibrous septa, iron is prominent in bile ductules and macrophages. Eventually, as with other forms of micronodular cirrhosis, macronodular cirrhosis supervenes.

SKIN: In HH, the skin is pigmented, but iron deposits in the skin in only 1/2 of patients. Most patients have increased melanin in the basal melanocytes.

PANCREAS: Diabetes due to deposition of iron in the pancreas is common in HH. The organ is rust colored and

TABLE 20-4
CAUSES OF IRON OVERLOAD

Increased Iron Absorption
Hereditary hemochromatosis
HFE associated: C282Y and H63D homozygotes and C282/H63D heterozygotes
Hemochromatosis associated with mutations in transferrin receptor 2 (TfR2) and ferroportin
Juvenile hemochromatosis: mutations in hemojuvelin and hepcidin
Chronic liver disease (e.g., alcoholic liver disease)
Iron-loading anemias
Porphyria cutanea tarda
Dietary iron overload; excess medicinal iron
Parenteral Iron Overload
Multiple blood transfusions
Injectable medicinal iron

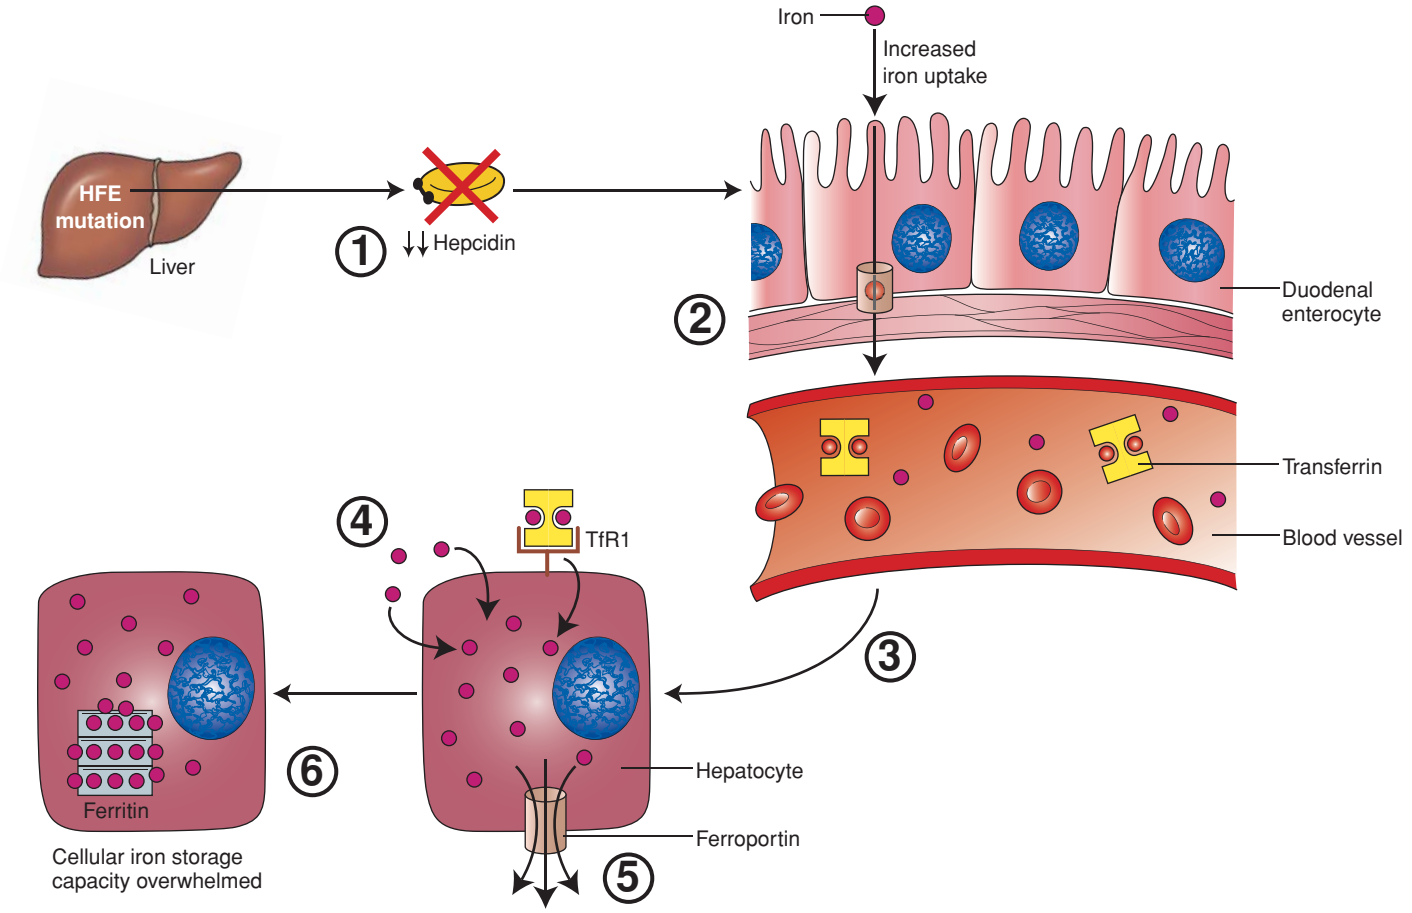

FIGURE 20-41. The fate of iron in the absence of hepcidin in hereditary hemochromatosis (HH). 1. The genetic defect in HH leads to decreased hepatic production of hepcidin. 2. As a consequence, when iron in the duodenal lumen enters enterocytes, its export through ferroportin is not regulated appropriately. The situation mimics that which occurs in iron deficiency (when hepcidin production is suppressed because of the need for increased iron uptake), even though there is abundant iron. Too much iron is absorbed and transported through the enterocytes into the blood. 3. Normally, iron is transported in the blood bound to Tf, and Tf is usually about 1/3 saturated with iron. In HH, not only is Tf iron-carrying capacity saturated (100%), but free iron (i.e., unbound to Tf) is also abundant in the blood. 4. Iron enters hepatocytes both as Tf-bound iron and as free iron. Tf-bound iron enters via the TfR1 pathway. Free iron enters via a different, poorly understood pathway. 5. Lacking inhibition by hepcidin, ferroportin export of iron is very active. 6. However, probably because of overwhelming entry of free iron into hepatocytes, iron storage and export capacities are overwhelmed. Therefore, the excess iron accumulates.

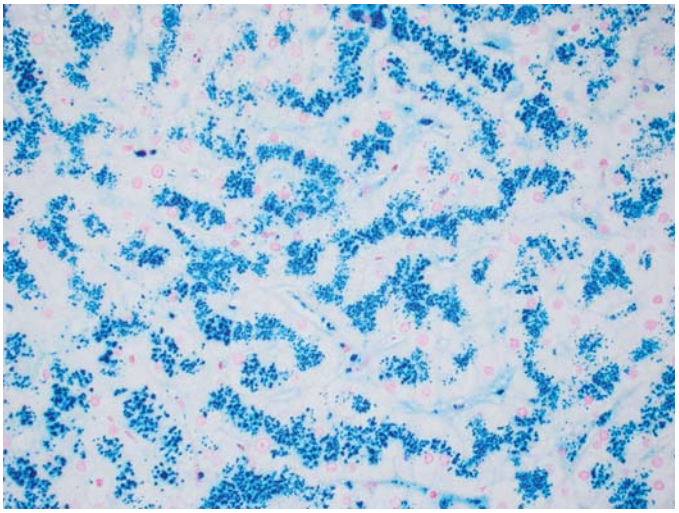

FIGURE 20-42. Hemochromatosis. Perl iron stain demonstrates marked iron (blue) in hepatocytes along the bile canaliculi.

fibrotic. Exocrine and endocrine cells have excess iron, and there is cell loss both in acini and islets of Langerhans. The combination of pigmented skin and glucose intolerance in HH is called **bronze diabetes**.

HEART: Congestive heart failure is a frequent cause of death in HH. Myocardial fibers contain iron pigment, more extensively in ventricles than in atria. Cardiac myocyte necrosis and resulting interstitial fibrosis are common.

ENDOCRINE SYSTEM: Many endocrine glands are affected in HH, including the pituitary, adrenal, thyroid and parathyroid glands. Except for the pituitary, in which release of gonadotropins is impaired, tissue damage does not occur in these organs. As a result, testicular atrophy is seen in 1/4 of male patients, even without iron deposition in the testes. Altered pituitary–gonadal axis function presents as loss of libido and amenorrhea in women, and impotence and sparse body hair in men.

JOINTS: About 1/2 of patients with HH show arthropathy, which is worst in the fingers and hands. HH arthritis affecting larger joints, like the knee, can be disabling.

CLINICAL FEATURES: HH generally becomes symptomatic in midlife. The liver disease usually progresses slowly, but 1/4 of untreated patients eventually die in hepatic coma or from gastrointestinal hemorrhage. Cirrhosis may lead to HCC; the 10-year cumulative chance of liver cancer may reach 30%.

Treatment of HH involves removal of iron from the body, most effectively by repeated phlebotomy. Weekly phlebotomies for 2–3 years can remove 20–40 g of iron, after which phlebotomies every 2–3 months maintain iron balance. In homozygotes without cirrhosis or diabetes, iron depletion allows a life expectancy identical to that of the general population. Without treatment, 10-year survival with HH is only 6%.

Secondary Iron Overload Occurs in People without HH Mutations

PATHOPHYSIOLOGY: Within certain limits, the amount of iron absorbed is a function of the amount ingested. For example, hemochromatosis is unlikely to develop in someone with a diet low in iron. Many patients (up to 40%) with secondary iron overload have a long history of alcohol abuse; it is thought that alcohol increases both iron storage and associated cell injury.

Iron accumulation among blacks of sub-Saharan Africa, commonly misnamed "Bantu siderosis," is an example of secondary iron overload. This disorder occurs because these populations consume large amounts of iron-containing alcoholic beverages. As "home-brewed" beverages (low alcohol, high iron) have been replaced by Western spirits (high alcohol, low iron), the incidence of siderosis has declined, whereas alcoholic cirrhosis has increased.

Massive iron overload occurs in patients with certain diseases with ineffective erythropoiesis, such as sickle cell anemia, thalassemia major and other anemias. The excess iron derives from hemolysis or transfused blood. Increased iron absorption also occurs despite Tf saturation. Multiple blood transfusions alone are generally insufficient to produce secondary iron overload, even in patients with hypoplastic anemia given many transfusions (250 mg iron/500 mL unit of blood). In these patients, iron is concentrated principally in mononuclear phagocytes, and cirrhosis is rare.

PATHOLOGY: In transfusion-related and other types of siderosis, there is uniform, initial iron deposition in Kupffer cells, eventually spilling over into hepatocytes. Cirrhosis associated with secondary iron overload shows varying degrees of iron accumulation, but hepatic iron deposition is generally less than that in HH and is often restricted to the periphery of the nodules.

A Footnote to Hepcidin-Regulated Iron Metabolism

The centrality of hepcidin to iron metabolism may have implications far beyond hereditary iron storage disorders. As mentioned above, in chronic renal failure, the inability of the kidneys to eliminate hepcidin may lead to its accumulation. Excess hepcidin production, such as is stimulated by IL-6 in settings of chronic infection and inflammation, and in some malignancies, may also lead to excessively high levels of hepcidin.

In this setting, elevated hepcidin concentrations may severely restrict ferroportin function. This could impair iron absorption in the gut and lead to excessive iron retention in stores due to inadequate release from macrophages and hepatocytes. If hepcidin remains elevated for prolonged periods of time, iron deficiency anemia may develop. Thus, anemia in some chronic inflammatory diseases, such as Crohn disease and rheumatoid arthritis, or in some tumors, such as certain lymphomas, may be associated with anemia and high circulating hepcidin levels. Such anemias, although they show low blood iron levels, are not amenable to treatment with dietary iron, as high hepcidin levels impede enteric iron absorption.

HERITABLE DISORDERS ASSOCIATED WITH CIRRHOSIS

Wilson Disease Is an Inherited Disorder of Copper Metabolism

WD is an autosomal recessive disease in which excess copper is deposited in the liver and brain (Fig. 20-43). One in 150–180 people is a carrier, and 1 in 30,000 children develop clinical disease.

MOLECULAR PATHOGENESIS: Dietary copper intake usually exceeds the body's needs. The excess is excreted by the liver into the bile. Copper is normally bound to ceruloplasmin in hepatocytes and then secreted into the blood. The gene for WD, namely *ATP7B* on chromosome 13, codes for an ATP-dependent, transmembrane cation channel, which transports copper

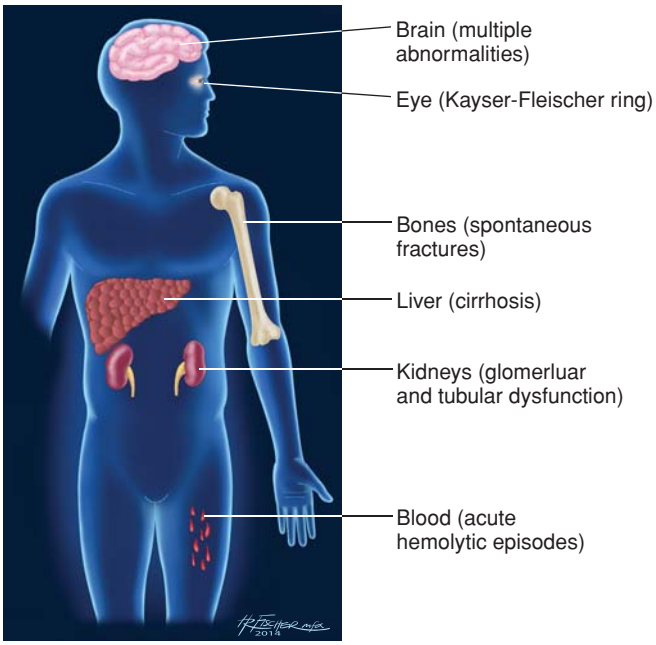

FIGURE 20-43. Wilson disease. The organs principally affected in Wilson disease.

within hepatocytes before it is excreted. ***Mutations in ATP7B impair copper transport. Both biliary copper excretion and incorporation into ceruloplasmin are deficient.*** Some 200 different mutations in the WD gene are known. In European and North American populations, a single mutation, H1069Q, accounts for 70% of WD, but this mutation is rare in India and Asia. Most patients are compound heterozygotes and possess two different mutant alleles.

In WD, serum ceruloplasmin levels are very low, a deficiency thought to be due to hepatic copper overload. Excess copper is toxic to hepatocytes, which die and release their copper into the blood, to then deposit in extrahepatic tissues. The central role of the liver in WD is underscored by the fact that liver transplantation is curative.

Just how excess copper injures cells is unclear. Copper can replace iron in the Fenton reaction to convert hydrogen peroxide into hydroxyl radicals (see Chapter 1).

PATHOLOGY: ***In WD, the liver progresses from mild to severe chronic hepatitis. Cirrhosis may develop rapidly, even in childhood (Fig. 20-44).*** Features of severe hepatocyte injury and steatosis may be seen. Hepatocytes often contain Mallory bodies, and cholestasis is common. Initially, cirrhosis is micronodular, but in time, it becomes macronodular. Chemical measurement of liver copper in unfixed tissue from livers of patients with WD reveals more than 250 µg of copper per gram of dry weight.

CLINICAL FEATURES: In 1/2 of patients with WD, some symptoms are shown by adolescence. The rest usually become ill early in adulthood, but WD can present later. Initial symptoms reflect chronic liver disease in about 1/2 of patients, 1/3 are first seen with neurologic complaints and about 1/10 have psychiatric illnesses.

LIVER: Liver-related symptoms are nonspecific at first and may progress to chronic liver disease indistinguishable from that of other forms of chronic hepatitis. Eventually, chronic hepatitis and cirrhosis result in jaundice, portal hypertension and hepatic failure. WD presents rarely as acute liver failure. Unlike hemochromatosis, there is no increased risk of liver cancer.

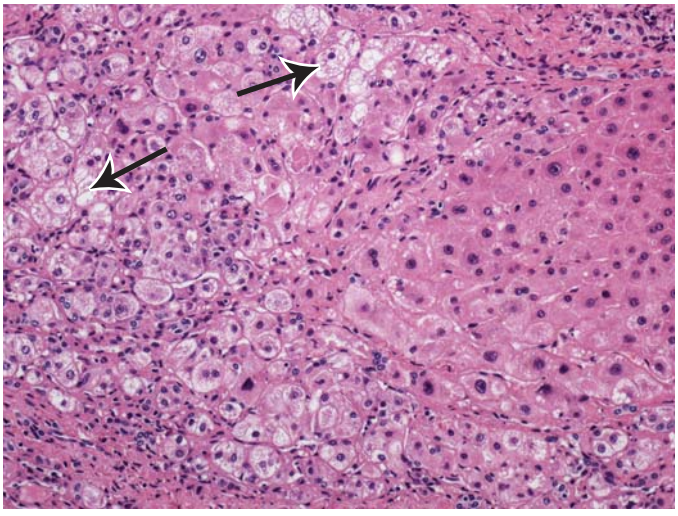

FIGURE 20-44. Wilson disease. The liver shows cirrhosis. There is severe hepatocyte injury with hydropic change (*arrows*).

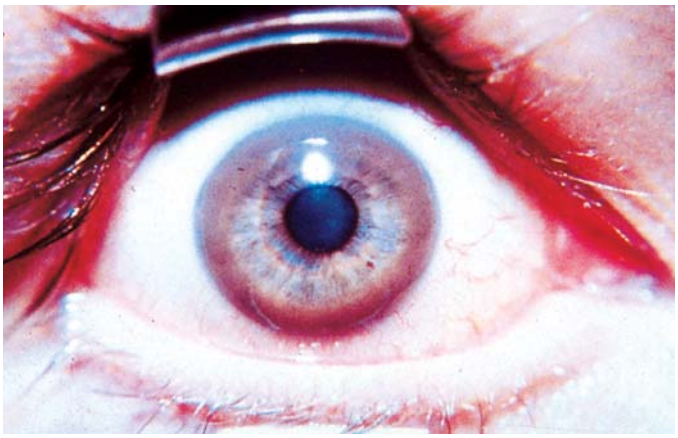

FIGURE 20-45. Kayser-Fleischer ring. The deposition of copper in the Descemet membrane is reflected in a peripheral brown color, which obstructs the view of the underlying iris.

BRAIN: Neurologic disease begins with mild incoordination and tremors. If untreated, dysarthria and dysphagia appear, then disabling dystonia and spasticity.

EYE: Ocular manifestations invariably accompany neurologic disease. **Kayser-Fleischer rings** are golden-brown, bilateral corneal discolorations around the edge of the iris that obscure its muscular pattern (Fig. 20-45). They represent copper deposited in Descemet membrane. In some patients, these rings are accompanied by "sunflower cataracts," which are green copper discs in the anterior capsule of the lens.

BONES: Skeletal lesions are common and include osteomalacia, osteoporosis, spontaneous fractures and various arthropathies.

KIDNEY: Renal glomerular and tubular dysfunction is common in WD and is manifested by proteinuria, lowered glomerular filtration, aminoaciduria and phosphaturia. These abnormalities are due to copper deposition in renal tubules.

BLOOD: Transient acute hemolytic episodes, presumably related to a sudden release of free copper from the liver, occur in 15% of patients with WD.

Treatment of WD prevents copper accumulation in tissues and removes copper already deposited. Copper-chelating agents, trientine and d-penicillamine, augment urinary copper excretion. Treatment often reverses central nervous system (CNS) dysfunction and liver disease. Presymptomatic patients are maintained with zinc, which blocks intestinal absorption of copper. Liver transplantation is curative for WD.

Cystic Fibrosis May Cause Biliary Obstruction

The cystic fibrosis transmembrane regulator (CFTR; see Chapter 6) is expressed in biliary epithelial cells. In cystic fibrosis (CF), tenacious mucus plugs obstruct intrahepatic biliary channels, sometimes as early as the first few weeks of life. Some infants die in hepatic failure. The most common hepatic lesion is focal or diffuse biliary cirrhosis. In patients who survive to adolescence, liver involvement becomes clinically symptomatic in 15%. Secondary biliary cirrhosis occurs in 10% of those who survive beyond 25 years. Liver disease accounts for 2.5% of deaths in CF, making it the most common nonpulmonary cause of death

in this disease. UDCA therapy improves liver function, chemistry and histology, but not survival.

α_1-Antitrypsin Deficiency Leads to Cirrhosis

α_1-AT deficiency is an autosomal recessive disease that was initially described as a cause of emphysema (see Chapter 12). Later, cases of liver disease without lung involvement were reported. Diseases involving both organs are recognized. α_1-AT deficiency is the most common genetic liver disease and the most common genetic disease treated by liver transplantation. Although it occurs in 1 of 2000 live births, only 10%–15% of those affected develop liver disease.

MOLECULAR PATHOGENESIS: α_1-AT is a serine protease inhibitor (serpin) made largely in the liver. It inactivates neutrophil elastase. Both pulmonary and hepatic disorders are due to inadequate α_1-AT secretion by the liver. The α_1-AT gene locus, *Pi,* has more than 75 known isoforms. PiZ is the most common (95% of cases) mutant α_1-AT protein, substituting a lysine for a glutamate at position 342. The mutant protein is retained within the hepatocyte ER, where it folds abnormally. Insoluble aggregates of the mutant protein cannot be exported and accumulate, thereby damaging the cell.

PATHOLOGY: Hepatocytes in patients with α_1-AT deficiency contain faintly eosinophilic, PAS-positive cytoplasmic droplets (Fig. 20-46), which contain amorphous material within dilated ER cisternae. The disease often presents with chronic hepatitis, which terminates in cirrhosis.

α_1-AT deficiency may cause hepatitis in the newborn (see below). Micronodular cirrhosis develops by the age of 2–3 years in these children and may ultimately become macronodular.

CLINICAL FEATURES: Liver disease in α_1-AT deficiency varies from rapidly fatal neonatal hepatitis to no hepatic dysfunction at all. ***Of infants with the ZZ genotype—who are susceptible to development of clinical disease—10% have neonatal cholestatic jaundice (conjugated hyperbilirubinemia).*** In fact, α_1-AT deficiency accounts for 30% of cases of neonatal conjugated hyperbilirubinemia. Most infants recover within 6 months, but 10%–20% develop permanent liver disease. Children with cirrhosis usually die before 10 years of age from hepatic failure or other complications of the disease. However, liver transplantation is curative.

Some patients are asymptomatic until early adulthood, when symptoms of cirrhosis may be the initial complaint. ***Cirrhosis in α_1-AT deficiency is prone to a high incidence of HCC.***

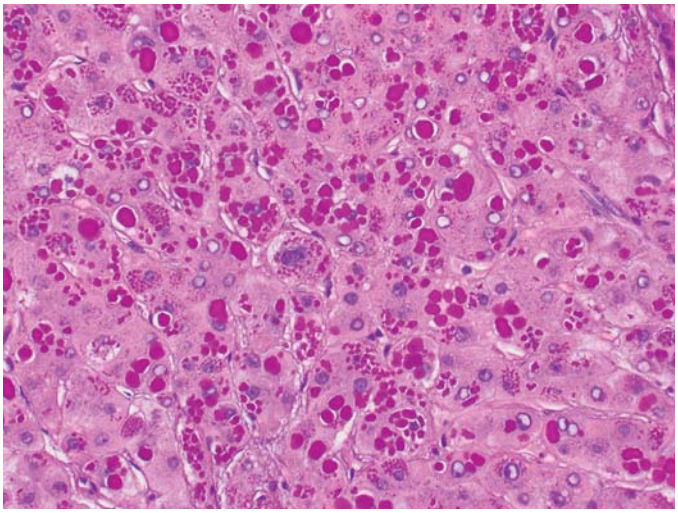

FIGURE 20-46. α_1-Antitrypsin deficiency. A cirrhotic liver stained by the periodic acid–Schiff (PAS) reaction with diastase digestion to remove glycogen reveals numerous cytoplasmic globules in the hepatocytes.

Inborn Errors of Carbohydrate Metabolism Affect the Liver

Glycogen Storage Diseases

The biochemical basis of glycogen storage diseases is discussed in Chapter 6. ***Only glycogenosis type IV (brancher deficiency, Andersen disease) is usually complicated by cirrhosis.*** A slowly developing cirrhosis may also occur in glycogenosis type III (debrancher deficiency, Cori disease) but is not inevitable. Glycogenosis type I (glucose-6-phosphatase deficiency, von Gierke disease) is associated with striking hepatomegaly, and type II (acid-glucosidase deficiency, Pompe disease) features mild hepatomegaly. Neither type I nor type II is complicated by cirrhosis.

GLYCOGENOSIS TYPE I: Hepatocytes are distended by large amounts of glycogen, which appears pale in sections stained with hematoxylin and eosin and red with PAS. Fat accumulation varies from mild to severe, but fibrosis is usually absent. Hepatic adenomas often develop in adolescence but regress with dietary therapy.

GLYCOGENOSIS TYPE II: Infants with Pompe disease typically present with muscle weakness (myopathy), poor muscle tone (hypotonia), hepatomegaly, and cardiomegaly. The hepatocyte appearance with abundant glycogen is similar to glycogenosis type I.

GLYCOGENOSIS TYPE III: Infants with Cori disease show severe hepatomegaly, and the liver morphologically resembles that seen in type I. Fat is less conspicuous, but fibrosis is present and may progress to cirrhosis.

GLYCOGENOSIS TYPE IV: Infants present with severe hepatomegaly and usually succumb to cirrhosis by 4 years of age. Sharply circumscribed, PAS-positive inclusions are seen in enlarged hepatocytes. These inclusions are fibrillar and represent abnormal glycogen. Deposits of mutant glycogen are also found in the heart, skeletal muscle and brain. Liver transplantation is curative for glycogenosis type IV.

Galactosemia

Galactosemia is an autosomal recessive trait in which galactose-1-phosphate uridyl transferase is lacking. This enzyme catalyzes the second step in the conversion of galactose to glucose. Thus, galactose and its metabolites accumulate in the liver and other organs. Affected infants who are fed milk rapidly develop hepatosplenomegaly, jaundice and hypoglycemia. Cataracts and mental retardation are common.

Within 2 weeks of birth, the liver shows extensive and uniform fat accumulation and striking bile ductule proliferation in and around portal tracts. Cholestasis is often seen in

canaliculi and bile ductules. Bile plugs fill many of these pseudoacini. At about 6 weeks of age, fibrosis begins to extend from portal tracts into the lobules and progresses to cirrhosis by 6 months. Institution of a galactose-free diet improves the disease and reverses many of the morphologic alterations.

Hereditary Fructose Intolerance

This disease is an autosomal recessive deficiency of fructose-1-phosphate aldolase. Fructose feeding early in infancy causes hepatomegaly, jaundice and ascites. However, if initial exposure to fructose occurs after 6 months, resulting disease is far milder; the only clinical impairment is spontaneous hypoglycemia. Infants with liver disease show many of the changes of neonatal hepatitis. Fat accumulation may be marked, resembling that in galactosemia. Progressive fibrosis culminates in cirrhosis.

Tyrosinemia

Tyrosinemia is an autosomal recessive trait in which tyrosine catabolism to fumarate and acetoacetate is impaired. The missing enzyme is fumarylacetoacetate hydrolase (FAH). More than 30 different mutations in the *FAH* gene are known. Succinyl acetone and succinyl acetoacetate accumulate. Both are potent electrophiles that can react with the sulfhydryl groups of glutathione and proteins, and damage the liver and kidneys.

Acute tyrosinemia begins within a few weeks or months of birth with hepatosplenomegaly. Liver failure and death are usual before 1 year of age. The liver is remarkably like that in galactosemia, and progression to cirrhosis is the rule.

Chronic tyrosinemia begins in the first year of life, manifesting as growth retardation, renal disease and hepatic failure. Death usually supervenes before 10 years of age. Tyrosinemia is treated by liver transplantation. ***The incidence of HCC in untreated chronic tyrosinemia is extremely high.***

Miscellaneous Inherited Causes of Cirrhosis

Several inborn errors of metabolism are associated with cirrhosis, including storage diseases such as Gaucher disease, Niemann-Pick disease, mucopolysaccharidoses, neonatal adrenoleukodystrophy, Wolman disease and Zellweger syndrome.

INDIAN CHILDHOOD CIRRHOSIS

Indian childhood cirrhosis (ICC) is a fatal disorder mainly, but not only, affecting preschool children in India. ICC predominantly affects boys 1–4 years old. The liver shows micronodular cirrhosis and many Mallory bodies, as in alcoholic liver disease.

The etiology and pathogenesis of ICC are not well understood. Familial cases are reported, but no hereditary pattern is established. Interestingly, children with this disease have a marked excess of copper and copper-binding protein in the liver, but the significance of these findings remains obscure.

DRUG-INDUCED LIVER INJURY

Drug-induced liver injury can mimic nearly any type of liver disease, with severity ranging from asymptomatic elevations of transaminases to acute liver failure. ***In fact, drugs are the most common cause of acute liver failure in the United States.*** Chapter 1 includes a discussion of mechanisms by which toxins may produce liver necrosis. Chapter 4 reviews immune-mediated mechanisms of injury.

Drugs cause injury in either **predictable** or **unpredictable** patterns. The former refers to drugs that cause liver injury in a dose-dependent manner (e.g., carbon tetrachloride, the mushroom poison phalloidin, the analgesic acetaminophen). The latter reflects injury that can occur with low frequency, irrespective of dose and without obvious predisposition **(idiosyncratic reaction)**.

The defining characteristics of predictable drug-induced hepatoxicity are:

- The agent, in sufficiently high doses, always produces liver cell damage.
- The extent of hepatic injury is dose dependent.
- The same lesions are seen in different animal species.
- Liver necrosis is zonal and often, but not always, centrilobular.
- The time between exposure and development of liver cell necrosis is short.

Most drug reactions are unpredictable and seem to represent idiosyncratic events. This type of hepatotoxicity occurs in people with metabolic or genetic predispositions. In them, injury usually reflects unusual sensitivity to a dose-related side effect. Thus, individuals may be predisposed to idiosyncratic reactions because their metabolic pathways differ from those of the general population (*metabolic idiosyncrasy*) or because they possess genetic variations in systems of biotransformation or detoxification of reactive metabolites. As well, some drugs or their metabolites may trigger immunologic reactions in the liver (autoimmune hepatitis).

There is no specific test to predict or diagnose drug-induced hepatotoxicity. A close history of medications, drugs and dietary supplements must be elicited from patients with elevated liver enzymes or jaundice. Other liver diseases must be ruled out (e.g., viral hepatitis, genetic disease, autoimmune hepatitis, alcoholic hepatitis). Liver biopsy is often of limited value in diagnosing drug injury, as histologic patterns of acute or chronic drug-induced liver disease overlap with non–drug-related diseases.

Histologic Patterns of Drug-Induced Liver Disease Are Diverse

Drug toxicities can span nearly the whole gamut of pathologies seen in non–drug-induced liver diseases. However, individual drugs usually have characteristic patterns of liver toxicity.

Zonal Hepatocellular Necrosis

Toxic doses of acetaminophen *predictably* cause centrilobular necrosis (Fig. 20-47A), but very high doses can cause panlobular necrosis (see Chapter 1). This zonal pattern probably reflects the greater activity of drug-metabolizing enzymes in the central zones. Classic agents that produce such injury are carbon tetrachloride and the toxin of the mushroom *Amanita phalloides.* In affected zones, hepatocytes show coagulative necrosis, hydropic swelling and variable small droplet fat. Inflammation is sparse. Patients either die in acute hepatic failure or recover without sequelae. ***Acetaminophen-induced***

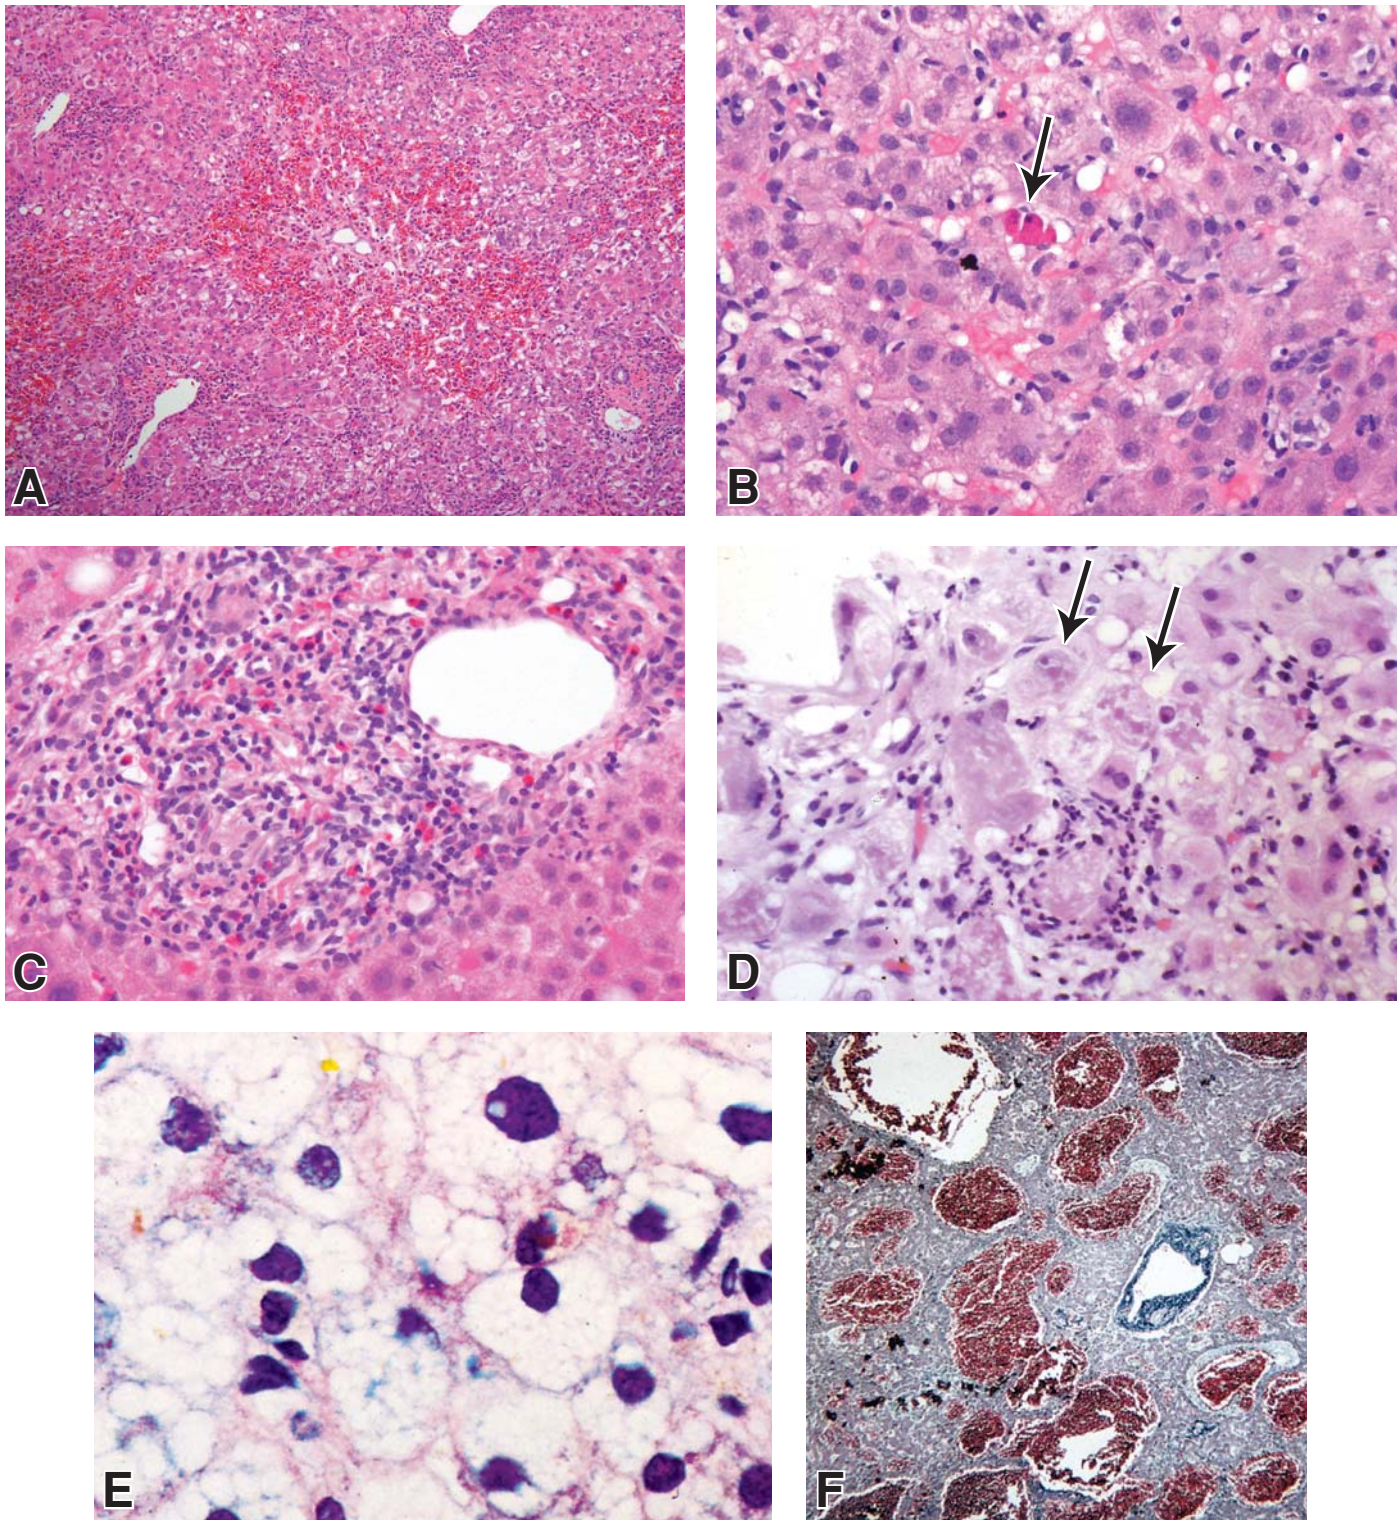

FIGURE 20-47. Drug-induced hepatotoxicity. A. Toxic centrilobular necrosis. This liver biopsy was from a 20-year-old man who attempted suicide with an overdose of acetaminophen. There is centrilobular hemorrhagic necrosis. Note that the surviving hepatocytes are markedly swollen. **B. Acute hepatitis.** The patient was started on isoniazid for treatment of tuberculosis. After 3 weeks, the aspartate aminotransferase (AST) and alanine aminotransferase (ALT) were elevated. The liver biopsy shows features of acute hepatitis including lobular disarray, inflammation, acidophilic bodies (*arrow*) and focal necrosis. **C. Eosinophilic portal inflammatory infiltrate.** A 33-year-old woman developed fatigue 2 weeks after initiating therapy with a nonsteroidal anti-inflammatory agent. The AST was 250 U/L. Portal tracts show expansion by acute and chronic inflammation with eosinophils. **D. Phospholipidosis.** Liver biopsy from a patient treated with amiodarone. The hepatocytes are swollen and display ample Mallory-Denk bodies (*arrows*). **E. Reye syndrome.** A liver biopsy specimen shows small-droplet fat in hepatocytes and centrally located nuclei. **F. Peliosis hepatis.** The patient was a 44-year-old weight lifter who used anabolic steroids. The liver contains numerous large, irregular, blood-filled spaces.

hepatotoxicity is the most common cause of acute liver failure in the United States and is frequently seen in suicidal gestures. Patients usually present soon after an ingestion.

Chronic exposure to some hepatotoxins that cause zonal necrosis (e.g., carbon tetrachloride) is not generally a problem: once acute toxic injury is recognized, reexposure to the offending agent is rare.

Cholestasis

Injury to intralobular and interlobular bile ducts is a common, unpredictable reaction to drugs. When it occurs, bile accumulates in hepatocytes and canaliculi. It is called *pure cholestasis* (Fig. 20-8) if there is no inflammation. Drugs that cause pure cholestasis include estrogens, androgens and several antibiotics (e.g., sulfamethoxazole). If cholestasis is accompanied by inflammation, the term **cholestatic hepatitis** is used.

Acute and Chronic Hepatitis

Inflammatory reactions are common in many *unpredictable* hepatotoxic drug reactions. All of the features of acute viral hepatitis can occur after exposure to a wide variety of drugs (e.g., isoniazid, antibiotics). The inflammation is a general response to cell injury and necrosis, such as in viral or autoimmune hepatitis (Fig. 20-47B). ***The entire range of acute liver injury, from mild anicteric hepatitis to rapidly fatal massive hepatic necrosis, is encountered.*** Typically, drug-induced hepatitis and liver enzyme elevations associated with it resolve when the offending drug is withdrawn. If exposure continues, chronic hepatitis and even cirrhosis may develop. Sometimes, inflammation may reflect **drug-induced autoimmune hepatitis** (e.g., nitrofurantoin) either as an immune response to the drug or by unmasking classical autoimmune hepatitis. The presence of eosinophils in the inflammatory infiltrate suggests such a drug reaction (Fig. 20-47C). ***An inflammatory infiltrate, regardless of its composition, is not specific for drug-associated hepatotoxicity***. Granulomatous hepatitis is also a rare reaction to drugs.

Fatty Liver

Accumulation of triglycerides within hepatocytes (i.e., hepatic steatosis or fatty liver) generally occurs in a predictable fashion. Although there may be substantial overlap, two morphologic patterns are recognized: macrovesicular and microvesicular steatosis.

Macrovesicular Steatosis

In addition to its association with chronic ethanol ingestion, macrovesicular fat results from accidental exposure to direct hepatotoxins, such as carbon tetrachloride. Corticosteroids and some antimetabolites, such as methotrexate, may also cause macrovesicular steatosis. Fat per se does not injure hepatocytes (see above). A variant of toxic macrovesicular steatosis that resembles alcoholic hepatitis **(steatohepatitis)** occurs after administration of certain drugs (e.g., the antiarrhythmic agent amiodarone). Both hepatocytes and Kupffer cells are enlarged, with foamy cytoplasm that represents accumulation of **phospholipids**. Mallory bodies are abundant (Fig. 20-47D). Macrovesicular steatosis is itself clinically inconsequential.

Microvesicular Steatosis

Unlike macrovesicular steatosis, microvesicular fatty liver is often associated with severe, and sometimes fatal, liver disease. Small fat vacuoles are dispersed throughout the cytoplasm of hepatocytes, and the nucleus retains its central position (Fig. 20-47E). The microvesicular fat is important, not in and of itself but as a manifestation of metabolic severe injury to subcellular structures, mainly mitochondria.

REYE SYNDROME: This rare acute disease of children is characterized by microvesicular steatosis, hepatic failure and encephalopathy. Edema and fat accumulation are reported in the brain. Symptoms usually begin after a febrile illness, such as influenza or varicella infection, and may correlate with aspirin administration. However, in some cases, the doses of aspirin involved were far too low to cause liver injury, and Reye syndrome is more complex than simple aspirin toxicity. In any event, as the use of aspirin and the incidence of influenza has declined in children, Reye syndrome has fortunately become uncommon.

Vascular Lesions

Occlusion of hepatic veins **(Budd-Chiari syndrome; Fig. 20-18)** may follow use of oral contraceptives, perhaps because they induce hypercoagulability in some people.

Peliosis hepatis is a peculiar hepatic lesion with cystic, blood-filled cavities that are not lined by endothelial cells (Fig. 20-47F). Anabolic sex steroids, contraceptive steroids and the antiestrogen tamoxifen sometimes produce this lesion.

Mass Lesions and Altered Hepatic Morphology

Hepatocellular adenoma, induced by exogenous steroids (estrogens and anabolic steroids), and **hemangiosarcoma,** caused by intravenous administration of the radioactive contrast agent thorium dioxide (Thorotrast; see Chapter 8) dye (no longer used), are among the very few mass lesions caused by drugs. Chronic exposure to inorganic arsenic, usually in insecticides, and occupational inhalation of vinyl chloride have also been linked to hepatic angiosarcomas.

Nodular regenerative hyperplasia may occur after therapy with antimetabolites (e.g., 6-thioguanine) and azathioprine. The liver appears nodular, grossly and on microscopic examination, but without fibrosis. Patients typically present with portal hypertension as the architectural distortion impairs flow of portal blood into the liver.

THE PORPHYRIAS

Porphyrias may be acquired or inherited. They are caused by deficiencies in heme biosynthesis and are characterized by accumulation of porphyrin intermediates (see Chapter 20). Porphyrias are divided into hepatic and erythropoietic porphyrias, based on where the defective heme metabolism and the accumulation of porphyrins and their precursors occur. Genetic porphyrias are heterogeneous, usually with unique mutations in individual families.

Hepatic porphyrias are inherited as autosomal dominant traits and are often precipitated by administration of drugs, sex hormones, starvation, hepatitis C, HIV infection and alcohol. The liver shows variable steatosis, hemosiderosis, fibrosis and cirrhosis. Needle-shaped cytoplasmic inclusions may be present.

ACUTE INTERMITTENT PORPHYRIA: This is the most common genetic porphyria and reflects a deficiency of

porphobilinogen deaminase activity in the liver. Only 10% of gene carriers show clinical symptoms, which generally affect young adults. Colicky abdominal pain and neuropsychiatric symptoms predominate.

PORPHYRIA CUTANEA TARDA: This chronic hepatic porphyria is the most frequent porphyria. It may be acquired or inherited as an autosomal dominant trait and is characterized by deficient uroporphyrinogen decarboxylase activity. Typical patients are of middle age or elderly, with cutaneous photosensitivity and liver disease with hepatic iron overload.

Other inherited porphyrias, termed **erythropoietic porphyrias** and **congenital erythropoietic porphyrias,** are caused by enzyme deficiencies in erythrocytes. They are characterized by cutaneous photosensitivity and occasionally liver disease.

VASCULAR DISORDERS

Congestive Heart Failure Is the Major Cause of Liver Congestion

Acute Passive Congestion

At autopsy, the liver is often acutely congested, presumably because of a terminal failing heart (see Chapter 7). On cut section, the liver is diffusely speckled with small red foci, which represent centrilobular zones with dilated and congested sinusoids and terminal venules. These changes are not clinically significant.

Chronic Passive Congestion

Chronic passive liver congestion occurs when congestive heart failure increases the back-pressure in the peripheral venous circulation, impeding venous outflow from the liver. Chronically congested livers are often small with an accentuated lobular pattern of alternating light and dark areas (Fig. 20-48A), called **nutmeg liver.** In severe cases, centrilobular terminal venules and adjacent sinusoids are greatly dilated and filled with blood (Fig. 20-48B). Liver cell plates in this zone are thinned by pressure atrophy.

If **right-sided heart failure** is severe and long-standing (e.g., tricuspid valvular disease or constrictive pericarditis), chronic passive congestion may progress to hepatic fibrosis (Fig. 20-48C). Delicate fibrous strands envelop terminal venules, and septa radiate from centrilobular zones. Fibrous septa may link adjacent central veins, producing a "reverse lobulation." Pressure atrophy of centrilobular hepatocytes is prominent. This is not "cardiac cirrhosis": complete septa and regenerative nodules, as are seen in true cirrhosis, are rarely encountered.

Chronic passive liver congestion rarely affects hepatic function. Infrequently, features of portal hypertension, such as splenomegaly and ascites, may develop.

Shock Results in Decreased Liver Perfusion

Shock from any cause may cause ischemic necrosis of centrilobular hepatocytes and hemorrhage. The centrilobular zone—that is, zone 3 (Fig. 20-2)—is farthest from the blood that originates in the portal tracts and thus is the area most vulnerable to ischemic insult.

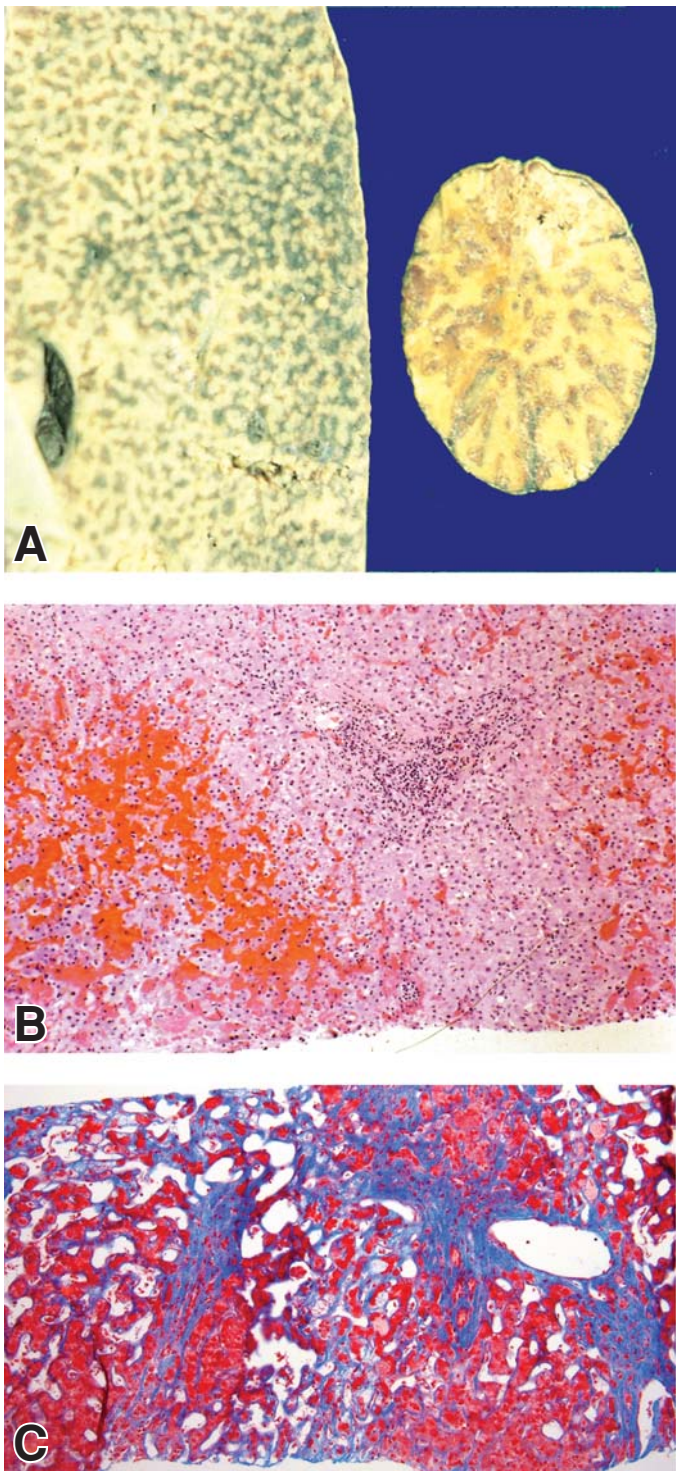

FIGURE 20-48. Chronic passive congestion of the liver. A. The surface of this fixed liver exhibits an accentuated lobular pattern, an appearance resembling that of a nutmeg (*right*). **B.** There is congestion and widening of central sinusoids. **C.** A Masson-trichrome stain shows fibrosis (*blue*) emanating out of central veins.

Liver Infarction Is Uncommon Because of Its Dual Blood Supply

Acute occlusion of the hepatic artery or its branches is rare and due to embolism, polyarteritis nodosa or accidental ligation

during surgery. In such an event, irregular pale areas, often surrounded by a hyperemic zone, reflect the ischemic necrosis.

Acute occlusion of intrahepatic branches of the portal vein, generally in the setting of elevated hepatic venous pressure, classically produces a **Zahn infarct,** a dark-red, triangular area with its base at the liver surface. Only sinusoidal dilation and congestion are present, not necrosis. Thus, the term *infarct* is actually a misnomer.

BACTERIAL INFECTIONS

Bacterial infections rarely cause liver disease in industrialized countries and are mostly complications of infections elsewhere. Granulomas, abscesses and diffuse inflammation are the most common. Infections associated with granulomatous inflammation elsewhere (e.g., tuberculosis, tularemia, brucellosis) also cause granulomatous hepatitis.

Pyogenic liver abscesses are usually caused by staphylococci, streptococci and gram-negative enterobacteria. Gut anaerobes, mostly *Bacteroides* and microaerophilic streptococci, commonly cause liver abscesses. These resemble abscesses in other sites. Organisms reach the liver in arterial or portal blood, or via the biliary tract. In sepsis, the liver is seeded with organisms from distant sites through the arterial blood.

Pylephlebitic abscesses (Fig. 20-49) result from intra-abdominal suppuration, as in peritonitis or diverticulitis, with the organisms entering the liver in the portal blood. Pylephlebitis was once the most common cause of hepatic abscesses, but with antibiotic control of abdominal sepsis, this has become an uncommon route of infection.

Cholangitic abscesses in the liver are the most common form of hepatic abscess in Western countries today. Biliary obstruction from any cause is often complicated by bacterial infection of the biliary tree, called **ascending cholangitis**. Retrograde biliary dissemination of organisms (usually *E. coli*) then leads to cholangitic abscesses.

Hepatic abscesses occur more commonly in the right lobe of the liver. Diffuse inflammation of the liver from bacterial infection is distinctly uncommon today but may be encountered in septicemia, particularly in immunocompromised patients. The source of infection is unknown in about 1/2 of cases.

FIGURE 20-49. Pylephlebitic abscesses of the liver. The cut surface of the liver shows large, confluent, irregular abscess cavities.

CLINICAL FEATURES: A patient with a hepatic abscess typically presents with high fever, rapid weight loss, right upper quadrant abdominal pain and hepatomegaly. Jaundice occurs in 1/4 of cases; serum alkaline phosphatase is almost always elevated. Solitary abscesses are treated with percutaneous or surgical drainage and antibiotics, but if abscesses are multiple, treatment is more problematic. The main complications are rupture and direct spread of infection. Pleuropulmonary fistulas, from rupture of an abscess through the diaphragm, and peritonitis, from leakage into the abdominal cavity, occur. Dissemination of organisms in the blood may promote septicemia and metastatic abscesses elsewhere in the body. The mortality from hepatic abscess, even when treated, is high, ranging from 40% to 80%.

PARASITIC INFESTATIONS

Parasitic disease in the liver is a serious public health problem worldwide but is rare in industrialized countries (for details, see Chapter 9). We summarize these diseases here.

Protozoal Diseases Frequently Involve the Liver

AMEBIASIS: In the United States, the carrier rate for *Entamoeba histolytica* in the colon is probably less than 5%, but rates approaching 35% are reported in homosexual men. Amebiasis of the liver, the most common extraintestinal site, causes amebic abscesses, which are multiple in about 1/2 of cases (Fig. 20-50). Amebic abscesses are 8–12 cm, well circumscribed and filled with thick, dark pasty material. Trophozoites are usually seen by the edge of the necrotic debris.

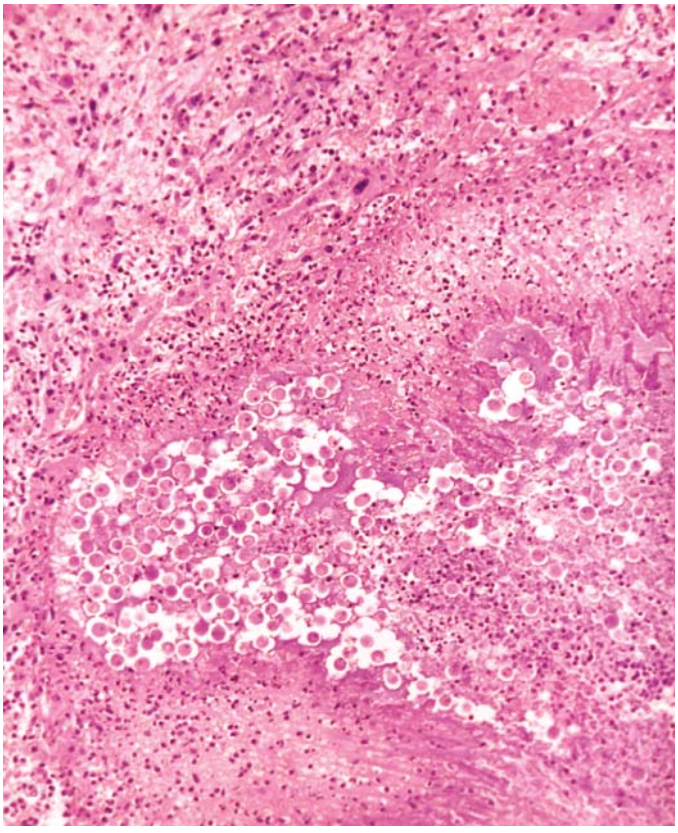

FIGURE 20-50. Amebic abscess of the liver. An amebic abscess shows fibroblastic proliferation surrounding the cavity and amebic trophozoites in the lumen.

The symptoms associated with amebic abscesses are similar to those of pyogenic abscesses. With appropriate treatment (tissue amebicides), the abscess may heal with only a residual scar remaining. Percutaneous or surgical drainage of large abscesses is important. If an amebic abscess continues to grow, it may rupture into the peritoneum and produce peritonitis, which carries a mortality rate as high as 40%. Amebae may also invade the blood and cause abscesses of the brain and lung.

MALARIA: Hepatic involvement in malaria is a common cause of hepatomegaly in endemic areas (see Chapter 9). It reflects Kupffer cell hypertrophy and hyperplasia owing to phagocytosis of debris from the rupture of parasitized erythrocytes. Liver function is intact.

VISCERAL LEISHMANIASIS (KALA-AZAR): As in malaria, chronic visceral leishmaniasis causes hyperplasia of mononuclear phagocytes in the liver. Unlike malaria, however, the Kupffer cells ingest the parasitic organisms themselves, which appear as **Donovan bodies**. Clinically, there is little evidence of hepatic dysfunction.

Helminthic Diseases Are Problems of Underdeveloped Areas

Diseases caused by helminths are described in Chapter 9, and **hepatic schistosomiasis** is discussed above in the context of portal hypertension.

ASCARIASIS: From the duodenum, *Ascaris lumbricoides* worms enter the biliary tree, where they may cause acute biliary colic. They lodge in intrahepatic biliary passages, where they disintegrate, liberating innumerable eggs that cause severe, suppurative cholangitis. Cholangitic abscesses may rupture into the peritoneum or pleural space. Spread into the hepatic or portal veins causes pylephlebitis, a highly dangerous complication. The liver is enlarged, with many irregular cavities full of foul-smelling material containing remnants of degenerated parasites.

LIVER FLUKES: The major parasitic flukes of the human liver are *Clonorchis sinensis* and *Fasciola hepatica.* Humans are the definitive host for *C. sinensis,* but sheep and cattle are the main reservoir of *F. hepatica.* Both parasites lodge in the intrahepatic biliary tree, where they provoke hyperplasia of the biliary epithelium, particularly severely in clonorchiasis (Fig. 20-51). In high-grade infestations with *C. sinensis,* degenerated worms, parasite eggs and viscid mucus (secreted by metaplastic goblet cells in the biliary epithelium) accumulate and obstruct intrahepatic bile flow. This leads to intrahepatic pigment gallstones. Secondary infection of the bile with *E. coli* causes cholangitis and cholangitic abscesses, which are common causes of surgical emergencies in some Asian countries. ***Biliary C. sinensis infestation is associated with the development of cholangiocarcinoma.***

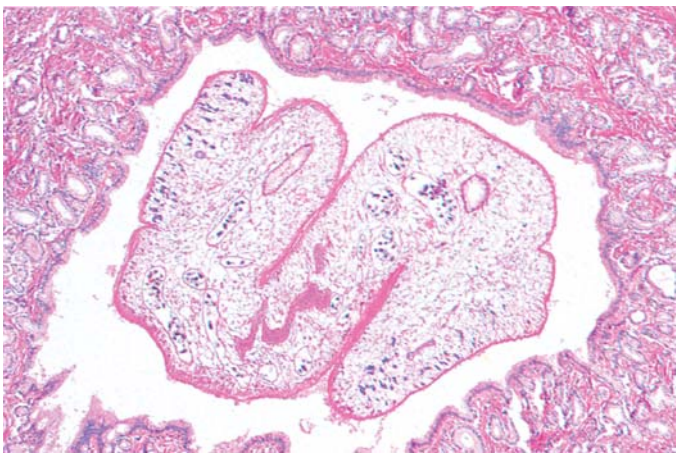

FIGURE 20-51. Infection of the liver by *Clonorchis sinensis.* The lumen of a bile duct contains an adult liver fluke, and the mucosa is hyperplastic.

ECHINOCOCCOSIS (CYSTIC HYDATID DISEASE): Hepatic infection with tapeworms of the genus *Echinococcus,* principally *E. granulosus,* is an important zoonosis affecting humans. Echinococcal cysts expand slowly and produce symptoms only after many years. The cysts behave as space-occupying lesions. Systemic manifestations reflect toxic or allergic reactions to the absorption of constituents of the organisms.

Leptospirosis Is an Accidental Human Infection from a Zoonosis

Leptospira spirochetes infect many animal species. Despite the large animal reservoir, fewer than 1/5 of patients who develop leptospirosis give a history of direct contact with animals. **Weil syndrome** is leptospirosis that is complicated by prolonged fever and jaundice, and, in severe cases, azotemia, hemorrhages and altered consciousness. Weil syndrome occurs in only 1%–6% of cases of leptospirosis. Liver pathology in fatal cases is nonspecific and includes focal necrosis, enlarged Kupffer cells and centrilobular cholestasis. The organisms are generally not demonstrable in the liver.

Liver Lesions May Occur in Congenital or Tertiary Syphilis

Congenital syphilis causes neonatal hepatitis, with diffuse fibrosis in portal tracts and around individual liver cells or groups of hepatocytes. In **tertiary syphilis,** hepatic gummas (i.e., focal lesions resembling granulomas) develop, which heal with dense scars. Retraction produces deep clefts and a gross pseudolobation of the liver called **hepar lobatum,** a condition that should not be confused with cirrhosis.

CHOLESTATIC SYNDROMES OF INFANCY

Diseases characterized by prolonged cholestasis and jaundice in infants either primarily affect hepatocytes or cause biliary obstruction.

Neonatal Hepatitis Entails Prolonged Cholestasis, Inflammation and Liver Cell Injury

ETIOLOGIC FACTORS: In about 1/2 of cases of neonatal hepatitis, the cause is known (Table 20-5). About 30% are due to α_1-AT deficiency. Most other cases of known etiology are due to congenital infections with HBV, toxoplasma, rubella, cytomegalovirus, herpes simplex virus or other agents. Hepatic injury caused by metabolic defects (e.g., galactosemia or fructose intolerance) account for some cases, and neonatal hepatitis occurs occasionally in patients with Down syndrome and other chromosomal disorders. The other 1/2 of cases of neonatal hepatitis are unexplained.

TABLE 20-5
CAUSES OF NEONATAL HEPATITIS

Idiopathic
Idiopathic neonatal hepatitis
Prolonged intrahepatic cholestasis
Arteriohepatic dysplasia (Alagille syndrome)
Paucity of intrahepatic bile ducts not associated with specific syndromes
Zellweger syndrome (cerebrohepatorenal syndrome)
Byler disease
Mechanical Obstruction of the Intrahepatic Bile Ducts
Congenital hepatic fibrosis
Caroli disease (cystic dilation of intrahepatic ducts)
Metabolic Disorders
Defects of carbohydrate metabolism
Galactosemia
Hereditary fructose intolerance
Glycogenosis type IV
Defects in lipid metabolism
Gaucher disease
Niemann-Pick disease
Wolman disease
Tyrosinemia (defect of amino acid metabolism)
α_1-Antitrypsin deficiency
Cystic fibrosis
Parenteral nutrition
Hepatitis
Hepatitis B
TORCH agents (toxoplasmosis, "other," rubella, cytomegalovirus and herpes simplex)
Varicella
Syphilis
ECHO (enteric cytopathic human orphan) viruses
Neonatal sepsis
Chromosomal Abnormalities
Down syndrome
Trisomy 18
Extrahepatic Biliary Obstruction

PATHOLOGY: The characteristic lesion of neonatal hepatitis is giant cell transformation of hepatocytes, hence the older term **giant cell hepatitis** (Fig. 20-52). These giant cells may contain up to 40 nuclei and may appear detached from other cells in the liver plate. Their pale, distended cytoplasm contains large amounts of glycogen and iron. Numbers of these cells decline with time, and they are rare in children older than 1 year. Bile pigment is prominent within canaliculi and hepatocytes. Ballooned

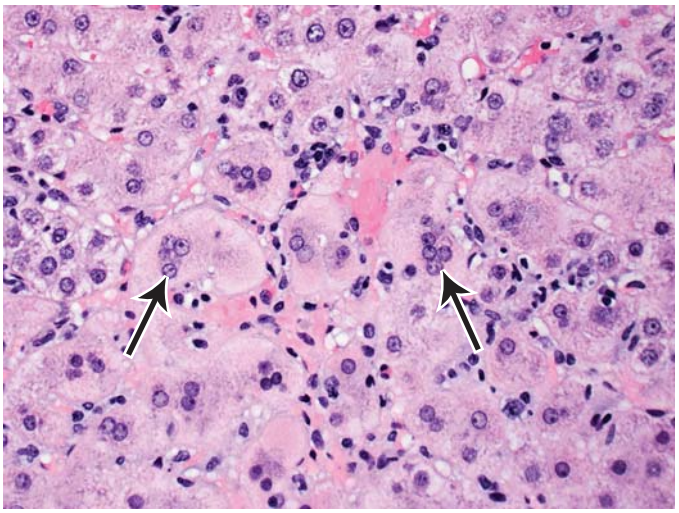

FIGURE 20-52. Neonatal hepatitis. Severe hepatocyte swelling (hydropic change), multinucleated giant hepatocytes (*arrows*), a mild chronic inflammatory infiltrate and fibrosis.

hepatocytes, acinar transformation of hepatocytes and acidophilic bodies are also typical of neonatal hepatitis. Extramedullary hematopoiesis is often conspicuous. Chronic inflammatory infiltrates are seen in the portal tracts as well as in the lobular parenchyma. Pericellular fibrosis around degenerating hepatocytes, singly or in groups, is common, and fibrous tissue septa extend from the portal tracts.

Part of the Biliary Tree Has No Lumen in Biliary Atresia

Extra- and intrahepatic biliary atresias may resemble neonatal hepatitis pathologically.

Extrahepatic Biliary Atresia

EHBA is a cholestatic disease in which inflammation obliterates the lumen of all or part of the biliary tree outside the liver, in the absence of calculi, tumor or rupture. EHBA is rare. Its estimated incidence is 1 in 5000–19,000 live births, with higher frequency being in East Asia. Biliary atresia is the most common indication for liver transplantation in children. EHBA is thought to represent the end result of heterogeneous conditions during gestational and perinatal development. Other organs, including the heart, intestine and spleen, show anomalies in 20% of cases. EHBA may occur together with known causes of neonatal hepatitis, such as a number of viral infections and chromosomal abnormalities (e.g., trisomy 18 and 21). Cholangiograms in EHBA show no bile flow into the duodenum or liver, depending on the site of the affected segment of the biliary tract.

PATHOLOGY: EHBA may involve all extrahepatic bile ducts or may be limited to parts of the proximal or distal biliary tree. The gallbladder is often atretic. At one extreme, acute and chronic periluminal inflammation is prominent, with epithelial necrosis, and cellular debris within the obstructed or narrowed lumen. At the other extreme, the original lumen is completely replaced by mature connective tissue, and little or

no inflammation is seen. Histologically, cholestasis and periportal bile ductular proliferation in the liver are evident. Some cases have multinucleated giant hepatocytes, like those in neonatal hepatitis. Although the intrahepatic bile ducts may initially appear normal, they are gradually obliterated with the persistence of cholestasis. Eventually, secondary biliary cirrhosis supervenes.

Intrahepatic Biliary Atresia

In intrahepatic biliary atresia, there are few bile ducts within the liver. This occurs under three circumstances:

- In association with known causes of neonatal hepatitis (e.g., α_1-AT deficiency, various chromosomal anomalies and metabolic derangements).
- **Alagille syndrome** (syndromic bile duct paucity), an autosomal dominant disease, also characterized by congenital abnormalities of the heart, eye, skeleton, kidneys and CNS. This syndrome involves mutations in the Notch signaling pathway. Affected patients show five major features: chronic cholestasis, peripheral pulmonary artery stenosis, butterfly-like vertebral arch, hypertelic facies and eye abnormality known as posterior embryotoxon. The liver pathology is characterized by the absence of bile ducts in portal tracts.
- Unassociated with other conditions (idiopathic).

Neonatal hepatitis, intrahepatic biliary atresia, EHBA and possibly choledochal cyst all probably result from infantile obstructive cholangiopathy, a common inflammatory process.

PATHOLOGY: In intrahepatic biliary atresia, there are very few bile ducts in the liver. Giant cell transformation, cholestasis and bile ductular proliferation are common; cirrhosis is not.

CLINICAL FEATURES: Most patients with uncomplicated neonatal hepatitis recover without sequelae, but if it is associated with intrahepatic biliary atresia, the prognosis is poor. Many such children develop biliary cirrhosis. By contrast, the outlook in Alagille syndrome is good. If uncorrected, EHBA invariably leads to progressive secondary biliary cirrhosis and death. Surgical correction may be curative in some anatomically favorable cases, but transplantation is the best treatment for both extra- and intrahepatic biliary atresia.

BENIGN TUMORS AND TUMOR-LIKE LESIONS

Liver Adenomas Are Benign Tumors That Occur Mainly in Women

Once rare, these tumors became more common with oral contraceptive use. Lower-dose estrogen and progesterone combinations have reduced the incidence of liver adenomas.

PATHOLOGY: Hepatocellular adenomas are usually solitary, sharply demarcated masses measuring up to 40 cm and weighing 3 kg (Fig. 20-53A). Multiple smaller adenomas are present in 1/4 of cases. If a liver has more than 10 adenomas, it is diagnosed as hepatocellular adenomatosis. These tumors are encapsulated and paler than nearby liver parenchyma. ***The neoplastic hepatocytes resemble normal hepatocytes but are not arrayed in a lobular architecture.*** Portal tracts and central venules are absent (Fig. 20-53B). The cells of adenomas may be very large and eosinophilic, or filled with glycogen or fat, which makes the cytoplasm appear clear or vacuolated. The presence of small arteries within the parenchyma suggests an adenoma as opposed to normal liver.

CLINICAL FEATURES: In about 1/3 of patients with hepatic adenomas (particularly pregnant women who have used oral contraceptives), these tumors bleed into the peritoneal cavity and require immediate surgery. Even large adenomas may disappear if oral contraceptives are discontinued. Occasional liver adenomas have been reported in men who use anabolic steroids.

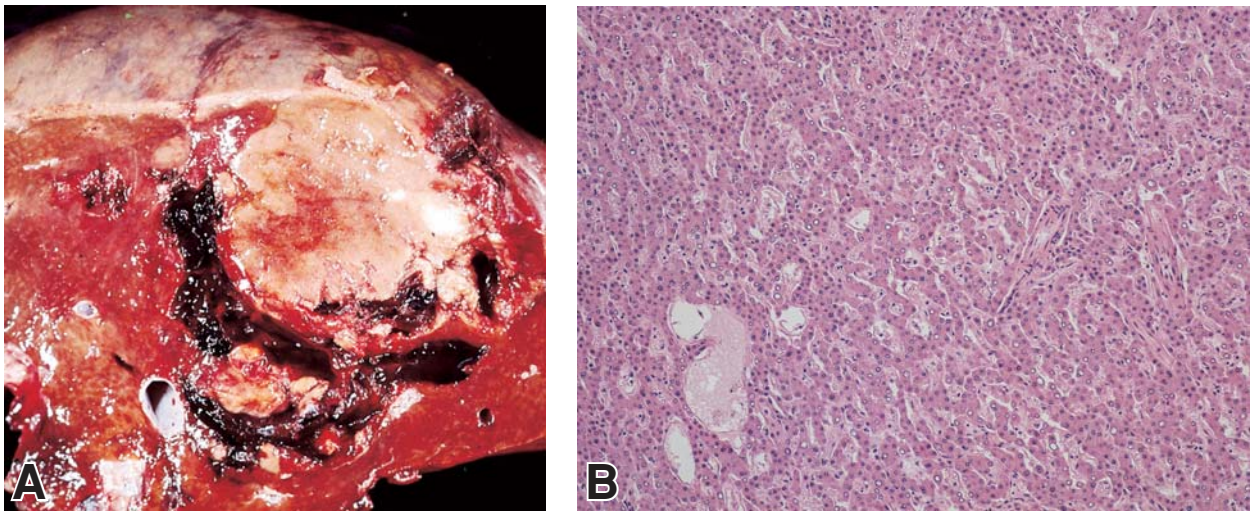

FIGURE 20-53. Hepatocellular adenoma. A. A surgically resected portion of liver shows a tan, lobulated mass beneath the liver capsule. The tumor has ruptured, resulting in intraparenchymal and intraperitoneal hemorrhage. The patient was a woman who had taken birth control pills for a number of years and presented with sudden intraperitoneal bleeding. **B.** The adenomatous hepatocytes do not differ from normal hepatocytes and are arranged without discernible lobular architecture. Note the absence of portal tracts.

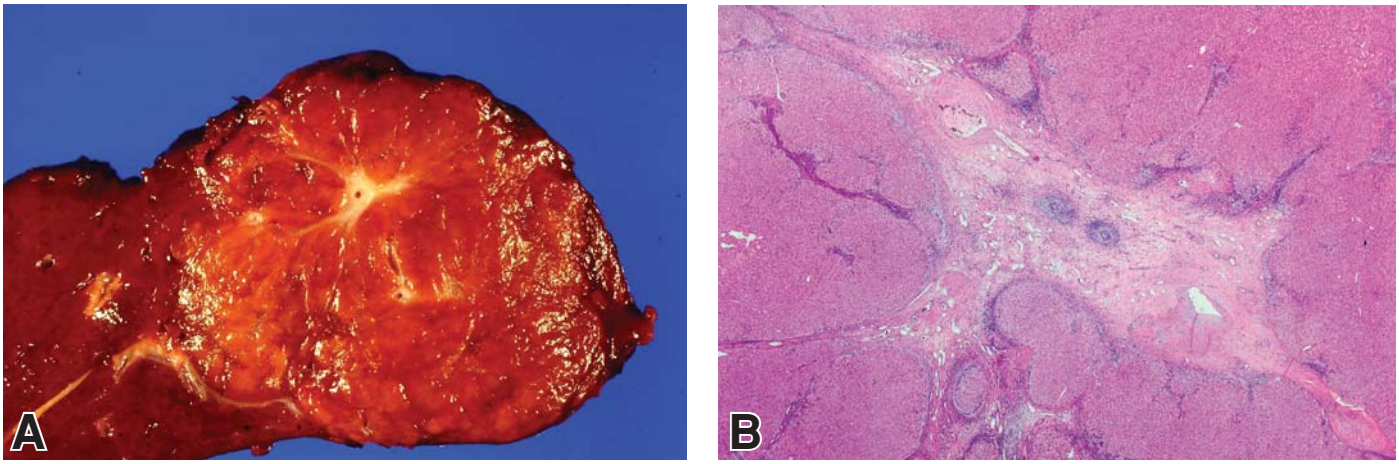

FIGURE 20-54. Focal nodular hyperplasia. A. A resected mass shows nodules with central scarring. **B.** This surgically resected mass from the liver shows a vascular central scar and irregular fibrous septa dissecting hepatic parenchyma, accounting for the resemblance to cirrhosis.

Focal Nodular Hyperplasia Resembles Cirrhosis

Focal nodular hyperplasia (FNH) is characterized by multiple fibrous septa and regenerative nodules (Fig. 20-54A). It measures up to 15 cm and weighs as much as 700 g. On occasion, FNH protrudes from the surface of the liver, and it may even be pedunculated. The cut surface has a central scar from which fibrous septa radiate. Hepatocytic nodules are circumscribed by fibrous septa (Fig. 20-54B), with many tortuous bile ductules and mononuclear inflammatory cells. Lobular architecture is absent within nodules. Septa contain large dystrophic arteries and veins, but little hemorrhage. These abnormal vessels suggest that FNH forms as a result of localized vascular malformation.

FNH occurs in both sexes and at all ages. It is not a neoplasm, is not associated with use of oral contraceptives, and rarely bleeds.

Nodular Regenerative Hyperplasia Causes Portal Hypertension

Nodular regenerative hyperplasia is also called *nodular transformation of the liver* or *partial nodular transformation.* It is neither neoplastic nor preneoplastic and is characterized by small, hyperplastic nodules without fibrosis in an otherwise normal liver. The lesion may be partial and located predominantly in the perihilar region, or it may be diffuse throughout the liver. Nodules are composed of liver cells in plates two and three cells thick, compressing the surrounding parenchyma.

Nodular regenerative hyperplasia is associated with portal hypertension and was once called **noncirrhotic portal hypertension**. Its etiology is unknown, but it has been associated with use of oral contraceptives or anabolic steroids, extrahepatic infections, tumors and chronic inflammatory and autoimmune diseases.

Hemangiomas Are the Most Common Tumors of the Liver

Benign hemangiomas in the liver occur at all ages and in both sexes. They are common, being present in up to 7% of autopsy livers (Fig. 20-55). They are normally small and asymptomatic, although larger tumors may cause abdominal symptoms and even hemorrhage into the peritoneum. Grossly, hemangiomas are usually solitary and under 5 cm, but multiple hemangiomas and giant forms (>15 cm) have been described. They resemble cavernous hemangiomas found elsewhere (see Chapter 10).

Cystic Disease of the Liver Represents a Spectrum of Lesions

BILE DUCT MICROHAMARTOMAS: These clinically inapparent lesions (also called *von Meyenburg complexes*) have anomalous, small cystic bile ducts in a fibrous stroma. They are usually multiple and vary from pinpoint grayish white foci to nodules up to 1 cm. Cysts are lined by bile duct epithelium and may have inspissated bile (Fig. 20-56).

SOLITARY AND MULTIPLE SIMPLE CYSTS: Simple liver cysts are lined by cuboidal to columnar epithelium and may be associated with adult polycystic kidney disease (see Chapter 16). They may be seen in livers with von Meyenburg complexes.

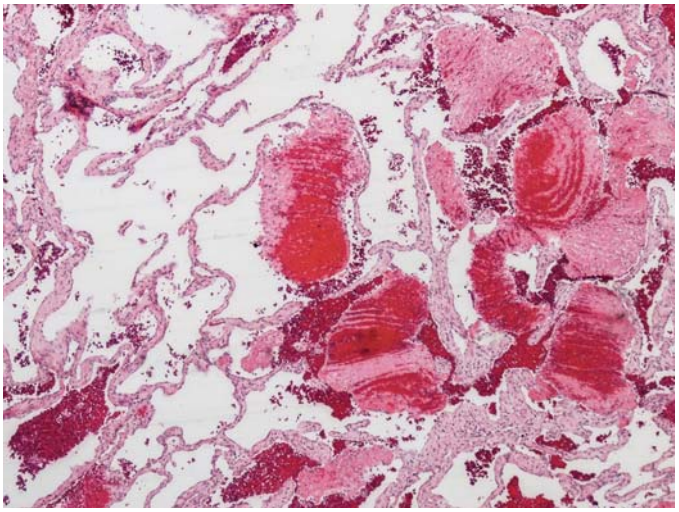

FIGURE 20-55. Cavernous hemangioma. A benign vascular tumor composed of blood-filled cavernous spaces.

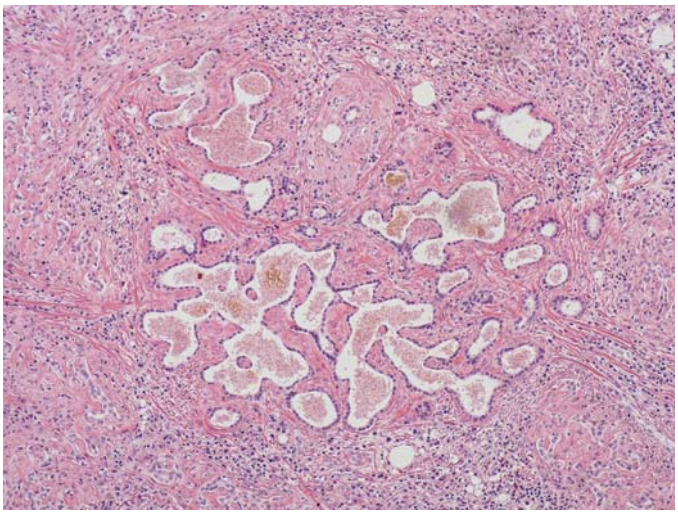

FIGURE 20-56. Bile duct microhamartoma (von Meyenburg complex). A photomicrograph of bile duct microhamartoma composed of cystically dilated spaces lined by a single layer of duct epithelium and containing inspissated bile.

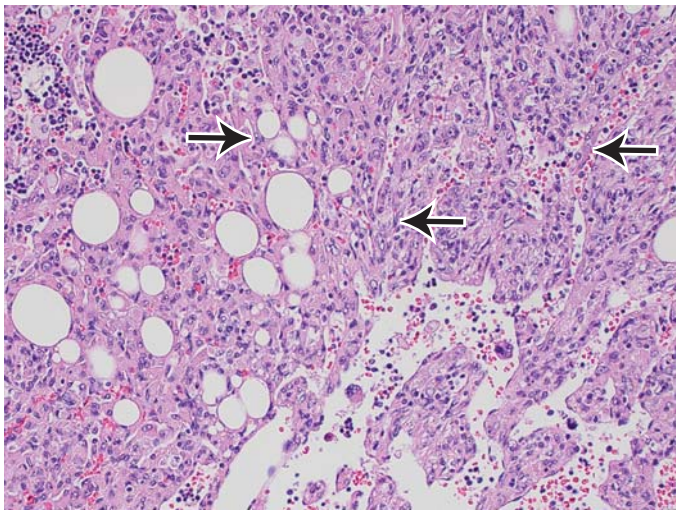

FIGURE 20-58. Angiomyolipoma. An angiomyolipoma composed of mixtures of epithelioid and spindle-shaped smooth muscle (*arrows*), vascular spaces and round fat cells.

CONGENITAL HEPATIC FIBROSIS: This recessively inherited disorder is marked by enlarged portal tracts with extensive fibrosis and many well-formed bile ductules (Fig. 20-57). It is seen mainly in children and adolescents. Bile ducts may be so dilated that they resemble microcysts, but they still communicate with the biliary system. Regenerative nodules are absent, distinguishing this condition from cirrhosis. The origin of the lesion is unknown. The main complication of congenital hepatic fibrosis is severe portal hypertension with recurrent bleeding from esophageal varices. **Infantile polycystic disease** of the liver resembles congenital hepatic fibrosis and is also inherited as an autosomal recessive trait.

Angiomyolipoma Is a Benign Tumor of Stromal Elements

Angiomyolipoma is a rare tumor composed of varying proportions of blood vessels, smooth muscle and mature fatty tissue (Fig. 20-58). It is derived from perivascular epithelial cells (PECs) and thus belongs to a group of tumors usually associated with tuberous sclerosis, referred as PEC-omas. Hepatic angiomyolipomas resemble the more common angiomyolipoma of the kidney (see Chapter 16).

Infantile Hemangioendothelioma Is a Type of Hemangioma That Occurs in Infants

Infantile hemangioendothelioma is a benign vascular tumor of intercommunicating vascular channels lined by a single layer of plump endothelial cells in a fibrous stroma (Fig. 20-59). It is mostly found in infants, usually females. Spontaneous involution is common. A large tumor may cause high-output cardiac or liver failure.

Mesenchymal Hamartoma Is a Developmental Malformation

Mesenchymal hamartoma is a benign liver tumor formed as a developmental malformation of liver mesenchyme. It

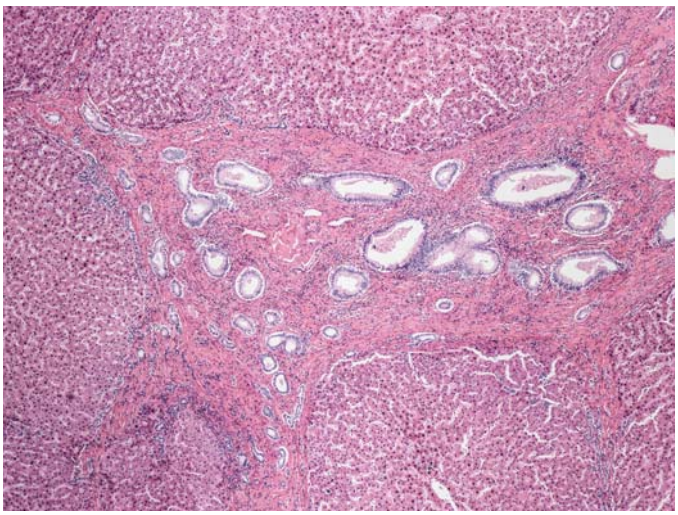

FIGURE 20-57. Congenital hepatic fibrosis. Enlarged and fibrotic portal tract containing ductal plate remnant microcysts.

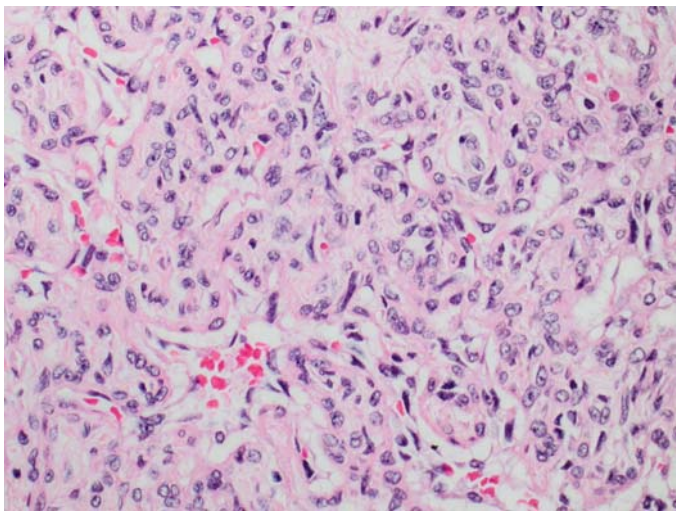

FIGURE 20-59. Infantile hemangioendothelioma. Plump endothelial cells lining anastomosing slit-like vascular spaces.

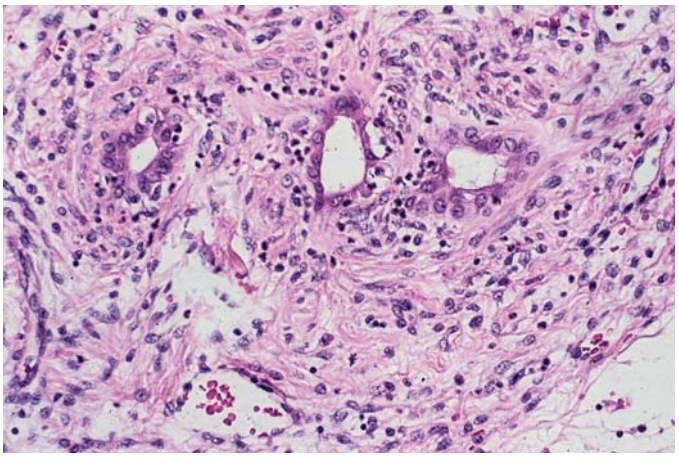

FIGURE 20-60. Mesenchymal hamartoma. Bile ducts in loose mesenchymal tissue stroma.

shows large, serous fluid cysts surrounded by loose mesenchyme containing a mixture of bile ducts, hepatocyte cords and clusters of vessels (Fig. 20-60). The mesenchymal tissue consists of scattered stellate-shaped cells in a loose matrix. Complete surgical excision is curative.

MALIGNANT TUMORS OF THE LIVER

Hepatocellular Carcinoma Is a Malignant Tumor of Hepatocytes

EPIDEMIOLOGY: HCC is probably the most common human cancer. It occurs all over the world but shows a striking geographical variability. In Western industrialized countries, HCC is uncommon, but its incidence has nearly doubled in the past 20 years, mostly in patients with chronic hepatitis C. In sub-Saharan Africa, Southeast Asia and Japan, HCC may occur up to 50 times more often. For example, in Mozambique, which has the highest incidence in the world, 2/3 of all cancers in men and 1/3 in women are HCC.

PATHOPHYSIOLOGY:

HEPATITIS B: More than 85% of cases of HCC occur in countries with a high prevalence of chronic HBV infection. Most patients have had chronic hepatitis B for years, often after perinatal transmission from an infected mother to her newborn child. Persistent HBV infection is very dangerous, with up to 200-fold increased risk for HCC. Of people with chronic hepatitis B acquired at or near birth, 1/4 will ultimately develop HCC. Risk of this cancer in men who are positive for HBsAg and HBeAg is about four times as great as in those only positive for HBsAg. Most (>80%) cases of HCC associated with HBV infection occur in patients with cirrhosis.

Cirrhosis has been blamed for the development of HCC in HBV-infected livers, but many HBV-associated HCCs occur in patients without cirrhosis. It is likely that integration of the HBV genome into cell DNA and expression of HBV genes are the key factors. Thus, the *X* gene of HBV encodes a viral protein (HBxAg) that inactivates tumor suppressor proteins and transactivates certain oncogenes.

HEPATITIS C: HCV is less common than HBV worldwide, but most cases of HCC in Europe, North America and Japan are associated with hepatitis C. In the United States, HCV infection is present in about 50% of HCC. As with HCC in hepatitis B, most patients with HCV who develop HCC have underlying cirrhosis, and the cumulative occurrence of HCC in HCV-induced cirrhosis is as high as 70% after 15 years.

Coinfection with HBV and HCV increases the risk of liver cancer threefold, relative to infection with either virus alone. Carcinogenesis by HCV is poorly understood, but interactions between virus proteins and cellular constituents is likely involved.

OTHER CAUSES OF HEPATOCELLULAR CARCINOMA: Alcoholic cirrhosis predisposes to HCC, but the risk is not large, and the mechanism is unknown. Because many alcoholics are infected with HBV and HCV, the role of alcohol alone in HCC is difficult to determine. Alcoholics with chronic hepatitis C have double the risk for HCC compared with HCV infection alone.

Hemochromatosis and **α_1-AT deficiency** carry a substantial risk of HCC: about 10% of patients with hemochromatosis may be expected to develop the tumor. On the other hand, HCC is not increased in patients with "autoimmune" chronic hepatitis and cirrhosis, WD or PBC. ***As with HCC in patients with chronic hepatitis B without cirrhosis, this suggests that cirrhosis itself is not sufficient to cause liver cancer but that it may magnify HCC risk due to other etiologies.***

Aflatoxin B_1 is a fungal contaminant of many foods, mostly in less developed countries. It causes HCC in a number of animal species. The incidence of liver cancer in humans correlates roughly with dietary content of aflatoxin. The presence of urinary aflatoxin B_1 metabolites is associated with a 3-fold increased risk of HCC. Aflatoxin and HBV infection are synergistic; combined exposure increases the risk of HCC 60-fold.

Mutations in the *TP53* gene are present in 1/2 of DNA samples from HCCs occurring in areas endemic for aflatoxin. Most of these mutations are G-to-T substitutions at codon 249, a change that is produced experimentally by aflatoxin B_1.

PATHOLOGY: HCCs are solitary or multiple soft, hemorrhagic tan masses (Fig. 20-61A). Occasionally, a green color indicates bile production. HCCs tend to grow into portal and hepatic veins, and they may extend from the latter into the vena cava and even the right atrium. The tumor may spread widely, but metastases favor the lungs and portal lymph nodes.

HCCs range from so well differentiated as to be hard to distinguish from normal liver to anaplastic or undifferentiated neoplasms. In most, tumor cells are arranged in trabeculae or plates as in normal liver ("trabecular pattern"). These plates are separated by endothelium-lined sinusoids. In a "pseudoglandular (adenoid, acinar) pattern," malignant hepatocytes are arranged around a lumen, which may contain

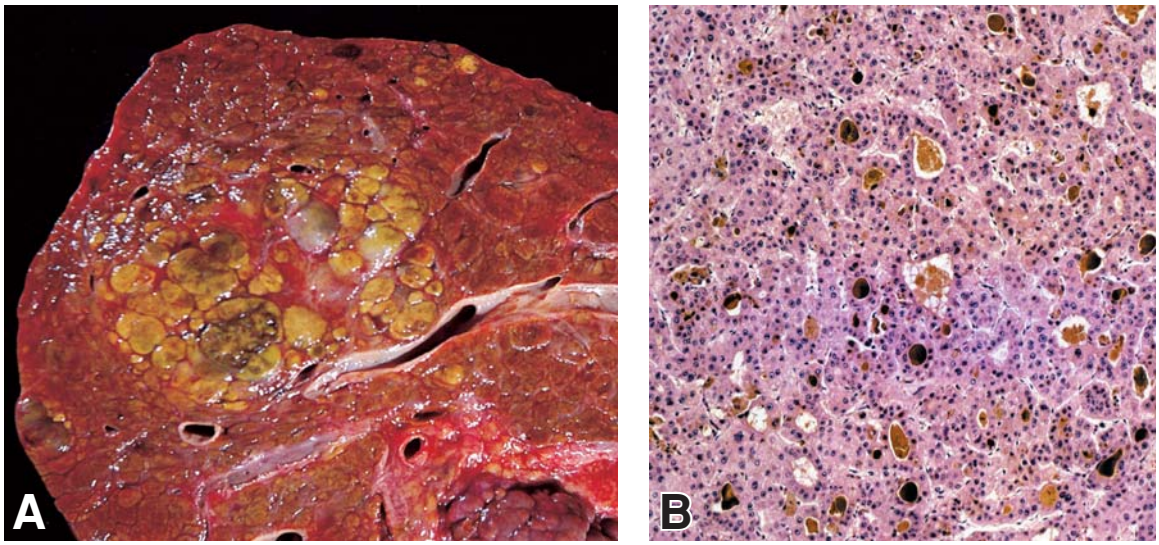

FIGURE 20-61. Hepatocellular carcinoma (HCC). A. Cross-section of a cirrhotic liver shows a poorly circumscribed, nodular area of yellow, partially hemorrhagic HCC. **B.** In this moderately differentiated tumor, HCC cells are arranged in an acinar pattern and surround concretions of inspissated bile.

bile (Fig. 20-61B). Despite their resemblance to glands, these are not true glands, and the lesion should not be confused with cholangiocarcinoma or other adenocarcinomas. Neither histologic pattern carries a particular prognostic significance.

Fibrolamellar HCC is an uncommon variant with a distinctive histology. It arises in apparently normal livers, mostly in adolescents and young adults, and is composed of clusters of large, eosinophilic, neoplastic hepatocytes surrounded by delicate collagen fibers (Fig. 20-62). The prognosis of fibrolamellar HCC is similar to that of other types of HCC.

CLINICAL FEATURES: HCC usually presents as a painful and enlarging mass. If discovered at an advanced stage, the prognosis is dismal. Patients die of malignant cachexia, rupture of the tumor with catastrophic bleeding into the peritoneal cavity or complications of cirrhosis.

HCC may cause paraneoplastic syndromes (e.g., polycythemia, hypoglycemia, hypercalcemia) due to ectopic hormone production by the tumor. α-Fetoprotein (AFP) levels are often elevated, as in other benign and malignant liver diseases and some extrahepatic disorders.

If a small tumor is confined to one hepatic lobe, segmental resection can provide acceptable tumor-free survival rates. Ablative therapies (e.g., absolute alcohol injection, radiofrequency ablation, cryotherapy and transarterial embolization) can slow tumor progression. In patients with cirrhosis and limited tumor burden, liver transplantation gives the best tumor-free survival.

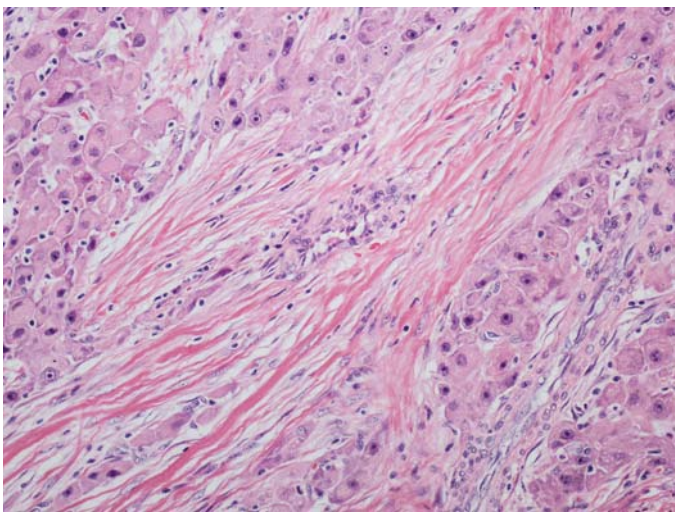

FIGURE 20-62. Fibrolamellar hepatocellular carcinoma. Clusters of eosinophilic tumor cells with abundant cytoplasm are separated by a lamellated fibrous band.

Cholangiocarcinomas Arise from Biliary Epithelium

Cholangiocarcinoma is a bile duct carcinoma that originates anywhere in the biliary tree, from large intrahepatic bile ducts at the porta hepatis to the smallest ducts at the edges of hepatic lobules, and peribiliary glands. It occurs mainly in older people of both sexes, with an average age at presentation of 60 years. It may occur anywhere but is particularly common in parts of Asia where the liver fluke (*C. sinensis*, see above) is endemic. In fact, the incidence of cholangiocarcinoma is also increasing in association with hepatitis C. PSC predisposes strongly to cholangiocarcinoma. Of livers with PSC removed for transplantation, 1/4 have cholangiocarcinoma. Choledochal cysts and Caroli disease (see below) are also risk factors.

PATHOLOGY: Peripheral tumors or intrahepatic cholangiocarcinomas contain small cuboidal cells in ductular or glandular patterns (Fig. 20-63). They often show substantial fibrosis and thus may be confused with metastatic breast or pancreas carcinomas on liver biopsy. Tumors with both HCC and intrahepatic cholangiocarcinoma morphology are **combined hepatocellular-cholangiocarcinoma**.

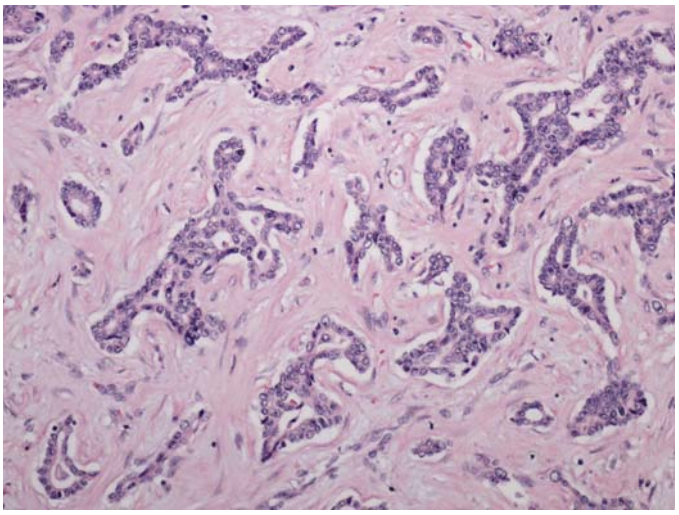

FIGURE 20-63. Cholangiocarcinoma. Well-differentiated neoplastic glands are embedded in a dense fibrous stroma.

Hilar cholangiocarcinomas are bile duct carcinomas that arise around the convergence of the right and left hepatic ducts. They present as (1) small sclerosing tumors that obliterate the duct, (2) tumors that spread within the duct wall or (3) a rare intraductal papillary variant. They may grow to "mass-forming" tumors. All produce symptoms of extrahepatic biliary obstruction.

Cholangiocarcinomas invade portal and hepatic veins less than do HCCs. They spread locally along nerves and metastasize throughout the body, particularly to portal lymph nodes. Liver transplantation is rarely successful in eradicating the tumor.

Hepatoblastoma Is a Rare Malignant Tumor of Children

Hepatoblastomas are usually discovered at birth or before the age of 3 years.

PATHOLOGY: Hepatoblastomas are circumscribed masses up to 25 cm that are partially necrotic and hemorrhagic, with epithelial- and mesenchymal-appearing cells. Occasionally, the latter are not seen. The epithelial component resembles embryonic and fetal cells. "Embryonal" cells are small and fusiform, arranged in ribbons or rosettes. The "fetal" cells resemble hepatocytes, contain glycogen and fat and form trabeculae with intervening sinusoids. The mesenchymal elements include connective tissue, cartilage and osteoid. Foci of squamous epithelium are occasionally encountered.

CLINICAL FEATURES: Abdominal enlargement, vomiting and failure to thrive are common presenting symptoms. Serum AFP is almost always elevated, and occasionally secretion of ectopic gonadotropin leads to sexual precocity. Congenital anomalies, including cardiac and renal malformations, hemihypertrophy and macroglossia, may be present. Untreated, these tumors are fatal, but liver transplantation or partial hepatectomy is often curative.

Epithelioid Hemangioendothelioma Is a Low-Grade Malignancy

This type of vascular tumor occurs predominantly in middle-aged women.

PATHOLOGY: Epithelioid hemangioendotheliomas typically may be single or multiple firm, gray tumors. They have a zonal pattern of cellularity with a hypocellular central area and a hypercellular periphery, the latter corresponding to its advancing front. The central zone is often sclerotic or calcified. Tumor cells, which are endothelial in origin, are spindle shaped, dendritic patterned or epithelioid (Fig. 20-64). The latter commonly form lumina, which may contain red blood cells.

CLINICAL FEATURES: Patients present with abdominal pain, enlarging mass, weight loss or malaise. Imaging studies show single or multiple avascular or calcified tumors. Treatment includes surgical resection for localized tumor or liver transplantation for patients with multiple tumors.

Hemangiosarcoma May Result from Chemical Exposures

Hemangiosarcoma is the only significant sarcoma of the liver. It is linked to thorium dioxide, vinyl chloride or inorganic arsenic and is now distinctly uncommon.

PATHOLOGY: These are mostly multicentric tumors, starting as multiple hemorrhagic nodules that may coalesce. Spindle-shaped, neoplastic, endothelial cells line sinusoids and compress liver cell plates (Fig. 20-65). Cavernous blood spaces and solid masses of neoplastic cells are common. Widespread metastases are usual.

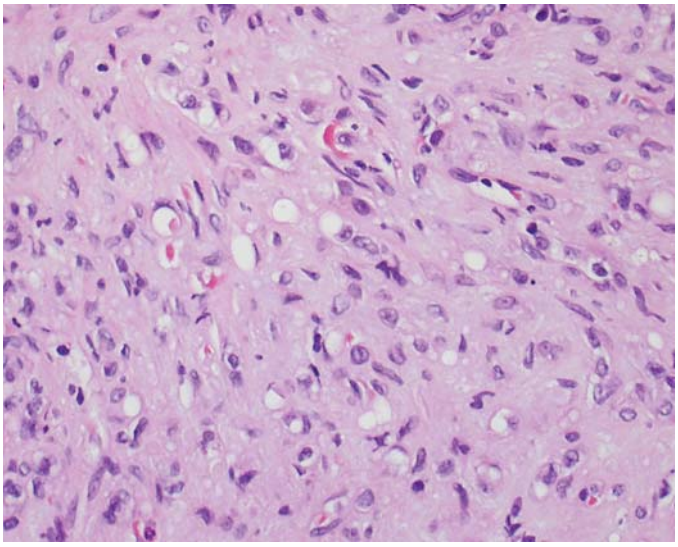

FIGURE 20-64. Epithelioid hemangioendothelioma. The tumor cells are scattered in a fibrous stroma. Some of them resemble a signet ring with intracellular lumen containing red blood cells.

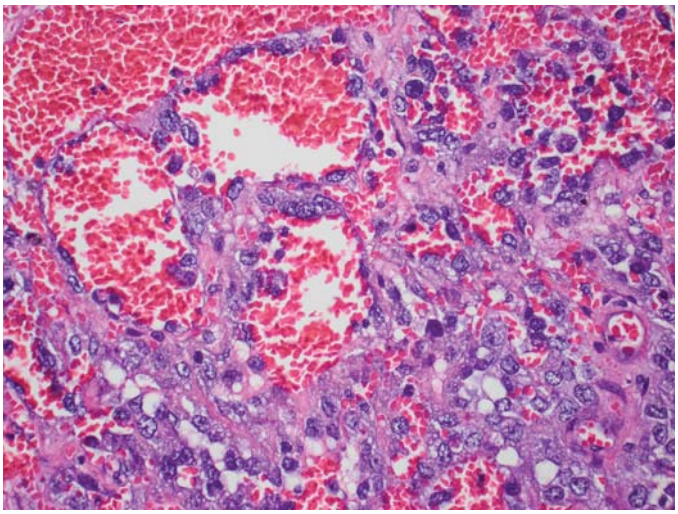

FIGURE 20-65. Hemangiosarcoma. Tumor cells with bizarre nuclei line the vascular spaces.

CLINICAL FEATURES: Patients present with hepatomegaly, jaundice and ascites. Hematologic abnormalities, including pancytopenia and hemolytic anemia, are often prominent and in many cases due to splenomegaly from noncirrhotic portal hypertension. Tumor rupture with vigorous intra-abdominal hemorrhage is common. The prognosis is dismal.

Metastatic Cancer Is the Most Common Malignancy in the Liver

Of all metastatic cancers, 1/3 affect the liver, including 1/2 of cancers of the gastrointestinal tract, breast and lung. Pancreatic carcinoma, malignant melanoma and hematologic malignancies also often metastasize the liver, but any tumor may do so.

PATHOLOGY: The liver may have a single metastatic nodule or be almost replaced by metastases (Fig. 20-66). The organ may exceed 5 kg. ***Such metastases are the most common cause of massive hepatomegaly.*** Metastatic tumors can appear on the liver surface as umbilicated masses. Hepatic metastases tend to resemble their primary tumors but may be so poorly differentiated that a primary site cannot be determined.

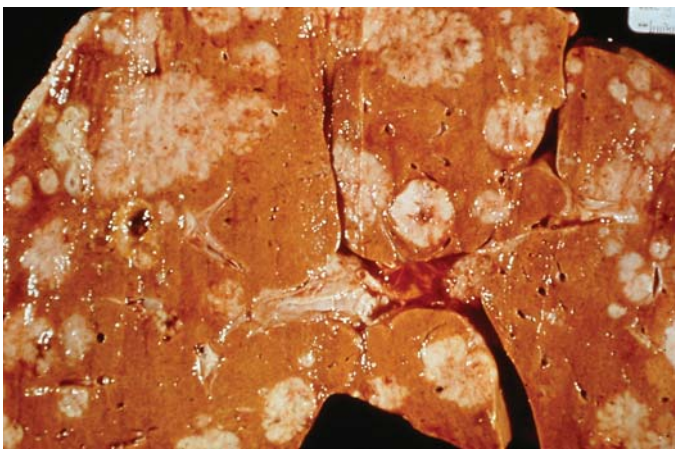

FIGURE 20-66. Metastatic carcinoma in the liver. The cut surface of the liver shows many firm, pale masses of metastatic colon cancer.

CLINICAL FEATURES: Metastatic cancers to the liver often present with weight loss. Portal hypertension and its complications may occur. Bile duct obstruction or replacement of most of the liver parenchyma may cause jaundice. If the patient lives long enough, hepatic failure may ensue. Often the first indication of a metastatic tumor is an unexplained increase in serum alkaline phosphatase. Most patients die within a year of diagnosis, but surgical resection of a solitary metastasis may be curative.

LIVER TRANSPLANTATION

The increasing use of hepatic transplantation and the diagnosis and treatment of allograft rejection require useful pathologic criteria by which outcome can be assessed and therapy recommended.

PATHOLOGY: In acute rejection, bile ducts are distorted by mixed cellular portal inflammation that may involve the ductal epithelium itself. Eosinophils are almost always present. Epithelial atypia may be seen (Fig. 20-67). Lymphocytes often adhere to the endothelium of terminal venules and small branches of the portal veins, with or without subendothelial inflammation (endothelialitis).

In allograft rejection lasting more than 2 months, there is damage to interlobular bile ducts. These small bile ducts are progressively destroyed, causing persistent cholestasis, the end stage of which is **chronic ductopenic rejection** or

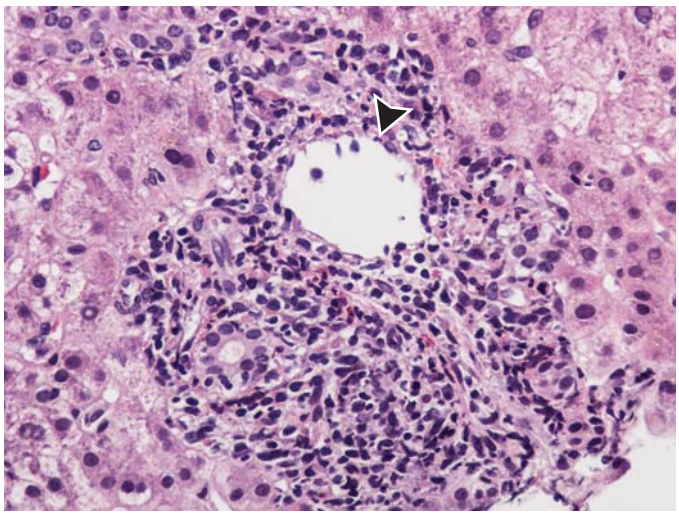

FIGURE 20-67. Acute rejection of a liver allograft. A portal tract is expanded by a polymorphous inflammatory infiltrate consisting of large and small lymphocytes, plasma cells, macrophages, neutrophils and eosinophils. The bile ducts (*arrows*) are damaged. A vein (*arrowhead*) is also inflamed (endophlebitis).

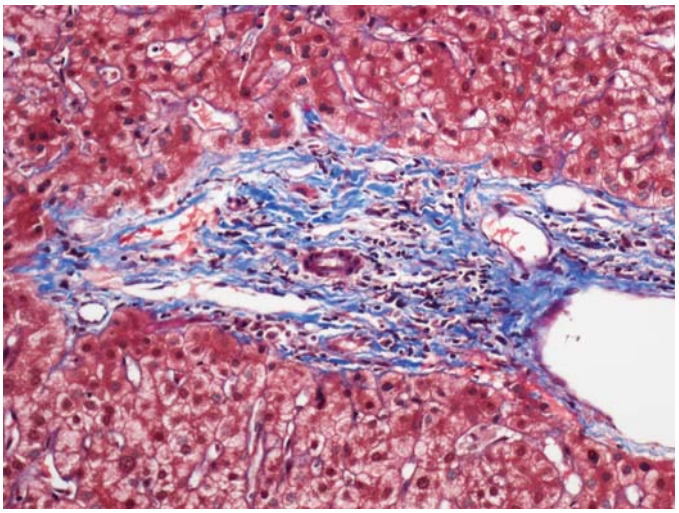

FIGURE 20-68. Chronic ductopenic rejection (vanishing bile duct syndrome). A portal tract shows mild chronic inflammation and absence of the bile duct.

vanishing bile duct syndrome (Fig. 20-68). Subintimal foam cells, intimal sclerosis and myointimal hyperplasia may cause arterial narrowing or occlusion (Fig. 20-69).

The Gallbladder and Extrahepatic Bile Ducts

ANATOMY

The gallbladder is a thin, elongated sac about 8 cm long and about 50 mL in volume, which occupies a fossa on the inferior surface of the liver between the right and quadrate lobes. It originates from the same foregut diverticulum that gives rise to the liver. Its primary function is storage, concentration and release of bile. The cystic duct is about 3 cm long and drains the gallbladder into the hepatic duct. It conducts dilute bile from the hepatic duct into the gallbladder, where it is concentrated and subsequently discharged into the common bile duct.

The gallbladder wall is composed of a mucous membrane, a muscularis and an adventitia. It is covered by a reflection of visceral peritoneum. The mucosa is thrown into folds and consists of columnar epithelium and a lamina propria of loose connective tissue. **Rokitansky-Aschoff sinuses** are mucosal diverticula that dip into the gallbladder wall.

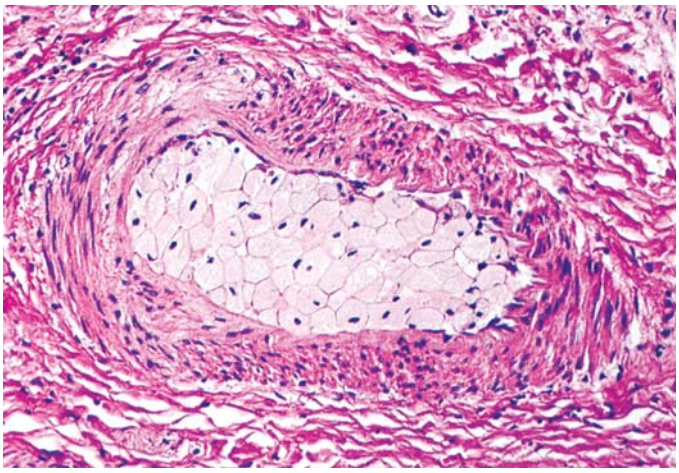

FIGURE 20-69. Arterial lesions in chronic rejection of a liver transplant. Subintimal foam cells, intimal sclerosis and myointimal hyperplasia virtually obliterate the lumen of a hepatic artery.

CONGENITAL ANOMALIES

Developmental anomalies of the gallbladder are rare and of little clinical significance except for surgeons. Bile duct anomalies include **duplication** and **accessory bile ducts.** Congenital bile duct dilations are **choledochal cysts** (85% of all cases), **choledochal diverticula** or **choledochoceles** (Fig. 20-70). Multiple cysts may occur as segmental dilations in the entire extrahepatic biliary tree. Similar multiple dilations in the intrahepatic biliary tree, called **Caroli disease,** predispose to bacterial cholangitis.

CHOLELITHIASIS

Cholelithiasis means stones in the gallbladder lumen or in the extrahepatic biliary tree. In the industrialized countries, 3/4 of gallstones are mainly **cholesterol;** the rest are **calcium bilirubinate** and **other calcium salts (pigment gallstones)**.

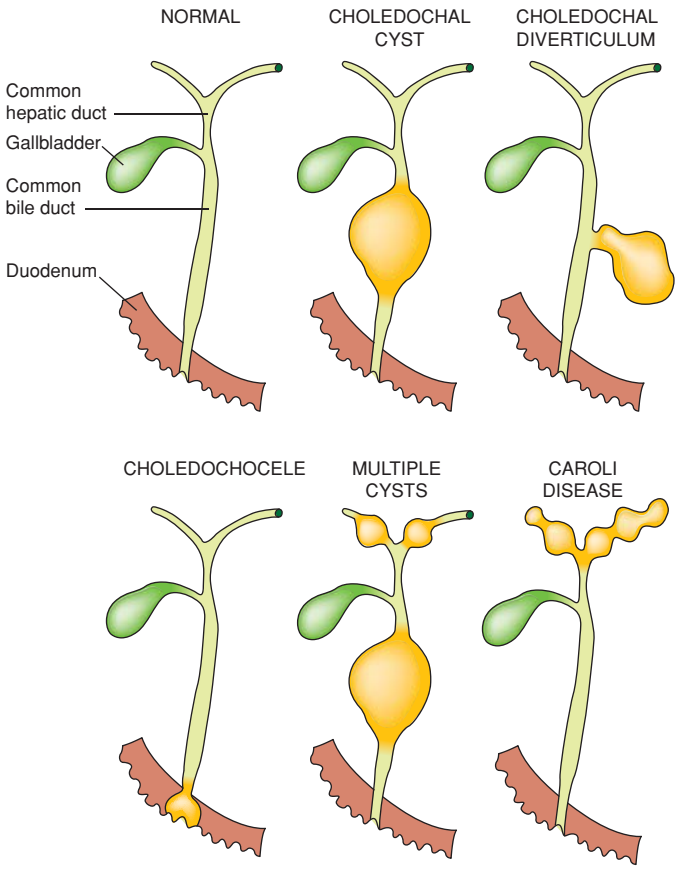

FIGURE 20-70. Congenital dilations of the bile ducts.

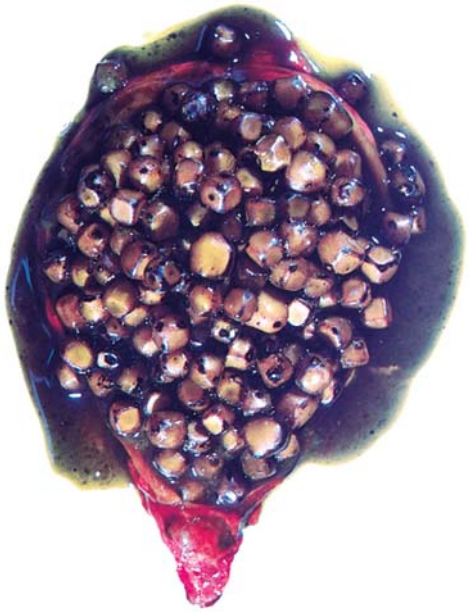

FIGURE 20-71. Cholesterol gallstones. The gallbladder has been opened to reveal numerous yellow cholesterol gallstones.

Pigment stones are more common in the tropics and Asia. Most gallstones are not radiopaque but are readily detected by ultrasonography. They are often asymptomatic but cause mild to severe pain **(biliary colic)** if they lodge in the cystic or common bile ducts.

Cholesterol Stones Are the Most Common Gallstones

Cholesterol stones measure up to 4 cm and may be round or faceted, yellow to tan, single or multiple (Fig. 20-71). They are mostly cholesterol, plus some calcium salts and mucin.

EPIDEMIOLOGY: Some 20% of American men and 35% of women older than 75 years have gallstones at autopsy. ***Premenopausal women develop cholesterol gallstones three times more often than do men. The incidence is highest in users of oral contraceptives and women with several pregnancies.*** Cholesterol gallstones are very common in Pima Indian women of the American Southwest; 75% are affected by age 25 years and 90% by age 60.

PATHOPHYSIOLOGY: Formation of cholesterol gallstones reflects the physicochemical qualities of bile and local factors in the gallbladder (Fig. 20-72):

- **Bile formation in the liver:** Cholesterol is insoluble in water. When secreted by hepatocytes into the bile, it is held in solution by the combined action of bile acids and lecithin and is carried as mixed lipid micelles. Bile containing too much cholesterol or that is deficient in bile acids becomes supersaturated in cholesterol. Cholesterol then precipitates as solid crystals to form stones **(lithogenic bile)**. Bile from people who have cholesterol gallstones contains more cholesterol and less bile salts as it leaves the liver than does bile of normal people. Obesity increases hepatic cholesterol secretion even more, further supersaturating the bile with cholesterol.
- **Local factors in the gallbladder:** Bile in the gallbladder from patients with gallstones crystallizes more easily than normal. Biliary proteins can function as nuclei of crystallization, and hypersecretion of gallbladder mucus accelerates cholesterol precipitation from gallbladder bile.
- **Gallbladder motility:** Impaired gallbladder motor function leads to stasis causing bile sludging, which progresses to macroscopic stones.

Estrogens increase hepatic secretion of cholesterol and decrease secretion of bile acids, perhaps explaining why women form cholesterol gallstones more often. Pregnancy magnifies these effects. Progesterone, the main hormone of pregnancy, inhibits discharge of bile from the gallbladder. The gallbladder empties more slowly, and the resulting stasis increases the opportunity for cholesterol crystals to precipitate. Similar mechanisms may also explain the increase in gallstones with oral contraceptive use.

Other major risk factors for cholesterol gallstones include increased biliary cholesterol secretion, decreased secretion of bile salts and lecithin or both.

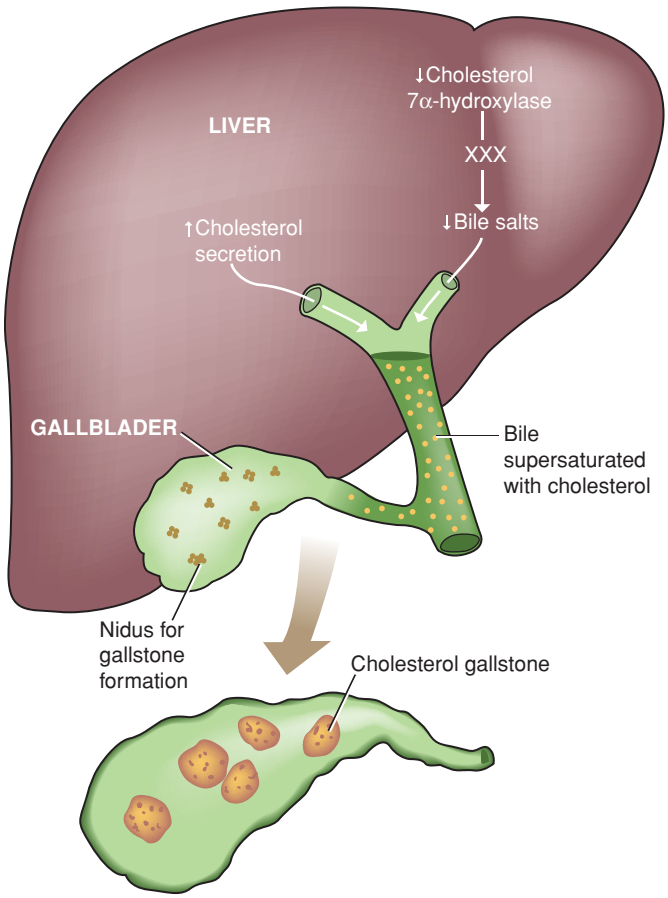

FIGURE 20-72. Pathogenesis of cholesterol gallstones.

Factors associated with **increased biliary cholesterol secretion** include:

- Increasing age
- Obesity
- Ethnicity (e.g., Native Americans, Chilean women, some northern Europeans)
- Familial predisposition
- Diet high in calories and cholesterol
- Certain metabolic abnormalities associated with high blood cholesterol levels (e.g., diabetes, some genetic hyperlipoproteinemias, PBC)

The risk of symptomatic gallstones is a direct function of body weight. In people who are obese, the relative risk of gallstones may be fivefold above normal. Hepatic cholesterol synthesis is stimulated by insulin, and the hyperinsulinism that accompanies increased body fat may explain why biliary excretion of cholesterol increases with obesity.

Decreased secretion of bile salts and lecithin occurs in nonobese whites who develop gallstones. Disorders that interfere with enterohepatic circulation of bile acids (e.g., pancreatic insufficiency in CF or Crohn disease) also decrease bile acid secretion and favor gallstone formation.

Cholesterol synthesis is elevated and bile salts and lecithin are lower in Pima Indians and in people taking certain drugs (e.g., clofibrate). Moderate alcohol intake lowers biliary cholesterol concentration and decreases the risk of gallstones.

Pigment Stones May Be Black or Brown

Black Pigment Stones

Black pigment stones measure less than 1 cm and are irregular and glassy (Fig. 20-73). They contain calcium bilirubinate, bilirubin polymers, calcium salts and mucin.

PATHOGENESIS: Black stones are more common in older or undernourished people. Chronic hemolysis, as in hemoglobionopathies, predisposes to development of black pigment stones. Either because it increases hemolysis or because of damage to liver cells, cirrhosis is also associated with a high incidence of black stones. However, usually no cause for formation of black pigment stones is found.

Unconjugated bilirubin is insoluble in bile and is normally present in only trace amounts. If increased unconjugated bilirubin is secreted by hepatocytes, it precipitates as calcium bilirubinate, probably around a nidus of mucinous glycoproteins. Patients without known predisposing factors who develop black pigment stones have increased concentrations of unconjugated bilirubin in the bile for unknown reasons.

Brown Pigment Stones

Brown pigment stones are spongy and laminated, containing calcium bilirubinate, cholesterol and calcium soaps of fatty acids. Unlike other types of gallstones, they are more common in intrahepatic and extrahepatic bile ducts than in the gallbladder.

FIGURE 20-73. Pigment gallstones. The gallbladder has been opened to reveal numerous small, dark stones composed of calcium bilirubinate.

ETIOLOGIC FACTORS: ***Brown stones are almost always associated with bacterial cholangitis, for which E. coli is the main cause.*** They are uncommon in Western countries but are not infrequent in Asia, where they are almost entirely seen in people infested with *A. lumbricoides* or *C. sinensis*, helminths that may invade the biliary tract. The rare cases in Western countries are seen in patients with chronic mechanical obstruction to bile flow, as in sclerosing cholangitis, or the presence of a catheter in the common bile duct after common bile duct surgery. Bacterial β-glucuronidase or other hydrolytic enzymes hydrolyze conjugated bilirubin to its unconjugated form, which favors formation of brown stones.

CLINICAL FEATURES: Gallstones in the gallbladder may remain "silent" for many years, and few patients die as a result of cholelithiasis itself. The 15-year cumulative probability that asymptomatic stones will lead to biliary pain or other complications is less than 20%. Laparoscopic cholecystectomy is the treatment of choice.

Most complications of cholelithiasis relate to gallstones obstructing the cystic or common bile ducts. Passage of a stone into the cystic duct often, but not always, causes severe biliary colic and may lead to acute cholecystitis. Repeated bouts of acute cholecystitis give rise to chronic cholecystitis, which may also result from the presence of stones alone. Gallstones entering the common duct **(choledocholithiasis)** may cause obstructive jaundice, cholangitis and pancreatitis. They are the most common cause of acute pancreatitis in people who do not drink alcohol. Passage of a large gallstone into the small intestine can even cause intestinal obstruction, known as **gallstone ileus.** In cystic duct obstruction, with or without acute cholecystitis, bile in

FIGURE 20-74. Hydrops of the gallbladder. The lumen of the dilated gallbladder is filled with clear mucus and contains cholesterol stones. Note the stone (*arrow*) obstructing the cystic duct.

the gallbladder is reabsorbed and replaced by a clear mucinous fluid secreted by gallbladder epithelium. **Hydrops of the gallbladder (mucocele)** (Fig. 20-74) entails a distended and palpable gallbladder, which may become secondarily infected.

ACUTE CHOLECYSTITIS

Acute cholecystitis is diffuse inflammation of the gallbladder, usually secondary to obstruction of the gallbladder outlet.

PATHOPHYSIOLOGY: ***People with gallstones account for 90% of cases of acute cholecystitis.*** The remaining cases **(acalculous cholecystitis)** are linked to sepsis, severe trauma, infection of the gallbladder with *Salmonella typhosa* and polyarteritis nodosa. Bacterial infection is usually a consequence of biliary obstruction rather than a primary event.

Obstruction of the cystic duct by a gallstone may lead to release of phospholipase by the gallbladder epithelium. This enzyme hydrolyzes lecithin to lysolecithin, a membrane-active toxin. The mucous coat of the epithelium is disrupted, exposing mucosal cells to the detergent action of concentrated bile salts. Bile supersaturated with cholesterol may be toxic to the epithelium.

PATHOLOGY: In acute cholecystitis, the external surface of the gallbladder is congested and layered with a fibrinous exudate. The wall is thickened by edema, and the mucosa is fiery red or purple. Gallstones are usually found in the lumen, and one is often seen obstructing the cystic duct. Rarely, in **empyema of the gallbladder,** the cystic duct is completely obstructed, allowing bacteria to invade the gallbladder and distending the organ with cloudy, purulent fluid.

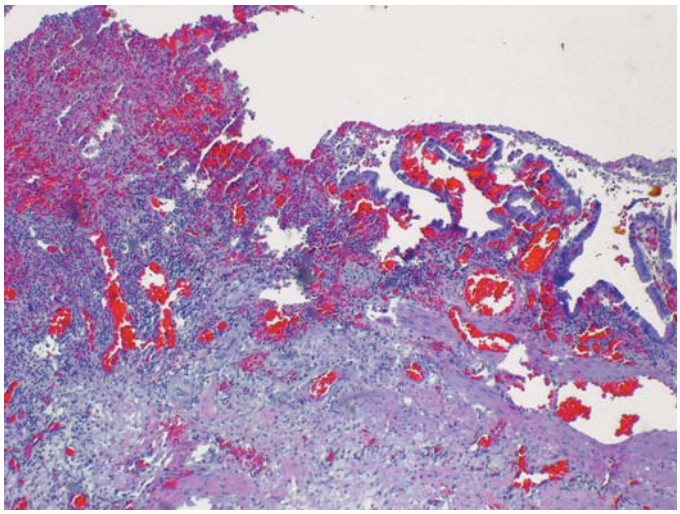

FIGURE 20-75. Acute cholecystitis. Gallbladder removed from a patient with acute cholecystitis demonstrates ulceration of the mucosa (*left*) and acute and chronic inflammation.

In the gallbladder wall, edema and hemorrhage are striking, with accompanying acute and chronic inflammation (Fig. 20-75). Suppuration in the wall often follows bacterial invasion. The mucosa shows focal ulcers or, in severe cases, widespread necrosis **(gangrenous cholecystitis)**.

Perforation is a dreaded complication of bacterial infection. Bile leakage into the peritoneum can cause **bile peritonitis**. More often, inflammatory adhesions form a **pericholecystic abscess** and limit spread of gallbladder contents after perforation. Erosion of gallbladder contents into a viscus may create a **cholecystenteric fistula**.

CLINICAL FEATURES: Right upper quadrant abdominal pain is usually the presenting symptom. Most patients have already had episodes of biliary colic. Mild jaundice, caused by stones in, or edema of, the common bile duct, is seen in 20% of patients. The acute illness generally subsides within a week, but persistent pain, fever, leukocytosis and shaking chills herald progression of the disease and the need for cholecystectomy. As inflammation resolves, the gallbladder wall becomes fibrotic and the mucosa heals. However, the function of the gallbladder remains impaired.

CHRONIC CHOLECYSTITIS

Chronic cholecystitis (i.e., persistent chronic inflammation) is the most common disease of the gallbladder. It is almost always associated with gallstones but may also result from repeated attacks of acute cholecystitis. In the latter case, the pathogenesis probably relates to chronic irritation and chemical injury to the gallbladder epithelium.

PATHOLOGY: The wall of a chronically inflamed gallbladder is thickened and firm (Fig. 20-76A), and its serosal surface commonly shows fibrous

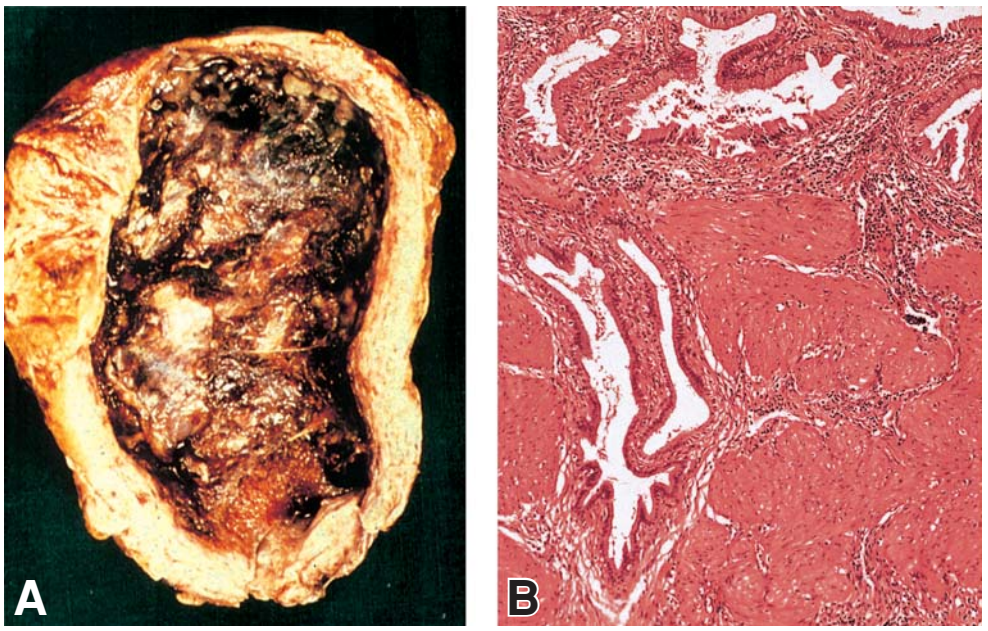

FIGURE 20-76. Chronic cholecystitis. **A.** The gallbladder is thickened and fibrotic. The lumen had contained several gallstones. **B.** The same specimen as in A shows chronic inflammation of the gallbladder and a sinus of Rokitansky-Aschoff extending into the muscularis.

adhesions to surrounding structures, which are residues of previous episodes of acute cholecystitis. Gallstones are usually found within the lumen. The bile frequently contains gravel or sludge (i.e., fine precipitates of calculous material) with coliform organisms in about 1/2 of cases. The mucosa tends to be focally ulcerated and atrophic but may be intact. The fibrotic wall is chronically inflamed throughout and penetrated by Rokitansky-Aschoff sinuses (Fig. 20-76B). Long-standing inflammation may lead to calcification of the gallbladder wall **(porcelain gallbladder)**.

CLINICAL FEATURES: Many patients with chronic cholecystitis complain of nonspecific abdominal symptoms, but it is not at all clear that these are related to the gallbladder disease. On the other hand, pain in the right hypochondrium is typical and often episodic. The diagnosis is best made by ultrasound examination, which shows gallstones in a thick, contracted gallbladder. Cholecystectomy is the final treatment.

CHOLESTEROLOSIS

Cholesterolosis of the gallbladder is accumulation of cholesterol-laden macrophages in the submucosa. It reflects supersaturation of bile with cholesterol and does not ordinarily cause symptoms. The mucosa shows scattered, yellow flecks (strawberry gallbladder), and mucosal folds are swollen with large, foamy macrophages, in which a small nucleus is displaced to the periphery.

TUMORS

Benign Tumors of the Gallbladder and Extrahepatic Biliary Ducts Are Rare

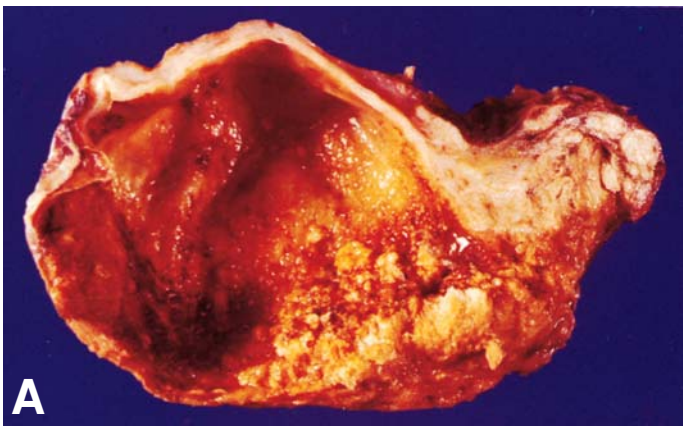
Papillomas are the most common benign tumors of the gallbladder and may be single or multiple. They are associated with gallstones in 75% of cases. A combined proliferation of smooth muscle and Rokitansky-Aschoff sinuses is an **adenomyoma and is adenomyomatus hyperplasia when it diffusely involves the gallbladder**. Fibromas, lipomas, leiomyomas and myxomas have also been recorded. Similar benign tumors may occur in the bile ducts, where they may obstruct biliary flow and cause jaundice and thus come to clinical attention.

Adenocarcinoma Is the Most Common Tumor of the Gallbladder

Adenocarcinoma of the gallbladder is not rare. It is found incidentally in 2% of patients who undergo cholecystectomy. Because this cancer is usually associated with cholelithiasis and chronic cholecystitis, it is much more common in women and in populations with a high incidence of cholelithiasis, such as Native Americans. Calcified (porcelain) gallbladders (see above) are particularly prone to developing gallbladder cancer.

PATHOLOGY: Gallbladder carcinoma may occur anywhere in the gallbladder but most often involves the fundus. The tumor is usually an infiltrative, well-differentiated adenocarcinoma. It is usually desmoplastic, and thus the gallbladder wall becomes thickened and leathery (Fig. 20-77). Anaplastic, giant cell and spindle cell forms, as well as adenosquamous carcinoma of the gallbladder, have been reported. Metastases occur via both lymphatic spread and direct extension into the liver, contiguous structures and peritoneum.

CLINICAL FEATURES: The symptoms of gallbladder carcinoma are like those of gallstone disease. However, by the time these tumors are symptomatic, they are almost always incurable; 5-year survival is less than 3%. For practical purposes, only those patients whose tumors are discovered incidentally during cholecystectomy are cured.



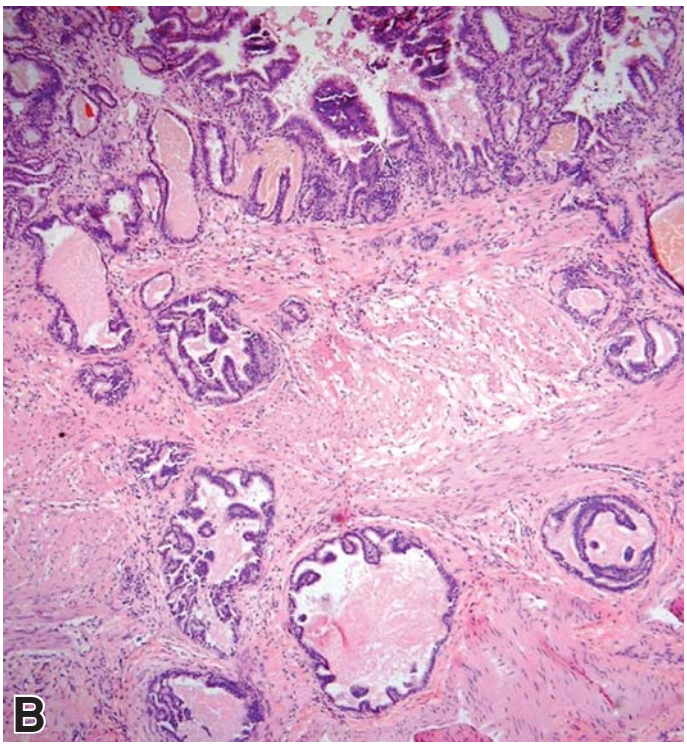


FIGURE 20-77. Carcinoma of the gallbladder. A. A surgically resected gallbladder has been opened to reveal a thickened wall infiltrated by adenocarcinoma, which also demonstrates exophytic growth into the lumen. **B.** The gallbladder wall is infiltrated by adenocarcinoma.

Carcinomas of the Bile Duct and Ampulla of Vater Present as Obstructive Jaundice

Cancer of the extrahepatic bile ducts (extrahepatic cholangiocarcinoma; see above) is almost always adenocarcinoma. It may occur anywhere along the duct, including the point where the right and left hepatic ducts join to form the common hepatic duct (hilar cholangiocarcinoma).

These tumors are less common than gallbladder cancer and affect both sexes comparably. Gallstones are often found in those affected, and there is an association with inflammatory diseases of the colon. The tumor may occur in choledochal cysts and in Caroli disease. In Asia, bile duct carcinoma is associated with biliary infestation by the fluke *C. sinensis.* As in carcinoma of the gallbladder, growth may be endophytic (into the lumen) or diffusely infiltrative. The prognosis is poor, but as symptoms arise early in the disease, the outcome is somewhat better than for gallbladder carcinoma.

Adenocarcinomas of the ampulla of Vater may also obstruct bile flow. They usually present as obstructive jaundice but occasionally as pancreatitis. Surgical treatment of cancer of the ampulla of Vater gives a 5-year survival rate of about 35%.

ANATOMY AND PHYSIOLOGY

Pancreatic development begins at 4 weeks as two endodermal outpouchings on the dorsal and ventral sides of the embryonic duodenal tube. The ventral pancreas and the common bile duct migrate posteriorly around the duodenum. The ductal systems of the two embryonic pancreatic anlagen merge at 7 weeks, to form a main pancreatic duct **(duct of Wirsung)**. This duct derives from the ventral pancreatic duct that extends from the ampulla of Vater at the duodenum into the distal portion of the dorsal pancreatic duct. The proximal dorsal duct remnant becomes the **duct of Santorini,** which may remain patent through the minor papilla into the duodenum, but this connection usually obliterates. The ducts branch progressively into smaller ducts and ductules that extend into the pancreatic lobules. Acinar cells arise from ductules and acquire their distinctive zymogen granules. The enzymatic secretions of the acinar cells drain into the smallest ductules between centroacinar cells, which bridge the acinar lumina into the ductal system. Islet cells are also derived from ducts and acquire several types of small, dense, secretory granules, corresponding to the various peptides they produce.

The pancreas is a mixed exocrine and endocrine gland, 10–15 cm long and weighing 60–150 g, that lies transversely in the upper abdomen, cradled between the loop of the duodenum and the hilum of the spleen. It is retroperitoneal, behind the lesser omental sac and the stomach, although the anterior surface is covered by peritoneum. It is thus inaccessible to physical examination. It has three anatomic subdivisions: (1) the **head** is in the concavity of the duodenum and extends to the superior mesenteric vessels, which pass through a groove immediately behind the organ; (2) the **neck** connects the head to the distal portion of the gland; and (3) the **tail** constitutes the distal two thirds of the pancreas and extends to the hilum of the spleen.

Exocrine pancreatic secretions drain into the major ducts of Wirsung and Santorini, which join the common bile duct and empty into the duodenum through the papilla of Vater. These pancreatic and biliary ducts usually merge a variable distance (1–5 mm) below the duodenal mucosa in a common channel that is the prototypical ampulla of Vater. In a significant minority of individuals, these ducts remain separated by a septum and enter the duodenum independently. The ampulla is surrounded by a circular complex of smooth muscle fibers, the **sphincter of Oddi,** that controls passage of pancreatic juice and bile into the duodenum.

Exocrine tissue makes up 80%–85% of the pancreas and contains acini with a single layer of pyramidal cells, whose basal cytoplasm is basophilic owing to abundant rough endoplasmic reticulum. The apical cytoplasm contains eosinophilic zymogen granules. Acinar cells synthesize some 20 different digestive enzymes, mostly in the form of inactive proenzymes. These enzymes include trypsin, chymotrypsin, amylase, lipase and elastase, which are secreted upon neural and hormonal stimulation and are subsequently activated in the duodenum. Amylase and lipase are secreted in their active forms. The daily secretion of 1.5–3 liters of pancreatic juice attests to the remarkable synthetic and secretory capacity of the exocrine pancreas.

The endocrine pancreas is organized into **islets of Langerhans**. These are present throughout the organ but account for only 1%–2% of the total pancreatic mass. Most islets consist of circumscribed lobules of cells derived from the dorsal embryonic pancreas. These *compact islets* contain several cell types, principally alpha and beta cells that produce glucagon and insulin, respectively; somatostatin-producing delta cells and pancreatic polypeptide cells are present in small numbers. Islets derived from the ventral embryonic pancreas are present in the head of the pancreas and mainly contain beta and pancreatic polypeptide cells. These *diffuse islets* are arranged in cords interspersed between acinar cells. Each islet cell makes only one peptide hormone, which is secreted directly into the blood (see below). The major endocrine disease of the pancreas, diabetes mellitus, is discussed in Chapter 22.

CONGENITAL ANOMALIES

There are many anatomic variations in the major pancreatic ducts and their relationship to the common bile duct, most of which are considered normal and are rarely of clinical significance. Other developmental variations have clinical consequences and are therefore regarded as developmental defects.

PANCREAS DIVISUM: Pancreas divisum, the most common congenital anomaly, results from failure of the two embryonic pancreatic ducts to fuse, leading to retention of two separate ductal systems, each draining into the duodenum through the major and minor papillae, respectively. Thus, the major portion of the pancreas is drained by the duct of Santorini through the minor papilla. Usually the two lobes of the organ do fuse, so the abnormality is not evident unless the course of the pancreatic ducts is specifically defined; sometimes the ventral and dorsal lobes fail to fuse entirely. Chronic pancreatitis develops in up to 25% of people with pancreas divisum.

HETEROTOPIC PANCREAS: Pancreatic tissue occurring outside its normal location, mostly in the walls of the duodenum, stomach and jejunum, is an incidental finding in 2%–15% of autopsies. Such heterotopic tissue may contain all components of normal pancreas, but some cases contain only ducts, and coexisting acini and islets are not always found. Smooth muscle is usually abundant in pancreatic heterotopia involving the tubular gastrointestinal tract. Pancreatic neoplasms of various types may arise in heterotopic tissue, most often infiltrating ductal adenocarcinoma.

ANNULAR PANCREAS: In this uncommon condition, the pancreatic head partly or completely surrounds the second portion of the duodenum. Infants with annular pancreas often have other congenital anomalies, including trisomy 21 (Down syndrome). Some affected patients also have duodenal atresia, which requires surgery immediately after birth. Half of patients with annular pancreas only develop symptoms in their 60s or 70s.

CYSTS: True nonneoplastic cysts of the pancreas are believed to arise from faulty development of pancreatic ducts. There is an association with other anatomic anomalies, including renal tubular dysplasia, anorectal malformations, polydactyly and thoracic dystrophy.

PARTIAL OR COMPLETE PANCREATIC AGENESIS: Homozygous mutations of homeodomain transcription factor IPF1 (PDX1) are reported in these rare conditions.

ACUTE PANCREATITIS

Acute Pancreatitis Results from Aberrant Release of Pancreatic Enzymes

It is not truly an inflammatory condition, but instead reflects myriad local, regional and systemic changes seen with release of these enzymes. The devastation of acute pancreatitis was described by Lord Moynihan in 1925 as the "most terrible of all calamities [of] the abdominal viscera. The suddenness of its onset, the illimitable agony which accompanies it and the mortality attendant upon it render it a formidable disease." For unknown reasons, the incidence of acute pancreatitis has increased in the past few decades.

The severity of acute pancreatitis varies greatly from case to case. At one end of the spectrum, it is a mild, self-limited disease, with acute inflammation and stromal edema, and little or no acinar cell necrosis. This is usually not associated with systemic manifestations of disease. At the other extreme is a severe, sometimes fatal, acute hemorrhagic pancreatitis with massive necrosis. In these cases, systemic manifestations such as shock, acute respiratory distress, acute renal failure and disseminated intravascular coagulation may develop in the face of massive enzymatic leak from the gland, reflected in extremely high serum levels of amylase and lipase.

Repeated bouts of acute pancreatitis may lead to chronic pancreatitis, which is characterized by recurrent attacks of severe abdominal pain and progressive fibrosis and atrophy of the gland, culminating in pancreatic insufficiency. However, antecedent acute episodes are only appreciated clinically in half of cases of chronic pancreatitis.

ETIOLOGIC FACTORS: Acinar cell injury and **duct obstruction** are the major causes of acute pancreatitis. These processes progress to inappropriate extracellular leakage of activated digestive enzymes and consequent autodigestion of pancreatic and extrapancreatic tissues. There may be some genetic predispositions to the development of acute pancreatitis; however, since the same molecular pathogenetic factors are generally associated with the development of chronic pancreatitis, they are discussed in that section.

ACTIVATED PANCREATIC ENZYMES: Inappropriate activation of pancreatic proenzymes occurs in all forms of pancreatitis. Acinar cells are shielded from the potentially destructive action of their digestive enzymes (proteases, nucleases, amylase, lipase and phospholipase A) by three mechanisms:

1. Enzymes are physically isolated from the cytosol by an intricate, intracellular, cavitary system of endoplasmic reticulum, Golgi complex and zymogen granule membranes.
2. Many digestive enzymes are synthesized as inactive forms (e.g., chymotrypsinogen, proelastase, prophospholipase and trypsinogen).
3. Specific enzyme inhibitors tend to protect the pancreas.

Inhibitors of proteolytic enzymes defend against inappropriate activation of pancreatic proenzymes and are present in many body fluids and tissues. The plasma protease inhibitors are α_1-antitrypsin, α_2-macroglobulin, C_1 esterase inhibitor and pancreatic secretory trypsin inhibitor. Several trypsin inhibitors are described in different body compartments, but they protect only incompletely from trypsin activation. Trypsin itself does not produce cell necrosis. Rather, it activates other pancreatic proenzymes, such as prophospholipase A_2 and proelastase, and so is central to the pathogenesis of acute pancreatitis.

SECRETION AGAINST OBSTRUCTION AND DUCT INSUFFICIENCY: Most enzymes secreted by acinar cells are discharged into the ductal system and enter the duodenum. A small amount diffuses back into periductular extracellular fluid and eventually into plasma. Whenever lumina of pancreatic ducts are narrowed or easy outflow of exocrine secretions is impaired, intraductal pressure and back-diffusion across the ducts increase. This is suspected to cause inappropriate activation of digestive proenzymes. Heavy meals may induce release of pancreatic secretagogues, and so augment production of pancreatic enzymes.

Gallstones sometimes obstruct pancreatic ducts, and 45% of patients with acute pancreatitis also have cholelithiasis.

Conversely, the risk of acute pancreatitis in patients with gallstones is 25 times higher than in the general population, and 5% of patients with gallstones develop acute pancreatitis. Also, if gallstones are not eliminated after one attack, pancreatitis recurs in half the cases. The reason for the association between pancreatitis and cholelithiasis is obscure. Under 5% of patients with acute pancreatitis have impacted stones at the ampulla of Vater. Neither ligation of the pancreatic duct nor its occlusion by tumor generally produces severe acute pancreatitis. Reflux of bile or duodenal contents into the pancreatic duct may cause pancreatitis, but there is little evidence to support this theory.

Anatomic anomalies (e.g., pancreas divisum) and **neoplasms** (ampullary and pancreatic neoplasms, including intraductal processes) can also lead to acute pancreatitis due to duct insufficiency or obstruction, respectively.

ETHANOL: Chronic alcohol abuse accounts for a third of cases of acute pancreatitis, although only 5%–10% of chronic alcoholics develop this complication. The pathogenesis of ethanol-induced pancreatitis (acute and chronic) is not well understood (see below). Ethanol does not cause significant injury to pancreatic acinar or duct cells.

Alcohol consumption may cause spasm or acute edema of the sphincter of Oddi, especially after an alcoholic binge. It also stimulates secretion from the small intestine, which triggers the exocrine pancreas to release pancreatic juice.

OTHER CAUSES OF ACUTE PANCREATITIS: Rare causes include:

- **Viruses,** such as mumps, coxsackievirus and cytomegalovirus. The incidence of acute pancreatitis is particularly high in patients with AIDS due to HIV-1 itself or, most commonly, cytomegalovirus (CMV) infection.
- **Therapeutic drugs.** These include immunosuppressive drugs (e.g., azathioprine), antineoplastic agents, estrogens, sulfonamides and diuretics. The mechanisms of pancreatic injury by these compounds are unclear.
- **Blunt trauma** to the upper abdomen with contusive injury to the pancreas and leakage of digestive enzymes into the pancreas and peripancreatic tissues. Patients undergoing endoscopic retrograde cholangiopancreatography (ERCP), fine needle aspiration biopsy and surgical manipulation occasionally develop acute pancreatitis.
- **Acute ischemia** due to shock, vasculitis and thrombosis.
- **Hyperlipidemia:** Hydrolysis of triglycerides in the extracellular space by inappropriate leakage of pancreatic lipase may be responsible. Released free fatty acids are cytotoxic.
- **Hypercalcemia.**
- **Obesity:** Obese people are at greater risk for severe pancreatitis. Increased peripancreatic fat may predispose them to greater fat necrosis after local release of pancreatic lipase.
- **Idiopathic pancreatitis:** This is the third most common form of the disease and accounts for 10%–20% of cases.
- **Parasites** (e.g., *Ascariasis*), bacteria (e.g., *Mycoplasma* species) and **pregnancy**.

Factors implicated in acute hemorrhagic pancreatitis are shown in Fig. 21-1.

PATHOLOGY: In acute hemorrhagic pancreatitis, the pancreas is initially edematous and hyperemic. Within a day, pale, gray foci appear, rapidly becoming friable and hemorrhagic (Fig. 21-2A). In severe cases, these foci enlarge so that most of the pancreas is converted into a large retroperitoneal hematoma, in which pancreatic tissue is barely recognizable. Yellow-white areas of fat necrosis appear around the pancreas, including in the adjacent mesentery (Fig. 21-2B). These nodules of necrotic fat have a pasty consistency that becomes firmer and chalk-like as more calcium and magnesium soaps are produced. Saponification reflects the interaction of cations with free fatty acids released by the action of activated lipase on triglycerides in fat cells. As a result, blood calcium may be depressed, sometimes to the point of causing neuromuscular irritability.

The most prominent microscopic findings in acute pancreatitis are acinar cell and fat necrosis, often with some degree of acute inflammation (Fig. 21-3). Necrosis is usually patchy and rarely involves the entire gland. Irregular fibrosis of the pancreas and occasionally calcification (i.e., chronic pancreatitis) result from healed acute pancreatitis.

PANCREATIC PSEUDOCYST: Half of patients surviving acute pancreatitis may develop pancreatic pseudocysts, which are usually centered in peripancreatic tissues (Fig. 21-4). Pseudocysts are surrounded by connective tissue, with no epithelial lining, and contain degraded blood, inflammatory cells, debris and fluid rich in pancreatic enzymes. Pseudocysts may enlarge to compress and even obstruct the duodenum or other structures. They may become secondarily infected and form abscesses. Rupture is a rare complication that may lead to chemical or septic peritonitis, or both.

CLINICAL FEATURES: Patients with acute pancreatitis present with severe epigastric pain that is referred to the upper back, nausea and vomiting. Within hours, catastrophic peripheral vascular collapse and shock may ensue. With sustained, profound shock, **acute respiratory distress syndrome** and **acute renal failure** may occur within the first week. Early in the disease, pancreatic digestive enzymes from injured acinar cells enter the blood and retroperitoneal area. ***Elevated serum amylase and lipase within 24–72 hours is diagnostic for acute pancreatitis.*** Infection of the pancreas with gram-negative bacteria from the intestinal tract greatly increases mortality.

CHRONIC PANCREATITIS

Chronic Pancreatitis Results from Progressive Destruction of Pancreatic Parenchyma and Its Replacement by Fibrosis

Since its original description and its association with stones two centuries ago, the pathogenesis, clinical course and treatment of chronic pancreatitis remain enigmatic. Its symptoms include recurrent or persisting abdominal pain or simply evidence of pancreatic exocrine or endocrine insufficiency.

ETIOLOGIC FACTORS: Most factors that cause acute pancreatitis also cause chronic pancreatitis. The fact that chronic pancreatitis is often characterized by intermittent "acute" attacks with periods of quiescence suggests that it may evolve from repeated episodes of acute pancreatitis, with scarring. However, half of patients give no history of acute pancreatitis.

- **Chronic alcoholism** is the major cause of chronic pancreatitis, accounting for nearly 80% of adult cases. Even

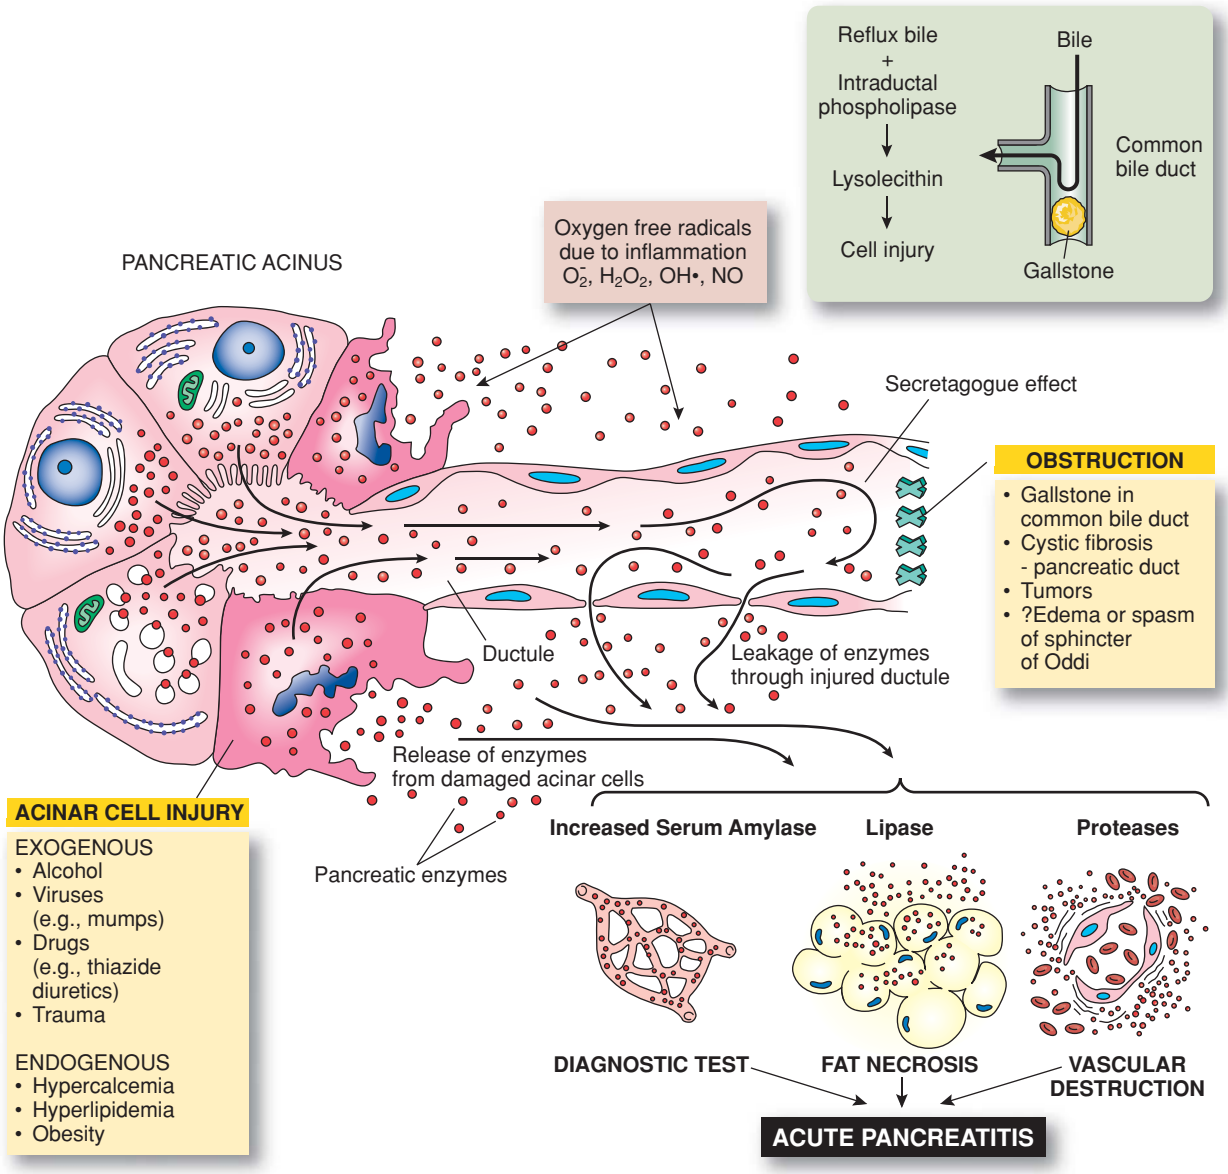

FIGURE 21-1. The pathogenesis of acute pancreatitis. Injury to the ductules or the acinar cells leads to the release of pancreatic enzymes. Lipase and proteases destroy tissue, thus causing acute pancreatitis. The release of amylase is the basis of a test for acute pancreatitis. H_2O_2 = hydrogen peroxide; $NO\bullet$ = nitric acid; O_2^- = superoxide ion; $OH\bullet$ = hydroxyl radical.

among alcoholics without symptoms of chronic pancreatitis, autopsy reveals evidence of this disease in about half. A comparable proportion of asymptomatic alcoholics show abnormal results for pancreatic exocrine function tests. The role of alcohol is undisputed, but the mechanism by which it causes chronic pancreatitis is still debated.

PATHOPHYSIOLOGY: The link between alcohol and pancreatitis may rest on the fact that alcohol is a pancreatic secretagogue. Hypersecretion of enzymes by acinar cells without increased fluid leads to precipitation of "protein plugs" in small pancreatic ducts. These deposits obstruct the small ducts, at first causing only mild acute pancreatitis. Resolution with fibrosis facilitates development of more plugs (that grow and become the nidus for calcium carbonate stones), causing a vicious cycle that increases the risk of developing more and worse acute pancreatitis. Since only a minority of severe alcoholics develop clinical chronic pancreatitis, other factors may also play a role. Malformations (e.g., pancreatic divisum) or mutations (e.g., cystic fibrosis) may predispose some alcoholics to developing chronic pancreatitis.

- **Obstruction or insufficiency of the pancreatic duct** sometimes causes chronic pancreatitis. However, acute obstruction by gallstones may cause acute pancreatitis but not progression to chronic pancreatitis.

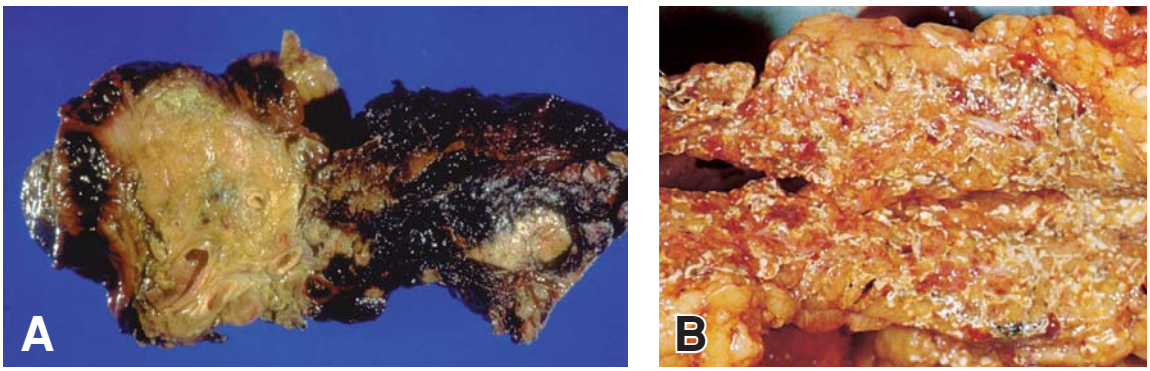

FIGURE 21-2. Acute hemorrhagic pancreatitis. A. Large areas of the pancreas are intensely hemorrhagic. **B.** The cut surface of the pancreas in a less severe case of acute pancreatitis, and at a somewhat later stage than in (*A*), shows numerous yellow-white foci of fat necrosis.

- **Groove** or **paraduodenal pancreatitis** is a particular form of chronic pancreatitis that develops within the "groove" between the head of the pancreas, the common bile duct and the duodenum. Its etiology is not entirely clear. But since it usually develops in alcoholics, some have suggested that certain anatomic variations in the region of the minor papilla predispose these people to develop disease in the underlying portion of the pancreas. Because of the location of the disease, patients frequently develop jaundice (secondary to bile duct obstruction) or duodenal obstruction. Cystic changes are also common in this condition. Because the process only focally affects the pancreas, patients are often brought to surgery for a suspected pancreatic neoplasm.
- **Chronic injury to acinar cells** (e.g., in hemochromatosis) is associated with pancreatic fibrosis and atrophy.
- **Chronic renal failure** increases the incidence of acute and chronic pancreatitis.
- **Autoimmune chronic pancreatitis (lymphoplasmacytic sclerosing pancreatitis, duct-destructive chronic pancreatitis, etc.)** often occurs in association with other autoimmune and sclerosing disorders (e.g., chronic sclerosing sialadenitis and retroperitoneal fibrosis). The disorder affects both sexes, often in early adulthood. Symptoms vary from abdominal pain to painless jaundice. Imaging studies may suggest a mass-like lesion (mimicking carcinoma) or irregular beading of the pancreatic or bile ducts.

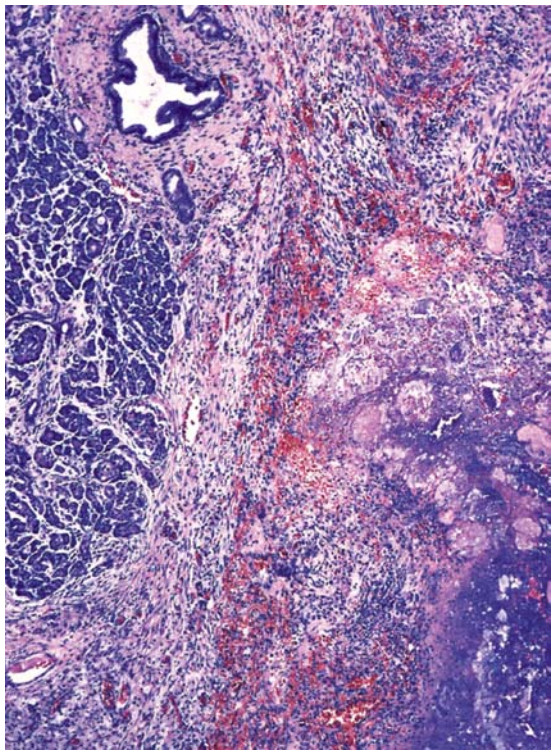

FIGURE 21-3. Acute hemorrhagic pancreatitis. A photomicrograph of the pancreas shows areas of acinar cell necrosis, hemorrhage and fat necrosis (*lower right*). An intact lobule is seen on the left.

PATHOPHYSIOLOGY: The pathogenesis of autoimmune pancreatitis is unknown, and two forms of the disease appear to exist. In the most classic form of autoimmune pancreatitis (type I), serum immunoglobulin G4 (IgG4) is often elevated and plasma cells immunolabeled for IgG4 are numerous in the

FIGURE 21-4. Pancreatic pseudocyst. A cystic cavity arises from the head of the pancreas.

parenchyma. Immunoglobulin deposits within basement membranes are described. The presence of hypergammaglobulinemia and autoantibodies, including antinuclear antibody (ANA), rheumatoid factor, antilactoferrin and anticarbonic anhydrase, support the suggestions of an autoimmune etiology.

- **Cystic fibrosis** (CF; see Chapters 6 and 22) may manifest as chronic pancreatitis. In patients with CF, intraductal secretions are abnormally viscid, accounting for the older name, **mucoviscidosis**. Plugs of inspissated mucus obstruct cystically distended pancreatic ducts, causing chronic pancreatitis and eventually exocrine pancreatic insufficiency. In late stages of CF, the entire organ is replaced by adipose tissue. Malabsorption is common in CF, causing bulky, fatty stools (steatorrhea). Death in CF is usually due to pulmonary disease.
- **Hereditary pancreatitis** is a rare autosomal dominant disease with 80% penetrance. It is characterized by recurring severe abdominal pain that often manifests in childhood.

MOLECULAR PATHOGENESIS: Most hereditary disease develops because of point mutations that increase trypsin levels within the pancreas, largely due to autoactivation of trypsinogen. Point mutations in the **cationic trypsinogen gene** (**protease serine 1,** *PRSS1;* chromosome 7q) and in the **serine protease inhibitor gene** (*SPINK1*) are associated with the disease, and most forms of hereditary pancreatitis are caused by one of three point mutations in the **cationic trypsinogen** gene.

Hereditary pancreatitis is occasionally accompanied by aminoaciduria, although the two conditions are not necessarily linked etiologically. Some patients exhibit hypercalcemia secondary to parathyroid hyperplasia or adenomas. ***About 40% of patients with hereditary pancreatitis later develop pancreatic ductal carcinomas.*** Clinically and pathologically, the features of hereditary pancreatitis are indistinguishable from those of other forms of chronic pancreatitis, including ductal stones and the late complications.

- **Idiopathic chronic pancreatitis** has a bimodal distribution: a juvenile form with a mean age of 25 years, and a second form in older patients with a peak at age 60. Mutations in the cystic fibrosis transmembrane conductance regulator *(CFTR)* gene are seen in 10%–30% of patients with idiopathic chronic pancreatitis. Somatic mutations in the gene for pancreatic secretory trypsin inhibitor *(SPINK1)* are also associated with this disease. Thus, many cases of chronic idiopathic pancreatitis may be related to CF or hereditary pancreatitis but lack other signs of the diseases.

PATHOLOGY: By the time chronic pancreatitis is clinically evident, it is usually advanced. The pathology may vary somewhat, based on the etiology. Chronic calcifying pancreatitis is the most common type of the disease and is associated with chronic alcoholism in over 90% of cases. The pancreas can be affected focally, segmentally or diffusely. The parenchyma is firm, and the cut surface lacks the usual lobular appearance (Fig. 21-5A). The main pancreatic duct and its tributaries are commonly dilated, owing to obstruction by thick proteinaceous plugs, intraductal stones or strictures. Pseudocysts or abscess formation are common.

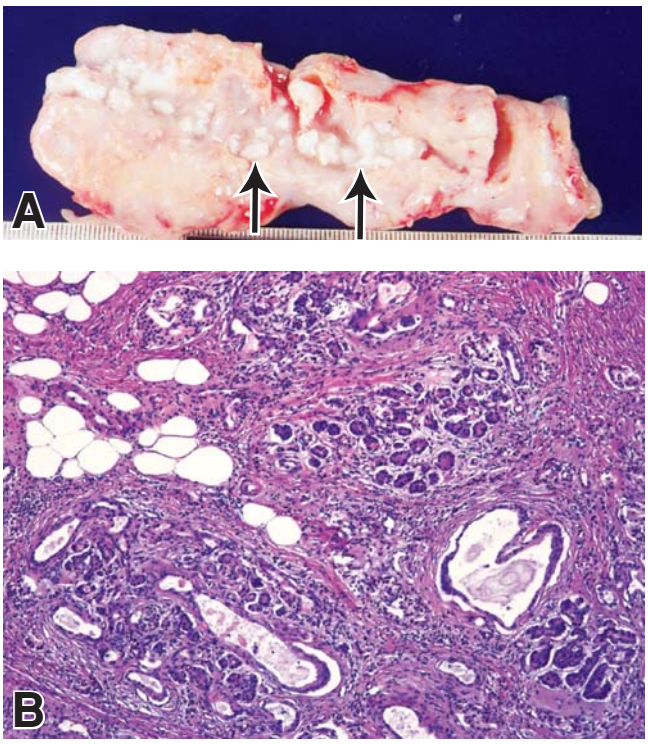

FIGURE 21-5. Chronic calcifying pancreatitis. A. The pancreas is shrunken and fibrotic, and the dilated duct contains numerous stones (*arrows*). **B.** Atrophic lobules of acinar cells are surrounded by dense fibrous tissue infiltrated by lymphocytes. The pancreatic ducts are dilated and contain inspissated proteinaceous material.

Microscopically, large regions of the gland show irregular areas of fibrosis with loss of acinar, then ductal and, eventually, endocrine parenchyma (Fig. 21-5B). Remaining pancreatic islets are embedded in the sclerotic tissue and may appear fused and enlarged until they, too, disappear. Some cases exhibit significant infiltration of adipose tissue into the gland, and the remaining islets may become suspended in the fat. Fibrotic areas show myofibroblasts and variable amounts of lymphocytes, plasma cells and macrophages. Pancreatic ducts of all sizes contain variably calcified proteinaceous material, a finding more commonly associated with alcoholism. Ductal epithelium may be atrophic or hyperplastic and may show squamous metaplasia.

In autoimmune pancreatitis, a dense lymphoplasmacytic inflammatory infiltrate and fibrosis surround the ductal epithelium (Fig. 21-6). Intraepithelial acute inflammation and obliterative venulitis may be seen with some forms of the disease.

CLINICAL FEATURES: Half of patients with chronic pancreatitis suffer repeated episodes of acute pancreatitis. One third of cases present with gradual onset of continuous or intermittent pain, with no acute attacks (Fig. 21-7). In some patients, chronic pancreatitis is initially painless but presents with diabetes or malabsorption. Once pancreatic calcifications are visible radiologically, most patients have diabetes, malabsorption or both.

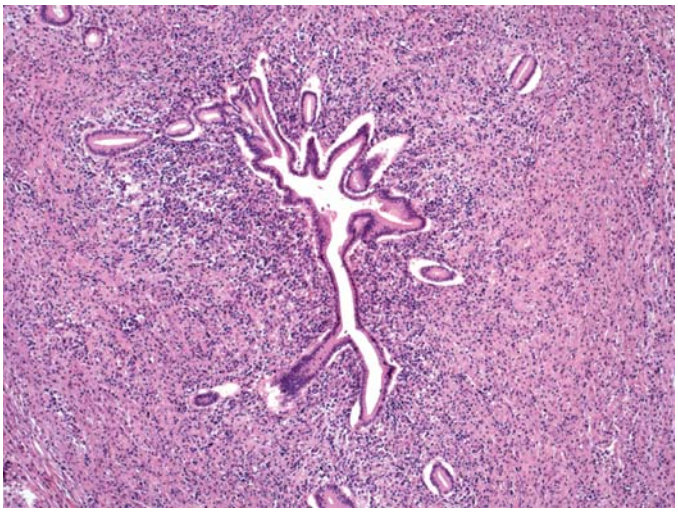

FIGURE 21-6. Autoimmune pancreatitis. There is loss of acinar tissue and the pancreatic duct is surrounded by a dense lymphoplasmacytic inflammatory infiltrate.

Conspicuous weight loss is common, and unrelenting epigastric pain, radiating to the back, may cripple the patient. Mortality is 3%–4% per year, approaching 50% within 20–25 years. One fifth of patients die of complications of attacks of acute pancreatitis. The other deaths are from other causes, particularly alcohol-related disorders. Autoimmune pancreatitis often responds favorably to steroid therapy, and a dramatic resolution of a mass lesion in response to steroids can be helpful in confirming the diagnosis in patients who have not had surgical resection.

PANCREATIC EXOCRINE NEOPLASIA

Most (~85%) Pancreatic Tumors in Adults Are Infiltrating Ductal Adenocarcinomas

Adenocarcinoma is the most common pancreatic malignancy and is often synonymous with "pancreatic cancer." It is the 4th most common cause of cancer death in American men and the 5th in women. The prognosis is dismal: 5-year survival is less than 5%, and even the 20% of patients who can undergo surgical resection are rarely cured—the 5-year survival is less than 20% even when lymph nodes are uninvolved. Pancreatic cancer is increasing in many countries and has tripled in the United States over the past 50 years.

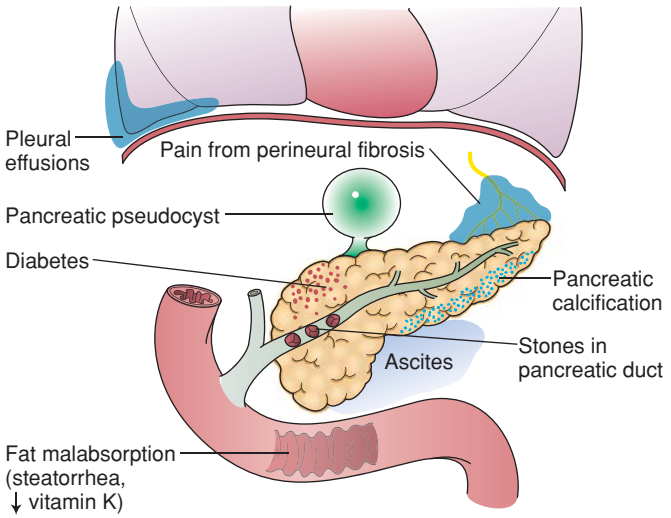

FIGURE 21-7. Complications of chronic pancreatitis.

EPIDEMIOLOGY: Pancreatic cancer occurs worldwide. The highest incidence (twice that in the United States) is among male Maoris, Polynesian aborigines of New Zealand and female natives of Hawaii. Over 45,000 new cases occur yearly in the United States, where it occurs 50% more often in Native Americans and blacks than in whites. Pancreatic cancer is a disease of late life, with peak incidence in people over 60 years old, although it may occur as early as the third decade. Males predominate (up to 3:1) at younger ages, but sex distribution equalizes in old age.

ETIOLOGIC FACTORS: The pathogenesis of pancreatic cancer is obscure. Epidemiologic studies implicate hereditary and environmental factors.

SMOKING: About 25% of pancreatic cancers are attributable to cigarette smoking; cigarette smoking increases pancreatic cancer risk 2–3-fold, proportionate to the number of cigarettes smoked per day. Smokers may show proliferative lesions (pancreatic intraepithelial neoplasia; see below) in the pancreatic ducts at autopsy. However, as only a small fraction of smokers develop pancreatic cancer, additional genetic and environmental factors are undoubtedly important.

BODY MASS INDEX (BMI) AND DIETARY FACTORS: Diets high in meat, fat and nitrates may increase the risk of pancreatic cancer. However, confounding factors such as methods of cooking (e.g., frying, boiling, barbecuing, etc.) may play a role. Increased BMI raises the risk of pancreatic cancer. Diets high in fruits, vegetables, fiber and vitamin C seem to protect against pancreatic cancer. There is no clear link to coffee or alcohol consumption.

DIABETES MELLITUS: Diabetics have greater risk for carcinoma of the pancreas. Up to 80% of patients with pancreatic cancer have evidence of diabetes mellitus at the time of cancer diagnosis. In some patients, the diabetes may be caused by the pancreatic cancer, rather than the reverse. However, patients with diabetes mellitus for 5 or more years have double the risk for pancreatic cancer.

CHRONIC PANCREATITIS: Chronic pancreatitis is a risk factor for pancreatic cancer, although conventional types (such as alcoholic pancreatitis) likely account for few cases. Hereditary pancreatitis is more clearly linked to cancer. Since chronic pancreatitis is often mild and clinically silent, its role in development of pancreatic carcinoma may be underestimated. On the other hand, pancreatic cancers may cause obstructive chronic pancreatitis since they invade pancreatic ducts and obstruct the distal gland. Thus, the relationship of pancreatitis and cancer has been difficult to unravel.

ADDITIONAL FACTORS: Other environmental factors are suggested by increased risk linked to specific occupations. Workers exposed to coal gas, metal, dry cleaning agents and leather tanning have a higher incidence of pancreatic cancer.

FAMILIAL PANCREATIC CANCER: Hereditary factors play a role in pancreatic cancer risk, and several hereditary

TABLE 21-1
FAMILIAL CANCER SYNDROMES AND RELATIVE RISK FOR PANCREATIC CANCER

Syndrome	Chromosome	Gene Mutation	Relative Risk of Pancreatic Cancer
Peutz-Jeghers syndrome	19p13	*STK11/LKB1*	132-fold
Hereditary pancreatitis	7q35	*PRSS1*	50–80-fold
Familial atypical multiple mole melanoma syndrome (FAMMM)	9p21	*P16 (CDKN2A)*	9–38-fold
Hereditary breast-ovarian cancer syndrome (HBOC)	13q12–13	*BRCA2*	3.5–10-fold
Hereditary nonpolyposis cancer syndrome (HNPCC)	3p21, 2p22	*hMLH1, hMSH2*	Unknown

diseases are implicated (Table 21-1; also see Chapter 5). However, cases associated with known germline mutations represent only a small fraction of all pancreatic cancers, and even families with multiple affected members usually do not have a known hereditary syndrome. Increased risk may be linked to specific ABO blood types, but genetic bases for familial pancreatic cancers are largely unknown.

MOLECULAR PATHOGENESIS: Infiltrating ductal cancers exhibit a number of genetic alterations. Some of these occur in most cases; others are infrequent. A genetic tumor progression model is supported by morphologic findings of preneoplastic ductal proliferative lesions, called **pancreatic intraductal neoplasia (PanIN),** the more recent nomenclature for dysplasia of the ducts. PanINs are characterized by mucinous epithelium replacing the normal lining of the ducts. PanINs are separated into 3 grades with increasing cytoarchitectural and genetic abnormalities. Early events, found in PanIN1, include telomere shortening and mutational activation of the *KRAS* oncogene, which is mutated in up to 95% of ductal adenocarcinomas. Later in the sequence of neoplastic progression, there is mutational inactivation or deletion of tumor suppressor genes, including *TP53* (50%–75%), *p16/CDKN2A* (95%) and *SMAD4/DPC4* (deleted in pancreatic cancer, locus 4) (55%). Interestingly, deletions in chromosome 18 are present in 90% of pancreatic cancers. Although *SMAD4* is on chromosome 18, only half of all pancreatic cancers show loss or inactivation of this gene, suggesting that other nearby tumor suppressors contribute to tumor development in the remaining 40%. Overactivity or inappropriate expression of several growth factors and their receptors has been described, including epidermal growth factor (EGF) and its receptor (EGFR), transforming growth factor-β (TGF-β), fibroblast growth factor (FGF) and its receptor (FGFR) and HER2/neu. BRCA2 is inactivated in 7% of pancreatic carcinomas, and a similar fraction lose DNA mismatch repair genes. Many other genes involved in ductal adenocarcinoma are being identified, but most are implicated in only a small proportion of cases. The timing of abnormalities of the most common involved genes in the progression of PanIN to invasive carcinoma is shown in Fig. 21-8.

PATHOLOGY: Ductal adenocarcinoma may arise anywhere in the pancreas but is most common in the head (60%–70%), followed by the body (10%) and tail (10%–15%). Sometimes, the pancreas is diffusely involved. Tumors of the pancreatic head may cause biliary obstruction by compressing the intrapancreatic common bile duct or ampulla of Vater. Classically, both the bile and pancreatic ducts are dilated ("double duct sign"). Carcinomas of the head tend to be smaller at the time of diagnosis than those elsewhere, with less spread to regional lymph nodes or distant sites.

Ductal adenocarcinomas are usually firm, gray, poorly demarcated masses (Fig. 21-9A) that can be difficult to distinguish from surrounding areas of fibrosing chronic pancreatitis. Invasion of peripancreatic tissues and other local structures is common. Tumors of the head of the pancreas may invade the common bile duct and duodenal wall, and encasement of the superior mesenteric vessels is often found in unresectable cases. They may also obstruct

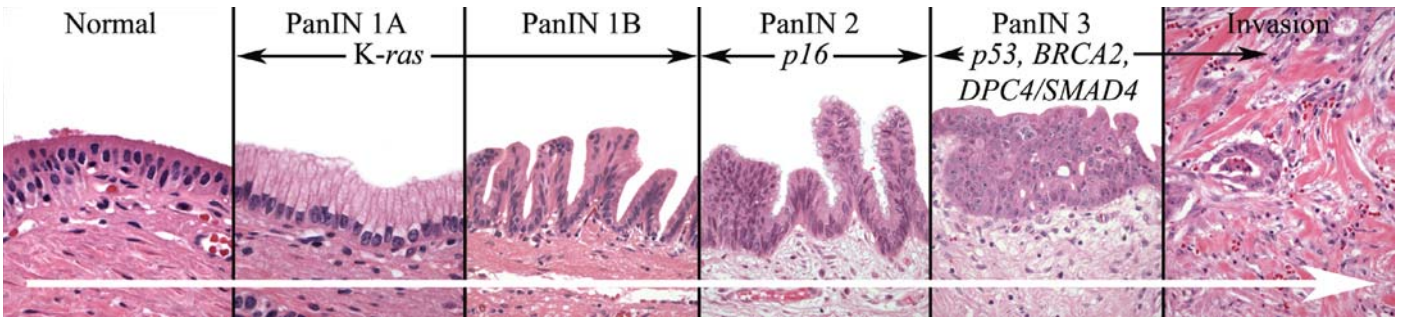

FIGURE 21-8. Pancreatic intraepithelial neoplasia (PanIN). From the left to the right, one proceeds from normal ductal epithelium to invasive carcinoma. Frequently mutated genes are shown when they are typically mutated within the spectrum of PanIN.

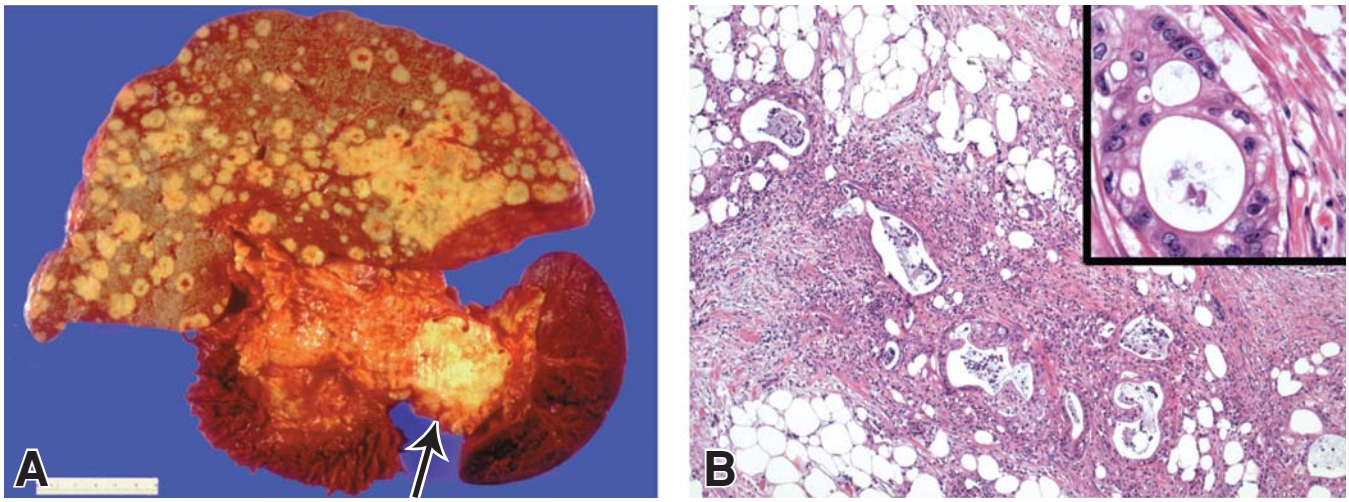

FIGURE 21-9. Infiltrating ductal adenocarcinoma of the pancreas. A. An autopsy specimen shows a large tumor in the tail of the pancreas (*arrow*) and extensive metastases in the liver. **B.** A section of the tumor reveals malignant glands infiltrating into adipose tissue with surrounding fibrous stroma. *Inset:* High-power image of a malignant gland.

the main pancreatic duct and cause atrophy of the body and tail. Carcinomas of the tail of the gland may extend into the spleen, transverse colon or stomach. Metastases in regional lymph nodes and liver are common. Other frequent metastatic sites include peritoneum, lungs, adrenals and bones; distant metastases and local spread render most cases unresectable.

Over 75% of infiltrating ductal adenocarcinomas are well to moderately differentiated (Fig. 21-9B), with well-formed individual tubular glands containing mucin-producing epithelial cells. Nuclear atypia may be focally marked, but some malignant glands may be so bland as to be difficult to distinguish from nonneoplastic ducts. Striking stromal desmoplasia around the neoplastic glands is the rule. The tumors are highly infiltrative and poorly circumscribed. Microscopic extension well beyond the gross limits of the tumor is common. Perineural invasion is a characteristic of these tumors and accounts for the early and persistent pain associated with them. Of the 25% of ductal adenocarcinomas that are poorly differentiated, sheets of cells or individual cells are seen. Additional variants include colloid carcinoma, medullary carcinoma, adenosquamous carcinoma and various undifferentiated carcinomas, including undifferentiated carcinoma with osteoclast-like giant cells.

Some ductal adenocarcinomas and variants arise in association with preinvasive cystic neoplasms such as mucinous cystic neoplasms and intraductal papillary mucinous neoplasms (see below).

CLINICAL FEATURES: Patients with pancreatic cancer present with anorexia, conspicuous weight loss and gnawing epigastric pain that often radiates to the back. Painless jaundice is seen in half of patients with cancer localized to the head of the pancreas but is uncommon in tumors of the body or tail. Depression may also be a presenting symptom. Serum levels of cancer antigen (CA) 19-9, a Lewis blood group antigen, are usually increased, but this finding is not specific. Early diagnosis of pancreatic cancer is unusual because the tumor is rarely symptomatic until it is advanced. Most have already metastasized at the time of diagnosis, and curative surgery is uncommon. Progressive deterioration almost invariably ensues, with intractable pain, cachexia and death. Half of patients die within a year of diagnosis, and overall 5-year survival is less than 5%.

Courvoisier sign is acute, painless gallbladder dilation accompanied by jaundice, due to common bile duct obstruction by tumor. In about one third of patients, it may be the first sign of pancreatic cancer, but it does not identify potentially curable tumors.

Migratory thrombophlebitis (Trousseau syndrome, deep venous thrombosis) develops in 10% of patients with pancreatic cancer, especially when the tumor involves the body and tail of the pancreas. It is not uncommon for migratory thrombophlebitis to be the first evidence of an underlying pancreatic malignancy, and it is also seen with other cancers. Unexplained thrombophlebitis in an otherwise healthy person demands a careful search for occult malignancy. The mechanisms underlying the hypercoagulable state that leads to migratory thrombophlebitis are not completely understood, but (1) a serine protease synthesized and released by malignant tumor cells directly activates plasma factor X, and (2) tumor cells shed plasma membrane vesicles, tissue factor and mucins, which have procoagulant activity.

The complications of pancreatic ductal carcinoma are shown in Fig. 21-10.

Acinar Cell Carcinoma Is an Uncommon Tumor of Older Adults

Acinar cell carcinomas are rare (1%–2% of pancreatic carcinomas) and recapitulate normal pancreatic acinar tissue, including production of exocrine enzymes. These tumors usually develop in people in their 60s but may rarely also occur in children. Some patients show a characteristic paraneoplastic syndrome of subcutaneous fat necrosis, polyarthralgia and peripheral eosinophilia, due to hypersecretion of massive amounts of lipase into the serum. The prognosis of acinar cell carcinoma is poor, but they are less rapidly fatal than are ductal adenocarcinomas. Acinar cell carcinomas are large and circumscribed and lack the desmoplastic stroma of ductal cancers. Microscopically, they

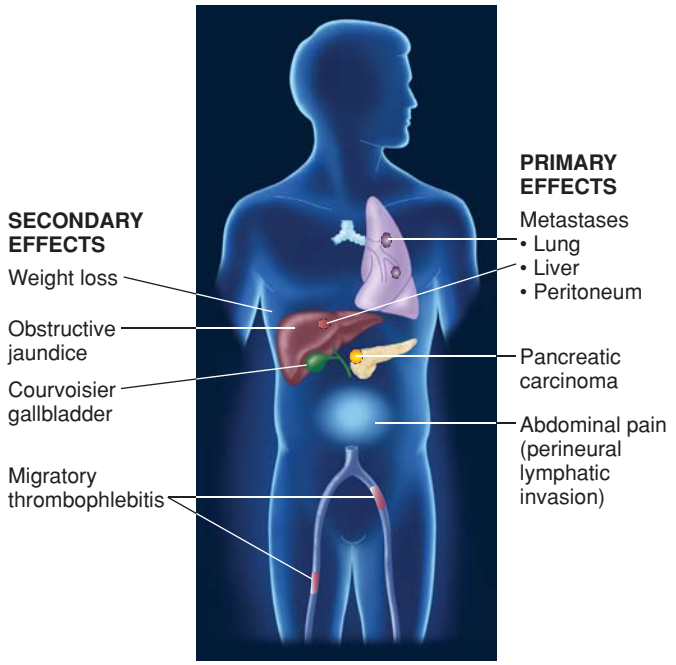

FIGURE 21-10. Complications of pancreatic ductal adenocarcinoma.

are composed of uniform cells arranged in small acini and nests (Fig. 21-11). Immunohistochemistry demonstrates production of exocrine enzymes such as trypsin and chymotrypsin. The molecular pathogenesis of acinar cell carcinoma differs from that of ductal adenocarcinoma. Some cases have abnormalities in the APC/β-catenin pathway, but the genes typically abnormal in ductal adenocarcinoma are not altered.

Pancreatoblastoma Is a Childhood Tumor

These tumors are usually seen in the first decade of life and may occur in the setting of Beckwith-Wiedemann syndrome. Serum α-fetoprotein levels may be elevated.

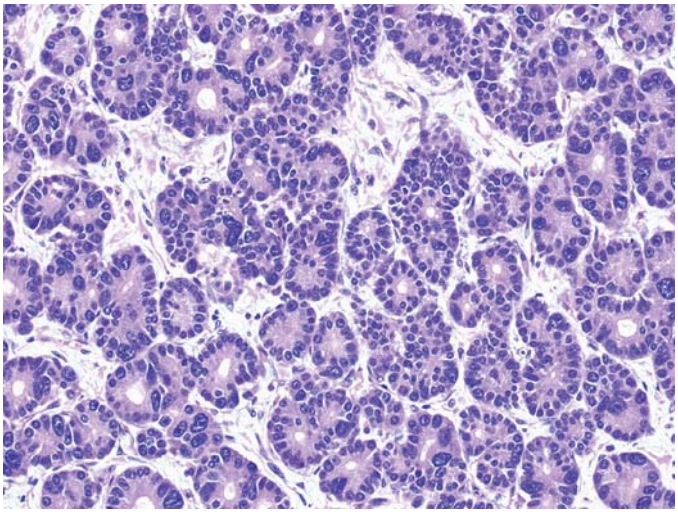

FIGURE 21-11. Acinar cell carcinoma. This malignant tumor is characterized by acinar formations reminiscent of normal pancreatic parenchyma.

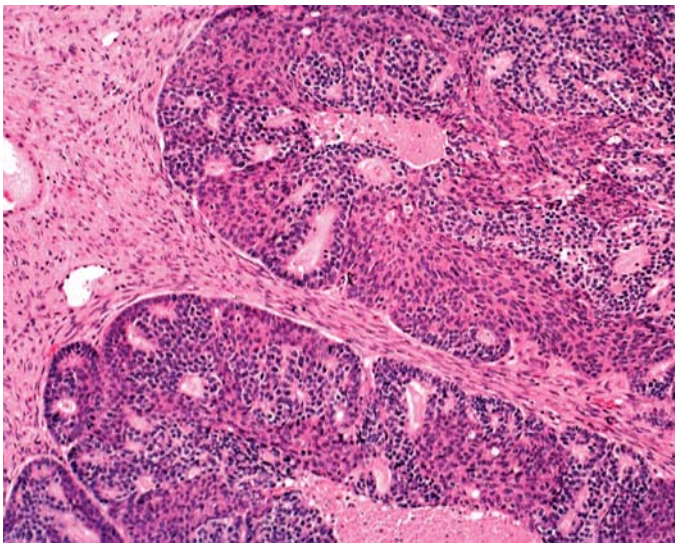

FIGURE 21-12. Pancreatoblastoma. There are spindle cell areas with scattered acinar structures.

Microscopically, tumors are composed of polygonal cells in solid islands and acinar structures, with interspersed squamoid nests (Fig. 21-12). Acinar differentiation, with production of exocrine enzymes, is consistently present, and some cases also have ductal or neuroendocrine differentiation. Lymph node or hepatic metastases occur in 1/3 of patients and are associated with a poor prognosis. Surgery and chemotherapy can be curative in patients without metastatic disease.

Serous Cystic Neoplasms of the Pancreas Are Nearly Always Benign

Serous cystic neoplasms are composed of numerous small cystic structures uniformly lined by glycogen-rich cuboidal epithelium with marked cytoplasmic clearing (Fig. 21-13).

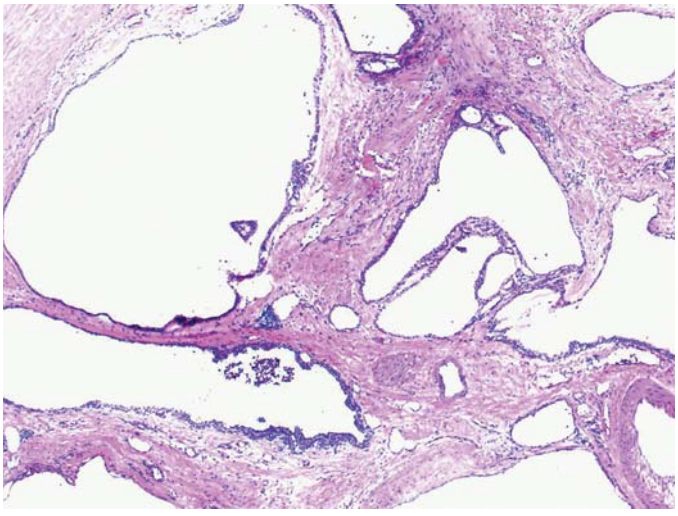

FIGURE 21-13. Serous cystadenoma. Cysts are embedded in a dense, fibrous stroma. The epithelial lining is composed of a single layer of glycogen-rich clear cells.

FIGURE 21-14. Intraductal papillary mucinous neoplasm. An exuberant papillary proliferation of tall mucin-secreting epithelium fills the pancreatic duct.

They usually occur in adults, in the pancreatic body or tail. Females predominate (3:1). Patients with von Hippel-Lindau syndrome are at increased risk for its development. It is not surprising, then, that these tumors are often associated with inactivation of the *VHL* gene. Serous cystadenomas range from 1 to 25 cm. Most patients present with nonspecific symptoms related to local mass effects, but many are asymptomatic. There is often a large, stellate central scar, sometimes with microcalcifications, giving a "sunburst" pattern on imaging studies. The tumors are sometimes removed owing to clinical concern for malignancy or because of symptoms.

Intraductal Papillary Mucinous Tumors May Be Associated with Invasive Carcinoma

Intraductal papillary mucin-producing neoplasms (IPMNs) are composed of dilated pancreatic ducts (>5 mm) lined by neoplastic mucinous epithelium and filled with mucus. Numerous papillary projections extend into the duct lumen (Fig. 21-14). IPMNs most often arise in the head of the pancreas and are usually diagnosed in late adulthood, after being found incidentally or in patients with symptoms of chronic pancreatitis. Duct involvement may be unifocal, multifocal or diffuse. Some IPMNs involve the main pancreatic ducts, while others are in peripheral (branch) ducts and mimic other cystic lesions on imaging studies. IPMNs exhibit varying degrees of epithelial dysplasia, similar to PanINs, and are graded in a similar fashion. Morphologically different types of epithelium occur in IPMNs, including gastric, intestinal, pancreatobiliary and oncocytic; each is associated with different immunohistochemical phenotypes and spectra of mutational changes. A focus of invasive adenocarcinoma is found in up to one third of larger cases. Because they may harbor invasive carcinomas, larger tumors or those with atypical radiographic features are often resected. The molecular pathogenesis of IPMNs involves many of the same genes altered in PanIN and pancreatic ductal adenocarcinoma. However, some develop via alternative molecular pathways, perhaps explaining the diverse phenotypes of these tumors compared to PanIN. Additionally, mutations in *GNAS*, *RNF43* and *APC* occur in 60%, 75% and 25% of IPMNs, respectively; these genes are not mutated in most conventional ductal adenocarcinomas.

Mucinous Cystic Neoplasms Occur Most Often in the Pancreatic Tails of Middle-Aged Women

Mucinous cystic neoplasm (MCN) is usually a multilocular cystic neoplasm lined by mucin-secreting epithelium with underlying cellular stroma (ovarian-like stroma) (Fig. 21-15). MCNs occur almost exclusively in middle-aged women. Tumors may reach 10 cm and do not communicate with the pancreatic duct system. They have a predilection for the pancreatic body and tail. Like IPMNs, these tumors may have varying degrees of epithelial atypia and are sometimes associated with invasive carcinoma. The prognosis of MCN (noninvasive) is excellent if it is completely removed. Molecular changes in MCNs are similar to those in PanIN and invasive pancreatic ductal adenocarcinoma, and like IPMNs, MCNs have mutations in *RNF43* in 1/2 of cases.

Solid Pseudopapillary Neoplasms Are Very-Low-Grade Tumors of Young Women

Solid pseudopapillary neoplasms (SPNs) are solid and circumscribed, often with large cystically degenerated areas filled with blood and necrotic debris. The tumors are composed of monomorphic cells forming loose solid sheets and pseudopapillary structures (Fig. 21-16). These result from degeneration of the cells distant from the numerous small vessels that traverse the neoplasm. The cell lineage of SPN is

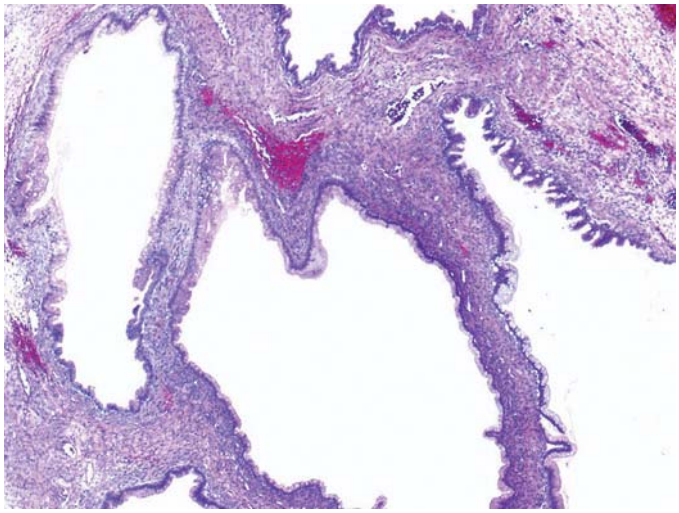

FIGURE 21-15. Mucinous cystic neoplasm. A mucin-rich epithelial lining of this cystic lesion rests on hypercellular, ovarian-like stroma.

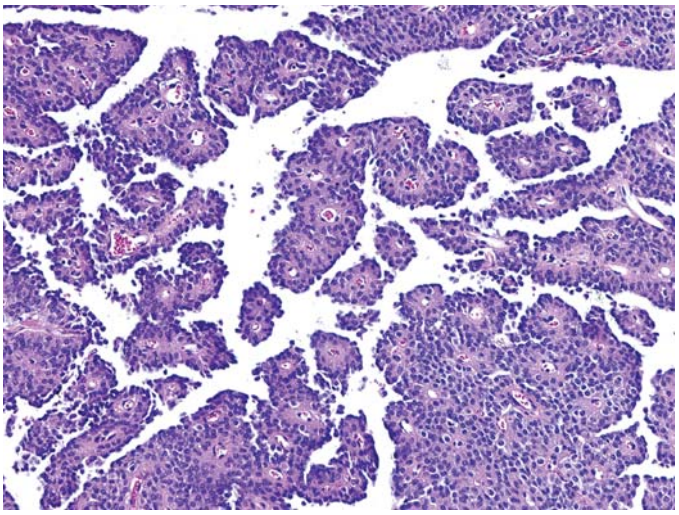

FIGURE 21-16. Solid pseudopapillary neoplasm. The tumor is composed of pseudopapillae with vascular cores.

unclear, and most cases fail to express any of the characteristic immunohistochemical markers of ductal, acinar or neuroendocrine differentiation. Most SPNs are very indolent and curable by complete surgical resection. Metastases, usually to the liver, occur in 10% of cases, and even those patients usually live for many years, underscoring the slow-growing nature of this neoplasm. Clinically, SPNs may mimic other malignancies of the pancreas. Most SPNs have mutations of the *β-catenin* gene, which results in abnormal nuclear localization of the protein—a useful diagnostic feature when detected using immunohistochemistry.

THE ENDOCRINE PANCREAS

The Islets of Langerhans Form the Endocrine Pancreas

The islets are irregularly scattered throughout the pancreas and consist of richly vascularized aggregates of endocrine cells arranged in spherical clusters (compact islets) or irregular trabeculae (diffuse islets). Four major distinct cell types are present in the islets, and each cell produces only one specific peptide hormone (Table 21-2).

TABLE 21-2
SECRETORY PRODUCTS OF ISLET CELLS AND THEIR PHYSIOLOGIC ACTIONS

Cell	Secretory Product	Physiologic Actions
Alpha	Glucagon	Catabolic; stimulates glycogenolysis and gluconeogenesis; raises blood glucose
Beta	Insulin	Anabolic; stimulates glycogenesis, lipogenesis and protein synthesis; lowers blood glucose
Delta	Somatostatin	Inhibits secretion of alpha, beta, D_1 and acinar cells
D_1	Vasoactive intestinal polypeptide (VIP)	Same as glucagon; also regulates tone and motility of the GI tract and activates cAMP of intestinal epithelium
PP	Human pancreatic polypeptide (hpp)	Stimulates gastric enzyme secretion; inhibits intestinal motility and bile secretion

cAMP = cyclic adenosine 3′,5′-monophosphate; GI = gastrointestinal.

- **Alpha cells** synthesize glucagon and are found at the periphery of islet lobules. They make up 15%–20% of the total islet cell population (Fig. 21-17A). Glucagon induces glycogenolysis and gluconeogenesis in the liver, thus raising blood glucose. Its secretion is stimulated by hypoglycemia and by ingestion of a low-carbohydrate, high-protein meal. By virtue of these responses, glucagon, together with insulin, serves to maintain glucose homeostasis.
- **Beta cells** make up 60%–70% of islet cells and produce insulin (Fig. 21-17B). They are found toward the centers of islets. By electron microscopy, beta cells contain characteristic polygonal and rhomboidal crystals enclosed in secretory vesicles. Insulin secretion is activated when glucose binds to receptors on the beta cell surface.
- **Delta cells** secrete somatostatin. They are few in number (5%–10%) and, like alpha cells, tend to be at the periphery of islets (Fig. 21-17C). Pancreatic somatostatin inhibits pituitary release of growth hormone and secretion by

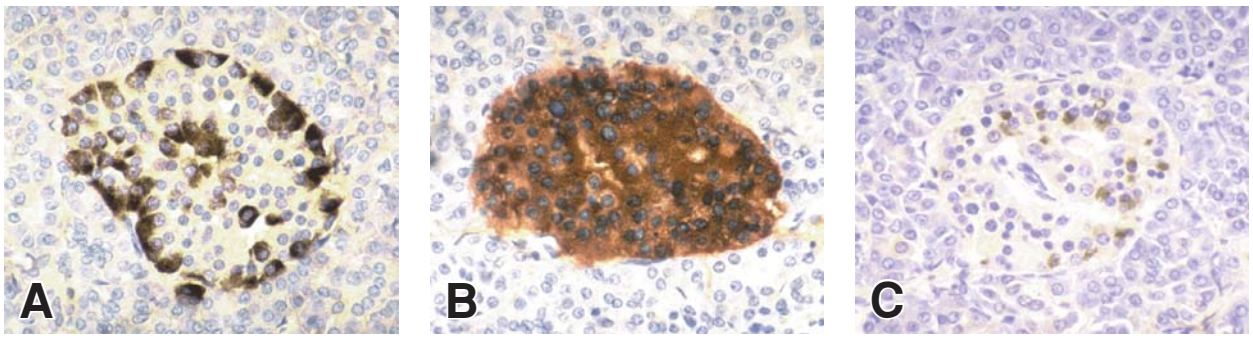

FIGURE 21-17. Localization of hormones of the pancreatic islet by specific antibodies. The immunoperoxidase technique reveals **(A)** glucagon in alpha cells at the periphery of the islet, **(B)** insulin in beta cells distributed throughout the islet and **(C)** somatostatin in sparsely distributed delta cells.

pancreatic alpha, beta and acinar cells and certain hormone-secreting cells in the gastrointestinal tract. These hormonal interactions suggest that somatostatin plays a regulatory role in glucose homeostasis.

- **Pancreatic polypeptide-secreting cells** are primarily in the diffuse islets within the part of the head of the pancreas derived from the embryonic ventral pancreas. They synthesize a polypeptide that appears to have diverse functions, including stimulation of enzyme secretion by the gastric mucosa, inhibition of smooth muscle contraction in the intestine and gallbladder, production of gastric acid and secretion by the exocrine pancreas and biliary system.

Well-Differentiated Pancreatic Neuroendocrine Tumors Make Up about 5% of Pancreatic Neoplasms

Pancreatic neuroendocrine tumors (PanNETs) are distinctive: they resemble normal islet cells and other well-differentiated endocrine (or neuroendocrine) tumors of the body, such as carcinoid tumors. Previously called "islet cell tumors," PanNETs may secrete hormones that cause dramatic paraneoplastic syndromes, or they may be nonfunctioning. Functioning varieties include insulinoma, glucagonoma, somatostatinoma, gastrinoma, VIPoma and other rare types.

These tumors show a range of clinical aggressiveness. If small, they can be cured by surgical resection, but larger tumors may develop incurable metastases. Predicting their likely clinical behavior is difficult, but features such as large size, high proliferative activity and more extensive invasion increase the chance of recurrence. Even in the presence of distant metastases, PanNETs often grow relatively slowly, and survival for years can occur. If functioning PanNETs cannot be completely removed by surgery, the hormonal syndromes they cause may be debilitating. Very small PanNETs (<0.5 cm), called pancreatic neuroendocrine microadenomas, are common incidental findings.

Most PanNETs are nonfunctioning, but among functioning PanNETs, insulinomas are most common. PanNETs occur at any age but are most common between 40 and 60 years, affecting men and women equally. The distinctive clinical syndromes of the more common functioning types are shown in Fig. 21-18 and discussed further below. Nonfunctioning PanNETs are detected incidentally by imaging studies and attract attention by local effects or metastases (e.g., in the liver).

MOLECULAR PATHOGENESIS: PanNETs are a component of multiple endocrine neoplasia syndrome type 1 (MEN1), which also involves pituitary and parathyroid adenomas, and less commonly endocrine tumors of other organs. Affected patients usually have multiple pancreatic neuroendocrine microadenomas and PanNETs, at least one of which is functioning. Patients with von Hippel-Lindau (VHL) syndrome also develop nonfunctioning PanNETs that may be histologically distinguished by their clear cytoplasm.

The genes involved in MEN1 and VHL syndromes (*MEN1* and *VHL* tumor suppressors, respectively) show biallelic inactivation in the hereditary PanNETs in these patients. Sporadic PanNETs also show mutations in the *MEN1* gene in 45% of cases. Other genes involved include members of the mammalian target of rapamycin (mTOR) pathway (e.g., *TSC1, PTEN, PIK3CA*) in 14% and a pair of genes involved in telomere maintenance, *DAXX* (death domain–associated protein) and *ATRX* (α-thalassemia/mental retardation syndrome X-linked), which are mutually exclusively lost in 43% of cases. PanNETs do not usually have mutations in the genes commonly mutated in ductal adenocarcinomas (see above).

Functioning PanNETs Produce Dramatic Paraneoplastic Syndromes

- **Insulinomas,** the most common functioning PanNETs, secrete sufficient insulin to cause hypoglycemia. Insulin secretion by the tumor cells is not regulated by blood glucose levels, so the tumors secrete insulin continuously. Although these tumors are usually small (75% are <2 cm), the symptoms may be profound and include both the direct central nervous system effects of hypoglycemia and the secondary effects of the resulting catecholamine response. Patients complain of sweating, visual changes, nervousness and hunger, which may progress to confusion, lethargy and even seizures or coma. Their abnormal behavior may falsely suggest a psychiatric disorder. Insulinomas occur somewhat more often in the tail of the pancreas (Fig. 21-19). Although 30% of the functioning PanNETs in patients with MEN1 are insulinomas, only 5% of insulinomas arise in the setting of MEN1. Compared to other PanNETs, insulinomas have a benign clinical course, perhaps because they are usually very small when detected. Surgical removal, even by enucleation, is usually curative.
- **Glucagonomas** are associated with a syndrome of (1) mild diabetes; (2) a necrotizing, migratory, erythematous rash; (3) anemia; (4) diarrhea; and (5) deep vein thromboses. Psychiatric disturbances also occur. Glucagonomas constitute 8%–13% of functioning PanNETs and occur between the ages of 40 and 70 years, with a slight female predominance. In patients with alpha cell tumors, plasma glucagon levels may be up to 30 times above normal. Like other functioning PanNETs (except insulinomas) and nonfunctioning PanNETs, glucagonomas exhibit malignant behavior in 50%–70% of cases.
- **Somatostatinomas** are rare and produce a syndrome of mild diabetes, gallstones, steatorrhea, hypochlorhydria, anemia and weight loss, due to the inhibitory actions of somatostatin on other cells of the pancreatic islets and on neuroendocrine cells of the gastrointestinal tract. Consequently, blood levels of insulin and glucagon are low.
- **Pancreatic gastrinoma** is a functioning PanNET composed of so-called G cells, which produce gastrin, a potent hormonal stimulus for gastric acid secretion. The location of this tumor in the pancreas is curious, because gastrin-producing cells do not normally occur in the islets. Pancreatic gastrinoma causes Zollinger-Ellison syndrome, a disorder showing (1) intractable gastric hypersecretion, (2) severe peptic ulceration of the duodenum and jejunum and (3) high blood gastrin levels. Among functioning PanNETs, gastrinomas are second in frequency to insulinomas, and they are the most common functioning tumor in MEN1 patients. However, the pancreas is a less common location for gastrinomas than is the duodenum, especially in cases not associated with MEN1. Gastrinomas of the pancreas are usually over 2 cm, but duodenal gastrinomas can measure only a few millimeters. Sometimes only lymph node metastases are found, with no

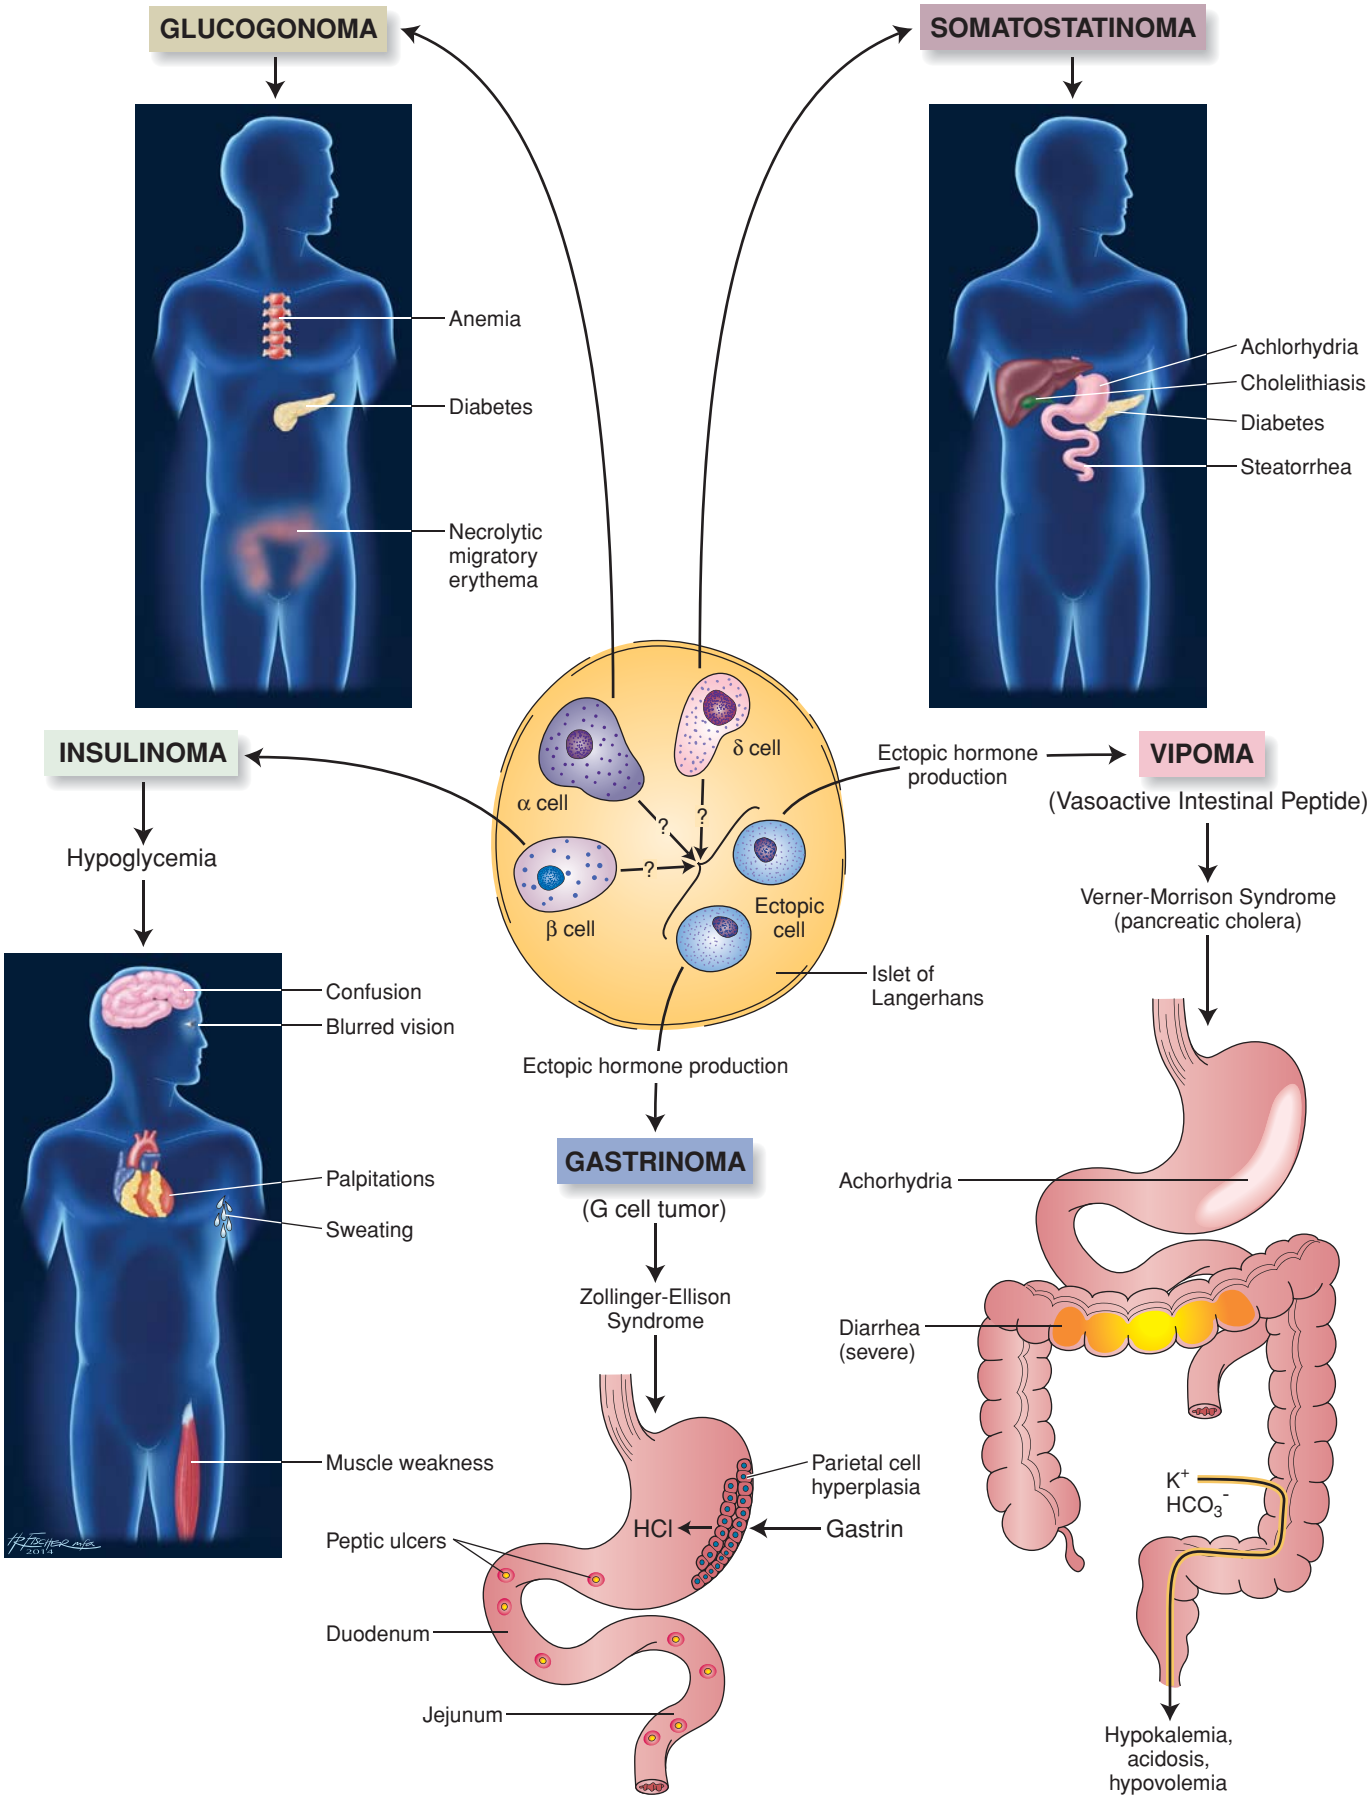

FIGURE 21-18. Syndromes associated with well-differentiated pancreatic neuroendocrine tumors.

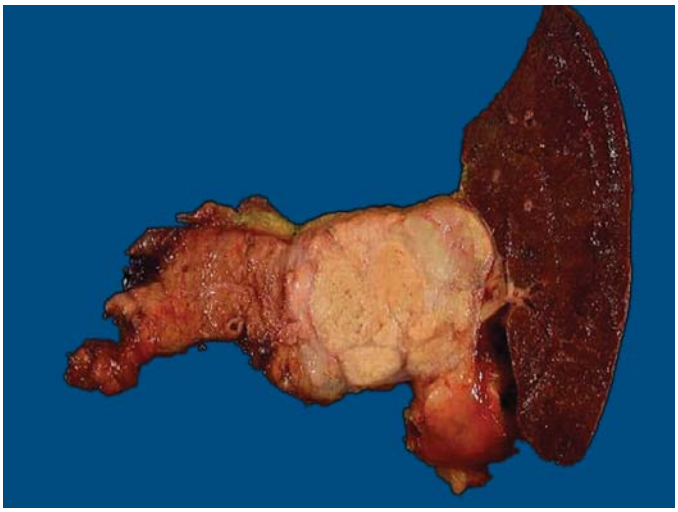

FIGURE 21-19. Well-differentiated pancreatic neuroendocrine tumor. This well-circumscribed somewhat nodular tumor was located in the tail of the pancreas near the spleen.

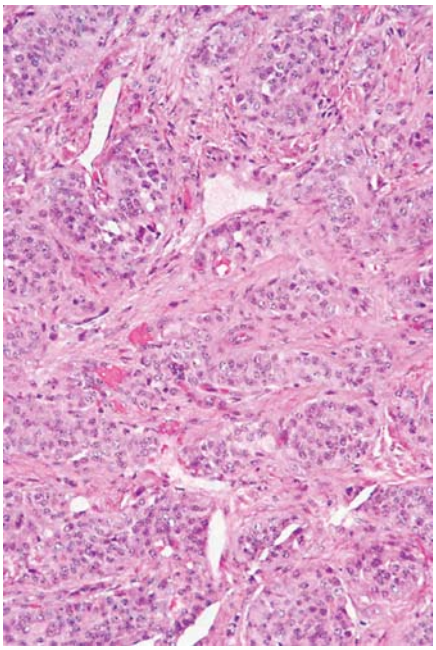

FIGURE 21-21. Insulinoma. Nests of tumor cells are surrounded by numerous capillaries.

evidence of a primary gastrinoma. Gastrinomas are most common between the ages of 30 and 50, with a slight male predominance. Most pancreatic examples arise in the head of the gland. Pancreatic gastrinomas are aggressive, although those arising in the duodenum usually remain localized, even when lymph node metastases are present.

- **VIPomas** are functioning PanNETs that produce vasoactive intestinal polypeptide (VIP). Like gastrin, VIP is not normally found in nonneoplastic islet cells but rather is made in ganglion cells and nerve fibers of the pancreas, gut and brain. VIP induces glycogenolysis and hyperglycemia and regulates ion and water secretion by the gastrointestinal epithelium. VIPomas induce Verner-Morrison syndrome, which is characterized by explosive and profuse watery diarrhea, hypokalemia and achlorhydria (also known as WDHA syndrome or pancreatic cholera). VIPomas are rare (3%–8% of all PanNETs and 10% of functioning PanNETs) and are usually large and solitary.
- PanNETs may rarely secrete **other hormones not ordinarily produced by the pancreas (ectopic hormones),** including adrenocorticotropic hormone (ACTH), parathyroid hormone, calcitonin and vasopressin. These ectopic hormones may be produced either alone or in combination with normally occurring pancreatic hormones. Pancreatic polypeptide can also be secreted by some PanNETs, dubbed "PPomas," but no specific clinical syndrome is attributed to this hormone, so technically PPomas are clinically nonfunctioning.

PATHOLOGY: Other than the smaller size for insulinomas, functioning and nonfunctioning PanNETs appear similar. They are usually solitary, circumscribed masses of pink to tan, soft tissue (Fig. 21-19). Larger tumors are multinodular and have areas of hemorrhage. Cystic degeneration can occur, or some cases are firm and fibrotic. They have uniform cells, arranged in so-called organoid patterns, including nests, ribbons, glands and festoons (Figs. 21-20 and 21-21). Nuclei are uniform and the chromatin is coarsely stippled. The proliferative rate is low; by definition, there should be fewer than 20 mitotic figures in 10 high-power microscopic fields, and under 20% of nuclei should be positive for the immunohistochemical proliferation

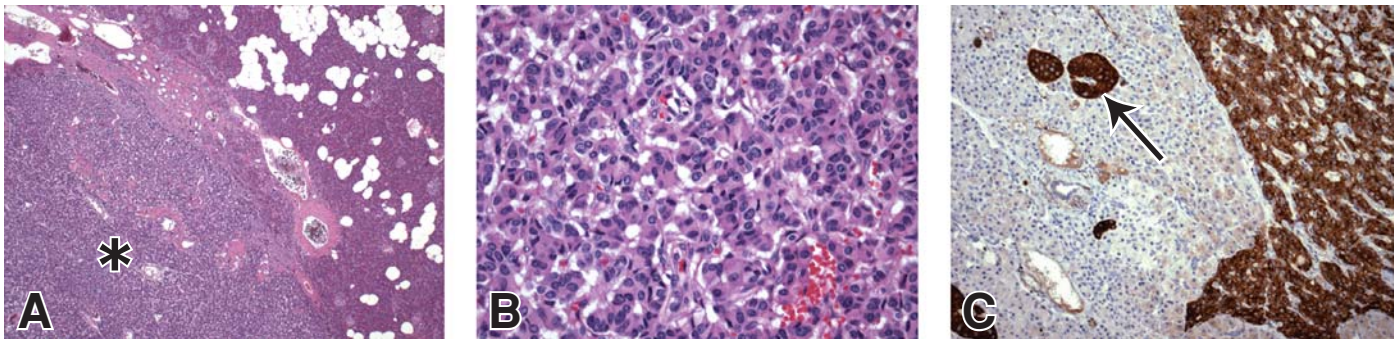

FIGURE 21-20. Well-differentiated pancreatic neuroendocrine tumor. A. The well-circumscribed nature of the tumor (*) can be appreciated at low power. **B.** A higher-power image showed the uniform neoplastic epithelioid cells to be arranged in cords. **C.** An immunohistochemical stain for chromogranin highlights tumor and the islets (*arrow*) within the adjacent pancreas.

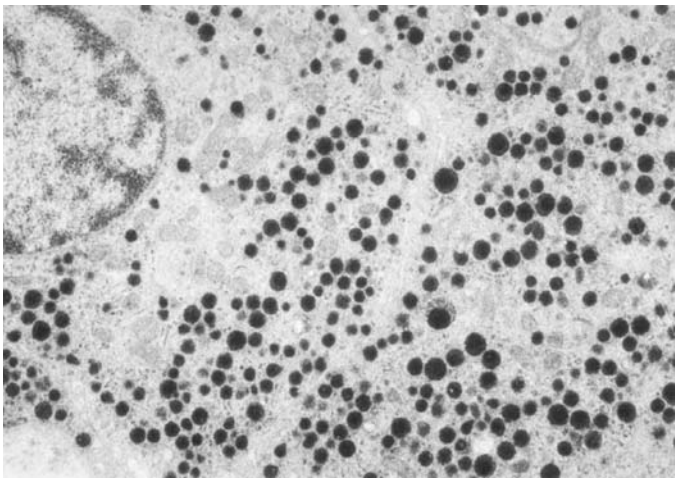

FIGURE 21-22. Alpha cells in a functional glucagonoma. The granules are indistinguishable from those of normal alpha cells (electron micrograph).

marker Ki67. Low- and intermediate-grade groups of PanNETs can be further defined based on these measures of proliferation, and the grade correlates well with prognosis. Sometimes the stroma contains amyloid, or it may be sclerotic.

Certain histologic patterns have been attributed to the various functioning types of PanNETs, but this relationship is loose at best and cannot be used to determine the cell type of the PanNET. The neuroendocrine nature of the tumor is demonstrated using immunohistochemistry with antibodies against chromogranin A (Fig. 21-20) and synaptophysin. Often, functioning PanNETs can be shown to produce the hormone responsible for the clinical syndrome using immunohistochemistry, but production of a number of different hormones in minor cell populations is not uncommon, even in clinically nonfunctioning PanNETs. Electron microscopy also shows characteristic neurosecretory granules (Fig. 21-22), and in some functioning PanNETs, granule morphology matches that of the specific granules in the nonneoplastic islet cell counterparts.

Anatomy

The kidneys are paired, bean-shaped organs located on both sides of the vertebral column in the retroperitoneal space. Adult kidneys average 150 g and are approximately 11 cm long, 6 cm wide and 3 cm thick. Each kidney consists of an outer cortex and an inner medulla (Fig. 22-1). When a kidney is bisected, the medulla has approximately 12 pyramids, with their bases at the corticomedullary junction. A medullary pyramid and its overlying cortex constitute a renal lobe. A pyramid has an inner and an outer zone. The inner zone, the **papilla,** empties into a calyx, a funnel-shaped structure that conducts urine into the renal pelvis, which empties into the ureter.

BLOOD VESSELS

The kidney is one of the most vascular organs in the body and receives about 20%–25% of the cardiac output. The blood supply to each kidney usually derives from a single main renal artery, although 1/4 of kidneys have one or more

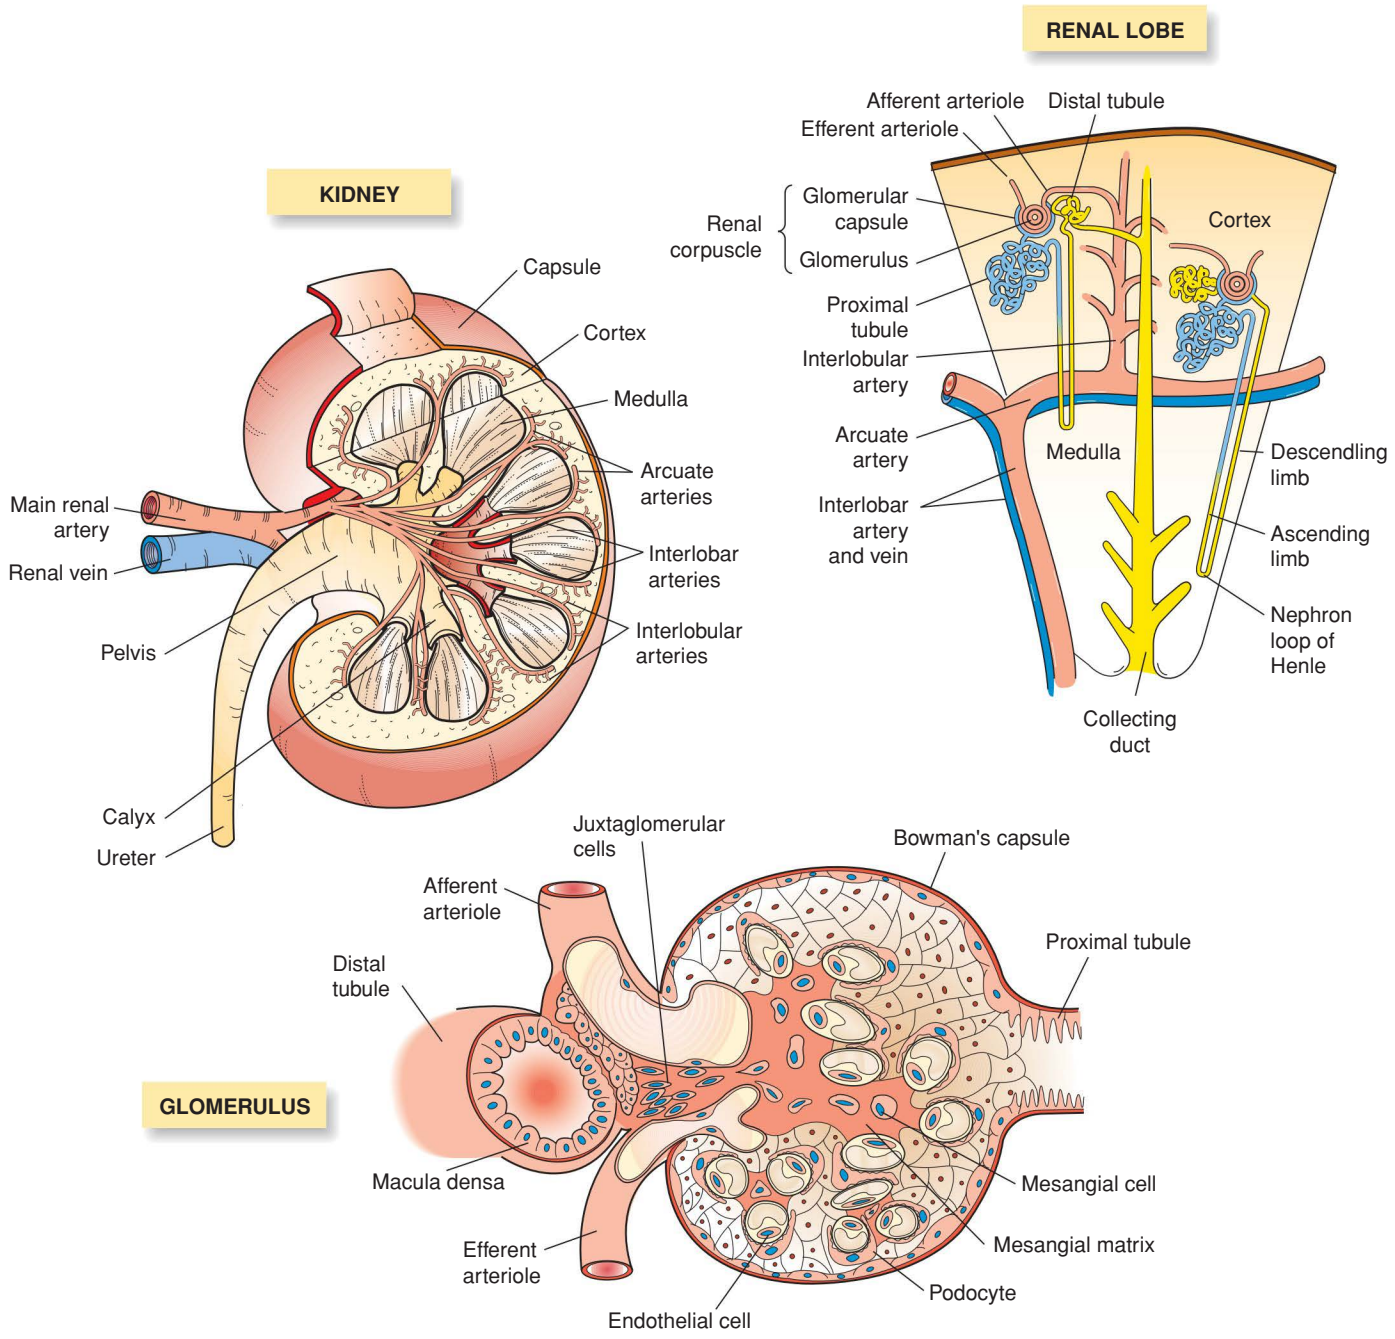

FIGURE 22-1. The gross and microscopic anatomy of the kidney.

accessory renal arteries. Before entering the renal parenchyma, the renal artery divides into anterior and posterior branches, which in turn give rise to interlobar arteries (Fig. 22-1). The latter branch into arcuate arteries, which run parallel to the renal surface near the corticomedullary junction. Interlobular arteries arise from the arcuate arteries and extend toward the renal surface, giving off afferent arterioles, each of which supplies a single glomerulus. Efferent arterioles drain the glomeruli and then branch into capillaries. Those in the outer cortex give rise to capillaries that supply blood to the cortical parenchyma, and those in the deep cortex, adjacent to the medulla, provide vessels that extend into the medulla to become the medullary peritubular vessels, the **vasa recta**.

The Glomerulus Is the Renal Filter

The **nephron** is the functional unit of the kidney and includes the glomerulus and its tubule, the latter terminating at a common collecting system (Fig. 22-1). The glomerulus is a specialized network of capillaries covered by epithelial cells called **podocytes** and supported by modified smooth muscle cells called **mesangial cells** (Figs. 22-1, 22-2, 22-3, 22-4). As it enters the glomerulus, the afferent arteriole branches into capillaries, which form the convoluted glomerular tuft and eventually coalesce into the efferent arteriole that exits the glomerulus. Glomerular capillaries are lined by fenestrated endothelial cells lying on a basement membrane. The outer surface of this basement membrane is covered by podocytes.

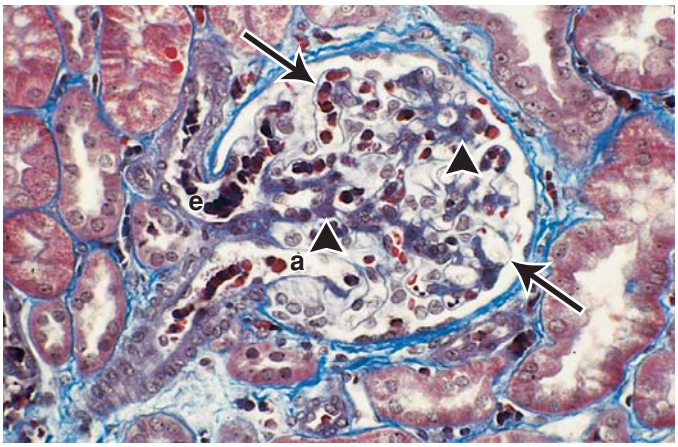

FIGURE 22-2. Normal glomerulus, light microscopy. The Masson trichrome stain shows a glomerular tuft with delicate blue capillary wall basement membranes (*arrows*), small amounts of blue matrix (*arrowheads*) surrounding mesangial cells and the hilum on the left. The afferent arteriole (*a*) enters below, and the efferent arteriole (*e*) exits above.

The Bowman space lies between the podocytes and the epithelial cells that line the Bowman capsule.

Glomerular Basement Membrane

The glomerular basement membrane (GBM) (Figs. 22-3, 22-4, 22-5) separates endothelial cells from podocytes in peripheral

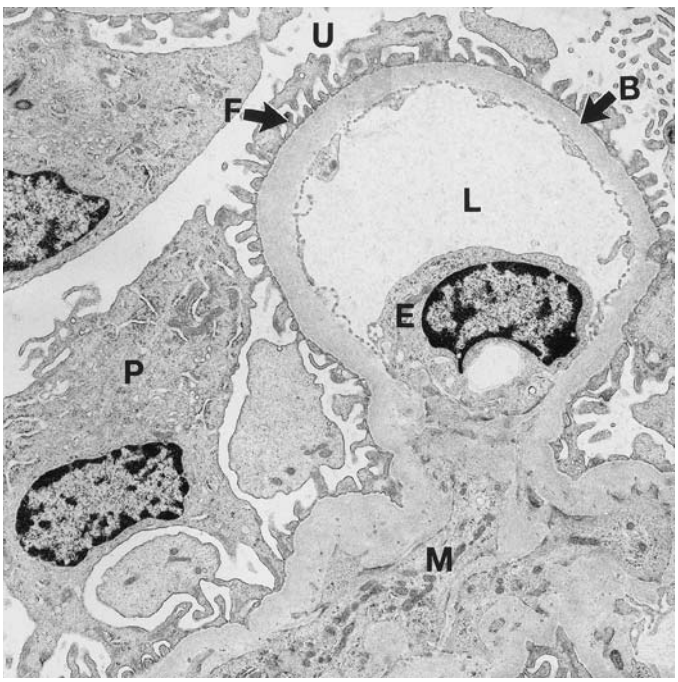

FIGURE 22-3. Normal glomerular capillary. In this electron micrograph of a single capillary loop and adjacent mesangium, the capillary wall portion of the lumen (L) is lined by a thin layer of fenestrated endothelial cytoplasm (shown at higher magnification in Fig. 22-5) that extends out from the endothelial cell body (E). The endothelial cell body is in direct contact with the mesangium, which includes the mesangial cell (M) and adjacent matrix. The outer aspect of the basement membrane (B) is covered by foot processes (F) from the podocyte (P) that line the urinary space (U). Compare this figure with Figs. 22-4 and 22-5.

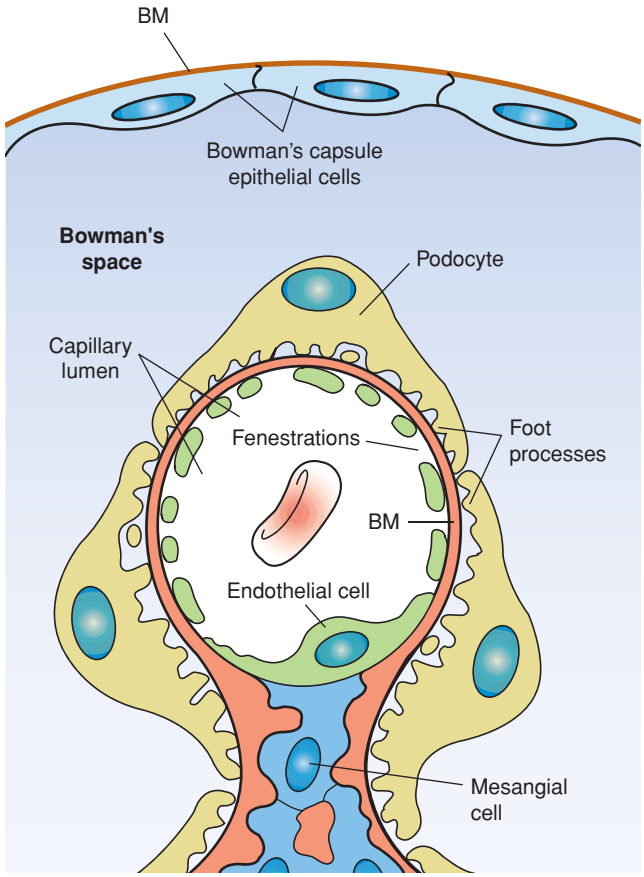

FIGURE 22-4. Normal glomerulus. The relationship of the different glomerular cell types to the basement membrane and mesangial matrix is illustrated using a single glomerular loop. The entire outer aspect of the glomerular basement membrane (peripheral loop and stalk) is covered by the visceral epithelial cell (podocyte) foot processes. The outer portions of the fenestrated endothelial cell are in contact with the inner surface of the basement membrane, whereas the central part is in contact with the mesangial cell and adjacent mesangial matrix. Compare with Fig. 22-3.

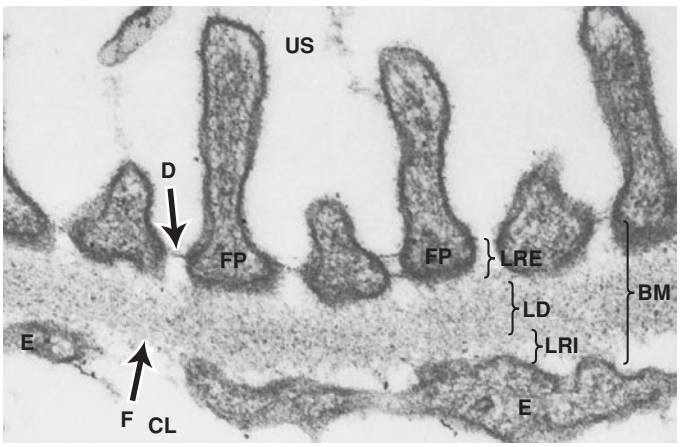

FIGURE 22-5. The glomerular filter. An electron micrograph illustrates the structures of the glomerular filter. Molecules that pass from the capillary lumen (CL) to the urinary space (US) traverse the fenestrations (F) of the endothelial cell (E), the trilaminar basement membrane (BM) (lamina rara interna [LRI], lamina densa [LD] and lamina rara externa [LRE]) and the slit pore diaphragm (D) that connects podocyte foot processes (FP).

capillary walls and also podocytes from the mesangium. Since the GBM does not completely surround each capillary lumen, but rather splays out over the mesangium as the paramesangial GBM, substances in the blood may potentially enter the mesangium without crossing the GBM.

Although morphologically similar to many other basement membranes, the GBM is functionally and chemically distinct. It is approximately 350 nm thick and has three ultrastructurally definable layers (Fig. 22-5):

- **Lamina densa:** A central electron-dense zone
- **Lamina rara interna:** A thin inner electron-lucent zone
- **Lamina rara externa:** A thin outer electron-lucent zone

The GBM is composed mainly of type IV collagen, which provides its major scaffolding. Genetic abnormalities in type IV collagen and autoantibodies directed against type IV collagen cause glomerular disease. Other constituents include glycosaminoglycans, laminin, entactin and fibronectin. The polyanionic glycosaminoglycans, which are rich in heparan sulfate, impart a strong negative charge to the GBM. This allows selective filtration of electrically neutral and cationic molecules and relative exclusion of negatively charged molecules such as albumin. The GBM also discriminates among molecules on the basis of size.

Glomerular Endothelial Cells

The glomerular endothelial cell layer is 50 nm thick and contains numerous 60–100-nm pores or fenestrations (Fig. 22-5) that are not spanned by diaphragms. Thus, they permit passage of fluid, ions and proteins (Fig. 22-4). Endothelial surface membrane proteins (e.g., adhesion molecules) and endothelial secretory products (e.g., prostaglandins and nitric oxide) play important roles in the pathogenesis of inflammatory and thrombotic glomerular diseases (Figs. 22-4, 22-5).

Podocytes

Podocytes rest on the outer aspect of the GBM and send cytoplasmic projections, **foot processes,** onto the lamina rara externa of the GBM (Fig. 22-5). Between adjacent foot processes is a thin membrane called the **slit diaphragm,** which is a modified adherens junction. Podocytes are the major glomerular barrier to protein loss in the urine. Mutations in proteins in podocytes and the slit diaphragm (e.g., **nephrin, podocin, α-actinin-4** and **transient receptor potential cation channel 6 [TRPC6]**) can result in abnormal protein loss into the urine (proteinuria).

Mesangium

The mesangium is a cellular and matrix network that supports the glomerulus. Mesangial cells are modified smooth muscle cells situated in the center of the glomerular tuft between capillary loops. Important functions of the mesangium are:

- Mechanical support for the glomerulus
- Endocytosis and processing of plasma proteins, including immune complexes
- Maintenance of basement membrane and matrix elements
- Modulation of glomerular filtration by mesangial cell contractility
- Generation of molecular mediators (e.g., prostaglandins and cytokines)

Tubules Comprise Most of the Nephron

The major segments of the tubule that arise from each glomerulus are the proximal tubule, loop of Henle and distal tubule, which empties into the collecting duct. At the origin of the proximal tubule from the glomerulus, the flat epithelium of the Bowman capsule abruptly transforms into tall columnar cells of the **proximal tubule,** which have numerous tall microvilli that form a brush border. The initial segment is very tortuous and is called the **proximal convoluted tubule**. As it descends into the medulla, the proximal tubule straightens into the thick **descending limb of the loop of Henle**. Further into the medulla, the thick descending limb thins into the **thin limb of the loop of Henle,** which eventually loops back toward the cortex.

Approaching the cortex, the thin limb becomes the **thick ascending limb**. This abuts the glomerulus from which it arose, contributes to that glomerulus' juxtaglomerular apparatus and then becomes the **distal convoluted tubule**. Several distal tubules unite to form a **collecting duct,** which ultimately empties into the ducts of Bellini, which discharge urine through the papillae into the calyces.

The Juxtaglomerular Apparatus Secretes Renin and Angiotensin

The juxtaglomerular apparatus is at the hilus of the glomerulus and consists of:

- **Macula densa,** a region of the thick ascending limb of the loop of Henle that has closely packed nuclei
- **Extraglomerular mesangial cells,** between the macula densa and the hilar arterioles
- **Terminal afferent arteriole** and **proximal efferent arteriole**

The wall of the afferent arteriole contains characteristic granular cells involved in the synthesis and secretion of renin and angiotensin.

The Interstitium Provides Structural Support

The renal interstitium is composed of interstitial cells that resemble fibroblasts and surrounding collagenous matrix. The interstitium occupies only 10% of cortical volume but constitutes 20%–30% of medullary volume. In addition to providing structural support, some cortical interstitial cells secrete erythropoietin and some medullary cells elaborate prostaglandins.

Congenital and Inherited Renal Diseases

CONGENITAL ANOMALIES

Potter Sequence Results from Insufficient Amniotic Fluid

Potter sequence (oligohydramnios sequence) is a syndrome of pathologic abnormalities that are caused by markedly

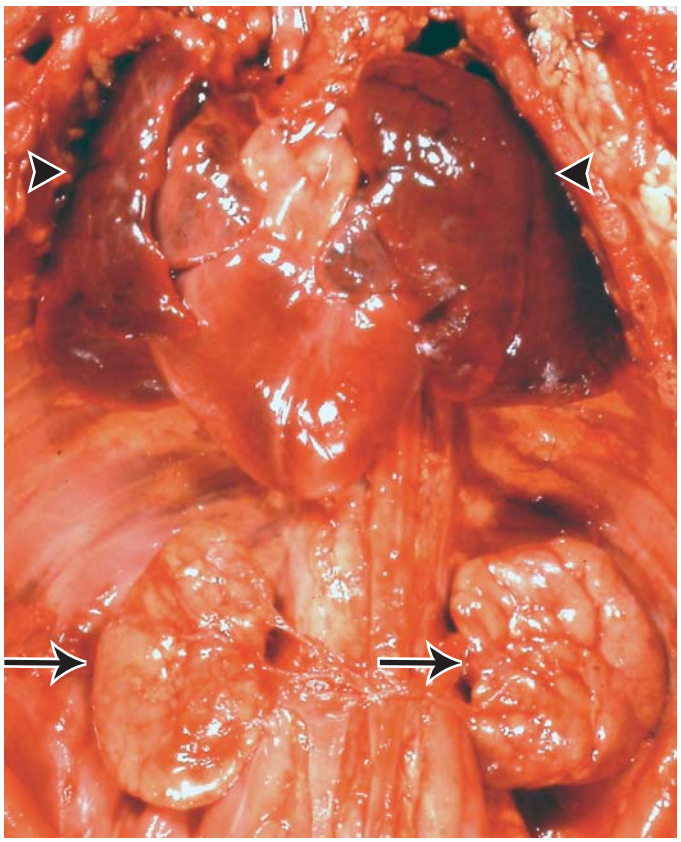

FIGURE 22-6. Bilateral renal agenesis. The Potter sequence includes congenitally nonfunctional kidneys, pulmonary hypoplasia and many other anomalies. In this case, there was bilateral renal agenesis, with only mesenchymal elements in the renal rudiments (*arrows*). Consequently, the lungs were hypoplastic (*arrowheads*). This infant was stillborn.

reduced intrauterine urine production (also see Chapter 6). Reduced urine production due, for example, to bilateral renal agenesis (Fig. 22-6) results in less amniotic fluid (oligohydramnios). The amniotic fluid normally cushions the fetus. With less fluid, the fetus is compressed by the uterus. This compression causes flattening of the face with low-set ears, a small receding chin and a beak-like nose; it also restricts movement of the arms and legs, often leading to abnormally bent lower extremities. The most life-threatening component of Potter sequence is pulmonary hypoplasia (Fig. 22-6), which is caused by inadequate maturational stimuli from amniotic fluid and by compression of the chest wall by the uterus. Because even neonates can be dialyzed, severe respiratory insufficiency due to Potter sequence (rather than renal insufficiency) may be the cause of death in infants with severe congenital renal anomalies.

Renal Agenesis Is the Complete Absence of Renal Tissue

Most infants born with bilateral renal agenesis (Fig. 22-6) are stillborn and have Potter sequence. Bilateral agenesis is often associated with other anomalies, especially elsewhere in the urinary tract or lower extremities. Unilateral renal agenesis is not serious if there are no associated anomalies, as the contralateral kidney hypertrophies sufficiently to maintain normal renal function. If unilateral renal agenesis is accompanied by hypoplasia of the contralateral kidney, there is an increased risk for developing progressive glomerular sclerosis (secondary focal segmental glomerulosclerosis [FSGS]) due to overwork of nephrons.

In Renal Hypoplasia, Kidneys Are Histologically Normal but Smaller

Congenital hypoplastic kidneys are formed by six or fewer renal lobes (medullary pyramids with overlying cortex). Hypoplasia must be differentiated from small kidneys due to atrophy or scarring. A frequent variant of hypoplasia features enlargement of the too few glomeruli and thus is called **oligomeganephronia**. This enlargement indicates overwork of too few nephrons and predisposes to developing FSGS.

Renal Ectopia Is a Normal Kidney in an Abnormal Location

The misplaced kidney is usually in the pelvis, due to failure of the fetal kidney to migrate from the pelvis to the flank. One or both kidneys may be affected. In **simple ectopia,** the ureters drain into the appropriate side of the bladder. In **crossed ectopia,** the ectopic kidney is on the same side as its normal mate; the ectopic ureter crosses the midline and drains into the contralateral side of the bladder.

Horseshoe Kidney Is a Single, Large, Midline Organ

The kidneys are fused, usually at the lower poles (Fig. 22-7). This anomaly increases the risk for obstruction and renal

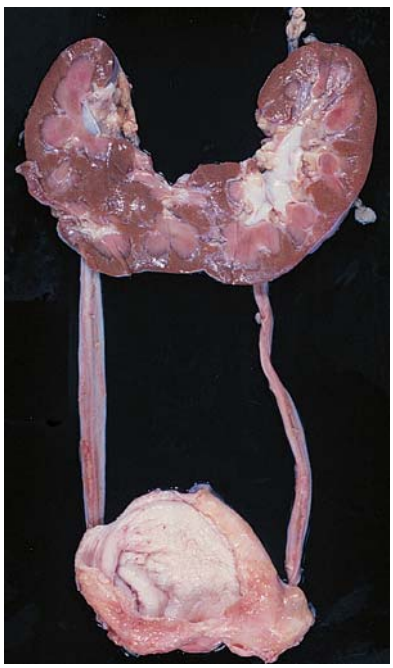

FIGURE 22-7. Horseshoe kidney. The kidneys are fused at the lower pole.

infection (pyelonephritis) because the ureters are compressed as they cross over the junction between the two kidneys when the organ is fused at the lower pole.

In Renal Dysplasia, Primitive Mesenchyme Surrounds Undifferentiated Tubules

This mesenchyme sometimes contains heterotopic tissue such as cartilage. Cysts often form from the abnormal tubules.

PATHOPHYSIOLOGY: Renal dysplasia results from abnormal metanephric differentiation and has multiple genetic and somatic causes. Some familial forms of dysplasia probably result from abnormal differentiation signals that affect the inductive interactions between the ureteric bud and the metanephric blastema. Many forms of dysplasia are accompanied by other urinary tract abnormalities, especially ones that cause obstruction of urine flow. This association suggests that obstruction to urine flow in utero can cause dysplasia. Frequent associated anomalies include:

- Ureteral agenesis
- Ureteral atresia
- Ureteropelvic junction obstruction
- Ureterovesical stenosis or posterior urethral valves

PATHOLOGY: The histologic hallmark of renal dysplasia is undifferentiated tubules and ducts lined by cuboidal or columnar epithelium. These structures are surrounded by mantles of undifferentiated mesenchyme that may contain smooth muscle and islands of cartilage (Fig. 22-8). Rudimentary glomeruli may be seen, and tubules and ducts may be cystically dilated. Renal dysplasia can be unilateral or bilateral, and the affected kidney may be quite large or very small:

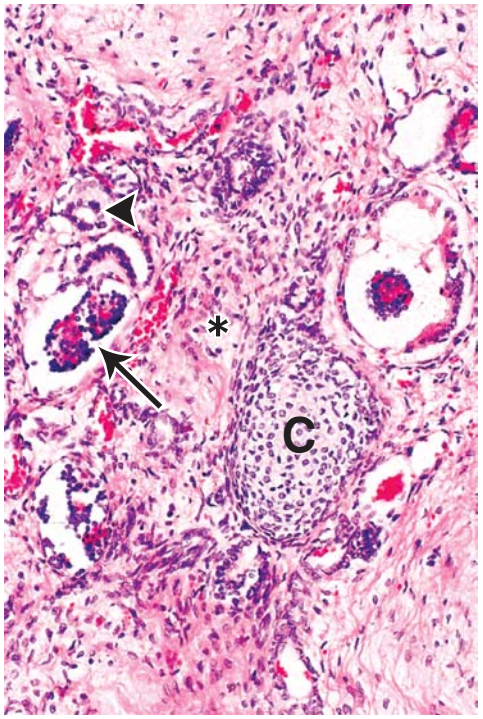

FIGURE 22-8. Renal dysplasia. Immature glomeruli (*arrow*), tubules (*arrowhead*) and cartilage (*C*) are surrounded by loose, undifferentiated mesenchymal tissue (*).

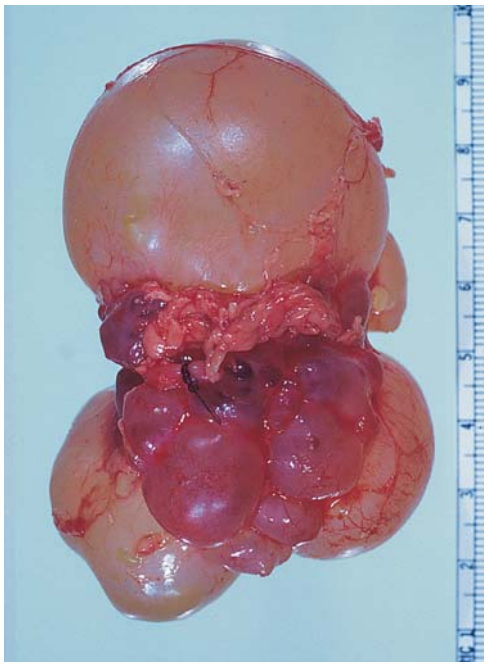

FIGURE 22-9. Multicystic renal dysplasia. An irregular mass of variably sized cysts does not have a reniform shape.

- **Aplastic renal dysplasia** results in very small misshapen dysplastic kidneys, which may be difficult to identify by gross examination.
- **Multicystic renal dysplasia** is usually unilateral and is characterized by renal enlargement by multiple cysts, ranging from microscopic to several centimeters in diameter. The kidney does not have the usual kidney shape but is rather an irregular mass of cysts (Fig. 22-9).
- **Diffuse cystic renal dysplasia** features more uniformly sized cysts and preservation of a kidney shape.
- **Obstructive renal dysplasia,** focal or diffuse, unilateral or bilateral, is caused by intrauterine obstruction to urine flow, such as posterior urethral valves or ureteropelvic junction stenosis.

CLINICAL FEATURES: In most patients with multicystic renal dysplasia, a palpable flank mass is discovered shortly after birth, although small multicystic kidneys may not be apparent until years later. ***Unilateral multicystic renal dysplasia is the most common cause of an abdominal mass in newborns*** and is adequately treated by removing the affected kidney. Bilateral aplastic dysplasia and diffuse cystic dysplasia cause oligohydramnios and the resultant Potter sequence and life-threatening pulmonary hypoplasia. Aplastic renal dysplasia and diffuse cystic dysplasia are more often hereditary than multicystic dysplasia, especially if they are associated with multiple anomalies in other organs, as in Meckel-Gruber syndrome.

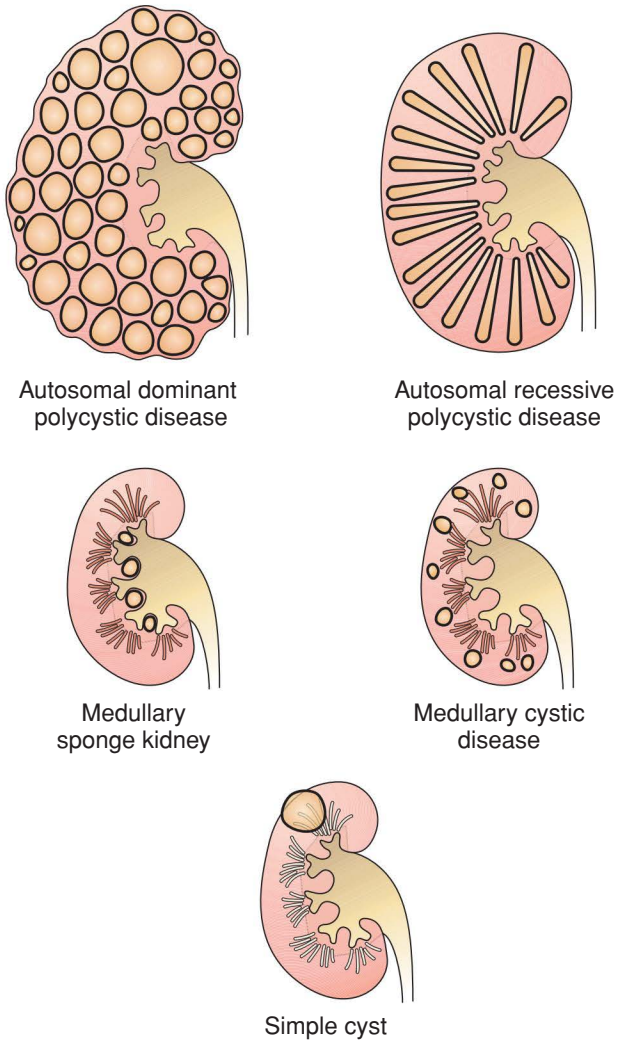

FIGURE 22-10. Cystic diseases of the kidney.

In Autosomal Dominant Polycystic Kidney Disease, Kidneys Are Enlarged and Multicystic

Autosomal dominant polycystic kidney disease (ADPKD) is the most common of a group of congenital diseases in which the renal parenchyma contains many cysts (Fig. 22-10). It affects 1:400–1:1000 people in the United States, 1/2 of whom eventually develop end-stage renal failure. ADPKD is responsible for 5% of end-stage renal disease (ESRD) requiring dialysis or transplantation. Only diabetes and hypertension cause more ESRD than does ADPKD.

MOLECULAR PATHOGENESIS: Some 85% of ADPKD is caused by mutations in polycystic kidney disease 1 gene (*PKD1*) and 15% by mutations in *PKD2*. The products of these genes, polycystin-1 and polycystin-2, are in the primary cilia of tubular epithelial cells and in cell–cell adhesion complexes. These structures sense the extracellular environment including urine flow, resulting in regulation of intracellular calcium and of tubule epithelial proliferation, cell polarity and apoptosis. Defects in these proteins result in dysfunction of primary cilia (ciliopathy) that disrupt calcium signaling, cause disturbed cell polarity and induce tubular epithelial cell proliferation.

Although the precise pathogenesis of ADPKD remains unclear, it is held that cysts arise in segments of renal tubules from a few cells that proliferate abnormally. The tubule wall becomes covered by undifferentiated cells with large nuclei and only few microvilli. Concomitantly, a defective basement membrane just below the abnormal epithelium allows the affected tubule to dilate. Cyst fluid is initially derived from the glomerular filtrate, but eventually most cysts lose connection with the tubules, in which case fluid accumulates by transepithelial secretion. The cysts in ADPKD originate in fewer than 2% of nephrons. Thus, factors other than crowding of normal tissue by expanding cysts likely impair functional renal tissue. Apoptotic loss of renal tubules and accumulation of inflammatory mediators have been incriminated in the destruction of normal renal mass.

PATHOLOGY: The kidneys in ADPKD both are markedly enlarged and weigh up to 4500 g (Fig. 22-11). The external contours are distorted by numerous cysts, as large as 5 cm, filled with a straw-colored fluid. These cysts are lined by cuboidal and columnar epithelium. Cysts arise from any point along the nephron, including glomeruli, proximal tubules, distal tubules and collecting ducts. Areas of normal renal parenchyma between the cysts undergo progressive atrophy and fibrosis as the disease advances with age.

Of patients with ADPKD, 1/3 also have **hepatic cysts,** whose lining resembles bile duct epithelium. Cysts occur in the spleen (10% of patients) and pancreas (5%) as well. **Cerebral aneurysms** occur in 1/5 of patients, and intracranial hemorrhage is the cause of death in 15% of patients with ADPKD. Interestingly, many patients with ADPKD also develop colonic diverticula.

CLINICAL FEATURES: Most patients with ADPKD do not manifest clinically until the fourth decade of life, which is why this condition was once

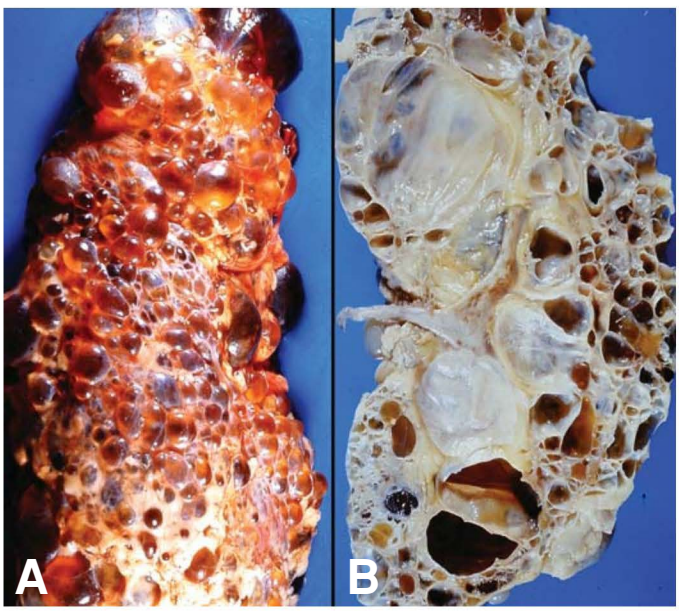

FIGURE 22-11. Autosomal dominant polycystic kidney disease. A. The kidneys are enlarged and studded with multiple fluid-filled structures. **B.** The parenchyma is almost entirely replaced by cysts of varying size.

called *adult* polycystic kidney disease. A small minority of patients develop symptoms during childhood, and rarely are they symptomatic at birth. Symptoms include a sense of heaviness in the loins, bilateral flank and abdominal pain, and abdominal masses. Hypertension is one of the earliest and most common manifestations. Eventually, hematuria, low-level proteinuria and progressive renal insufficiency develop.

Collecting Ducts Are Cystically Dilated in Infants with Autosomal Recessive Polycystic Kidney Disease

Compared with ADPKD, autosomal recessive polycystic kidney disease (ARPKD) is rare, occurring in about 1 in 6000–140,000 live births. In the neonatal period, 1/4 of these infants die, often because of pulmonary hypoplasia caused by oligohydramnios (Potter sequence) and because the large size of the kidneys impairs lung development and function. Children who survive the neonatal period have varying onset and rate of progression of renal insufficiency as well as hepatic fibrosis with portal hypertension.

MOLECULAR PATHOGENESIS: ARPKD is caused by mutations in the *PKHD1* gene. The gene product, **fibrocystin,** is found in the primary cilia of the collecting ducts of the kidney, biliary ducts of the liver and exocrine ducts of the pancreas, and it appears to be involved in regulation of cell differentiation, proliferation and adhesion. Mutations of *PKHD1* also cause pancreatic cysts and hepatic biliary dysgenesis and fibrosis.

PATHOLOGY: Unlike ADPKD, the external kidney surface in ARPKD is smooth. The disease is invariably bilateral. The kidneys are often so large that delivery of the infant is impeded. The cysts are fusiform dilations of cortical and medullary collecting ducts and have a striking radial arrangement, perpendicular to the renal capsule (Fig. 22-12). Interstitial fibrosis and tubular atrophy are common, particularly in children in whom disease presents later. As in ADPKD, the calyceal system is normal. The liver is usually affected by **congenital hepatic fibrosis,** with fibrous expansion of portal tracts with bile duct proliferation (see Chapter 20).

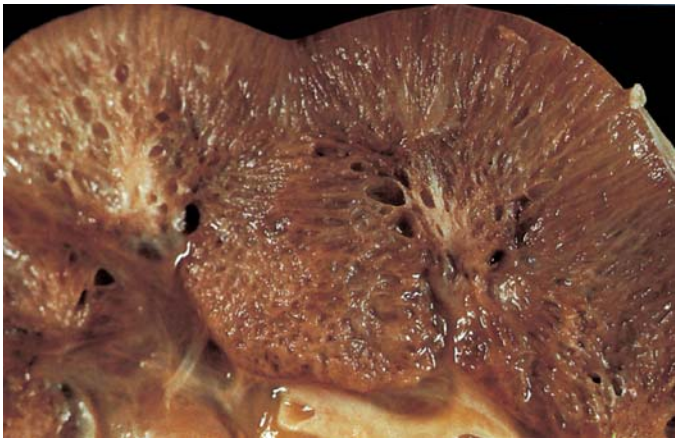

FIGURE 22-12. Autosomal recessive polycystic kidney disease. The dilated cortical and medullary collecting ducts are arranged radially, and the external surface is smooth.

The Bowman Capsule Is Dilated in Many Glomeruli in Glomerulocystic Disease

Glomerulocystic kidney disease may be an isolated process or a component of other cystic disease, such as ADPKD, nephronophthisis–medullary cystic disease complex and diffuse cystic dysplasia. Thus, there are multiple causes for glomerulocystic disease. One form is autosomal dominant, caused by mutations in the gene for hepatocyte nuclear factor-1β (HNF-1β).

PATHOLOGY: The kidneys may be large or small. The cut surface reveals numerous small round cysts rarely of more than 1 cm. Light microscopy shows dilation of the Bowman capsule in many glomeruli. The residual glomerular tuft is often distorted or appears immature.

Nephronophthisis and Medullary Cystic Disease Cause Tubulointerstitial Injury and Medullary Cysts

MOLECULAR PATHOGENESIS: Nephronophthisis and medullary cystic disease complex both cause pathologically similar progressive medullary tubulointerstitial disease. However, they have different genetic causes and inheritance. Nephronophthisis is autosomal recessive, with onset in infancy, childhood or adolescence. It is caused by mutations in *NPHP* genes (*NPHP1* through *9* identified to date). Their gene products, nephrocystins, link primary cilia to the *PKD* and *PKHD* gene products, also in primary cilia. Medullary cystic disease is autosomal dominant with onset in adolescence and renal failure in adulthood. It is caused by defects in the *MCKD1* gene or *MCKD2* gene (which codes for uromodulin).

PATHOLOGY: The kidneys often, but not always, have multiple, variably sized cysts (up to 1 cm) at the corticomedullary junction (Fig. 22-10). These cysts arise from distal portions of the nephron. Atrophic tubules with markedly thickened and laminated basement membranes and loss of tubules out of proportion to glomerular loss are early histologic features of the disease. Eventually, corticomedullary cysts may develop, and the rest of the parenchyma becomes increasingly atrophic. Secondary glomerular sclerosis, interstitial fibrosis and nonspecific inflammatory infiltrates dominate the late histologic picture.

CLINICAL FEATURES: Patients present initially with deteriorating tubular function, such as impaired concentrating ability and sodium wasting, manifested as polyuria, polydipsia and enuresis (bedwetting). Progressive azotemia and renal failure follow. Nephronophthisis is seen in three clinical variants: infantile, juvenile and adolescent. The juvenile form is most common and accounts for 5%–10% of ESRD in children. Symptoms begin between 4 and 6 years, and ESRD usually develops within 10 years. The onset and progression to ESRD of adolescent nephronophthisis overlap with the juvenile form, but the adolescent form results from defects in *NEPH3* and more often causes ESRD at 10–20 years. Defects in *NPHP2* are most common in the infantile form, which progresses to ESRD before 2 years. Among all patients with nephronophthisis, the *NEPH1* mutation is most common.

Medullary cystic disease is characterized by onset of renal failure after the fourth decade and usually presents with polyuria. Hyperuricemia and gout may be accompanying findings.

Medullary Sponge Kidney Is Distinguished by Cysts in the Papillae

The papillary cysts are multiple and small (<5 mm in diameter) (Fig. 22-10), arise from collecting ducts in the renal papillae and are lined by cuboidal or columnar epithelium. The disease is bilateral in 75% of patients. A few familial cases have been described.

Medullary sponge kidney is asymptomatic in young adults. Symptomatic cases are usually discovered between the ages of 30 and 60 years, presenting with flank pain, dysuria, hematuria or "gravel" in the urine caused by stone formation in the cysts. Although the disease itself does not pose a threat to health, the cysts may predispose to secondary pyelonephritis.

ACQUIRED CYSTIC KIDNEY DISEASE

Simple Renal Cysts Occur in Half of People Older Than 50 Years

Simple cysts are usually incidental findings at autopsy and are rarely clinically symptomatic unless they are very large. They may be solitary or multiple and are usually found in the outer cortex, where they bulge the capsule. Simple cysts occur less commonly in the medulla. Microscopically, they are lined by flat epithelium.

Long-Term Dialysis Leads to Acquired Cystic Disease

Multiple cortical and medullary cysts may form in kidneys of patients with ESRD who are maintained on dialysis. After 5 years of dialysis, more than 75% of patients show bilateral cystic kidneys. The cysts are initially lined by flat-to-cuboidal epithelium, but hyperplastic and neoplastic epithelial proliferation may develop within 10 years of initiating dialysis. **Renal cell carcinoma (RCC)** develops in approximately 5% of patients with acquired cystic disease.

Acquired Nonneoplastic Diseases of the Kidney

GLOMERULAR DISEASES

Many renal disorders are caused by injury to the glomerulus. Glomeruli may be the only major site of disease (primary glomerular disease; e.g., immunoglobulin [Ig]A nephropathy) or part of a disease affecting several organs (secondary glomerular disease; e.g., lupus glomerulonephritis). Signs and symptoms of glomerular disease fall into one of the following categories:

- Asymptomatic proteinuria
- Nephrotic syndrome
- Asymptomatic hematuria
- Acute nephritic syndrome
- Rapidly progressive nephritic syndrome
- Chronic kidney injury
- ESRD

Proteinuria Exceeds 3.5 g/day in Nephrotic Syndrome

It is also characterized by hypoalbuminemia, edema, hyperlipidemia and lipiduria. Increased glomerular capillary permeability allows loss of protein from plasma into the urine (proteinuria). Proteinuria is caused by many different glomerular diseases and by a variety of mechanisms.

Severe proteinuria causes the nephrotic syndrome (Fig. 22-13), but lower levels of proteinuria may be asymptomatic. Nephrotic syndrome results from **primary** glomerular diseases unrelated to a systemic disease, or they may be **secondary** to a systemic disease that affects other organs as well as the kidneys. Diabetic glomerulosclerosis is the most common cause of secondary nephrotic syndrome in adults. Table 22-1 lists the major causes and approximate frequency of the primary nephrotic syndrome in adults and children. Table 22-2 details selected pathologic features of some of these diseases (discussed below).

There are important differences in the rates of specific glomerular diseases that cause nephrotic syndrome in adults versus those in children. For example, minimal-change disease is responsible for most (70%) cases of primary nephrotic syndrome in children, but only 15% in adults. The primary glomerular diseases that most often cause primary nephrotic syndrome in adults are membranous glomerulonephritis and FSGS. The most common cause of secondary nephrotic syndrome is diabetes. Membranous glomerulonephritis is the most frequent cause in whites and Asians, whereas FSGS is the most common etiology in American blacks. The incidence

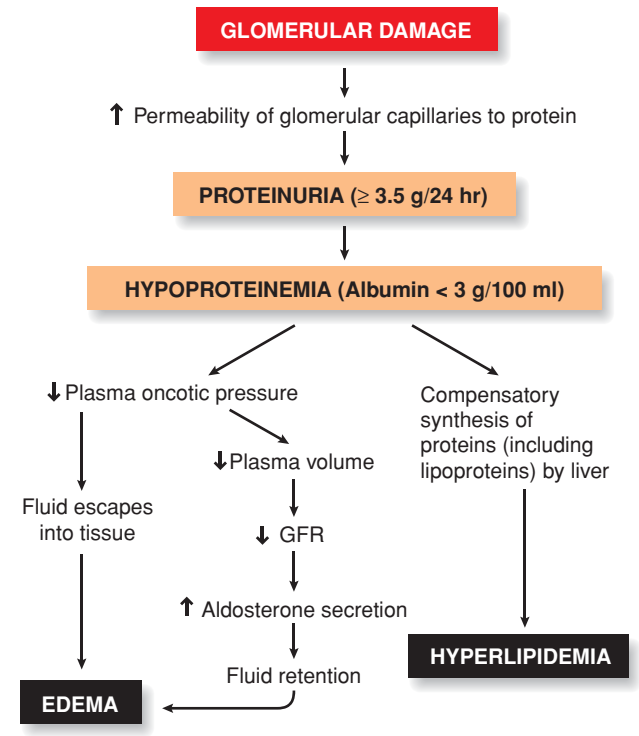

FIGURE 22-13. Pathophysiology of the nephrotic syndrome. GFR = glomerular filtration rate.

TABLE 22-1
FREQUENCY OF CAUSES FOR THE NEPHROTIC SYNDROME INDUCED BY PRIMARY GLOMERULAR DISEASES IN CHILDREN AND ADULTS

Cause	Children (%)	Adults (%)
Minimal-change disease	75	10
Membranous glomerulonephritis	5	30
Focal segmental glomerulosclerosis	10	35
Membranoproliferative glomerulonephritis	5	5
Other glomerular diseases*	5	20

*Includes many forms of mesangioproliferative and proliferative glomerulonephritis, such as immunoglobulin A nephropathy, which may cause nephritic and nephrotic features.

of FSGS has been increasing over the past decade. Systemic diseases that involve the kidney, such as diabetes, amyloidosis and systemic lupus erythematosus (SLE), account for many cases of nephrotic syndrome in adults. In third world countries, where chronic infectious diseases are common, immune complex membranoproliferative glomerulonephritis (MPGN) is a much more frequent reason for nephrotic syndrome.

Nephritic (Glomerulonephritis) Syndrome Is an Inflammatory Disease with Hematuria, Proteinuria and Decreased Glomerular Filtration Rate

Hematuria may be microscopic or grossly visible, and proteinuria varies. Decreased GFR causes elevated blood urea nitrogen and serum creatinine, oliguria, salt and water retention, hypertension and edema. Glomerular diseases associated with the nephritic syndrome are caused by inflammatory changes in glomeruli (e.g., infiltration by leukocytes, hyperplasia of glomerular cells and, in severe lesions, necrosis). Injury to glomerular capillaries results in spillage of protein and blood cells into the urine (proteinuria and hematuria). The inflammatory damage may also impair glomerular flow and filtration, resulting in renal insufficiency, fluid retention and hypertension. Nephritic manifestations may (1) develop rapidly and result in reversible renal insufficiency (acute glomerulonephritis); (2) progress rapidly, with renal failure that resolves only with aggressive treatment (rapidly progressive glomerulonephritis); or (3) persist for years continuously or intermittently and proceed slowly to renal failure (chronic glomerulonephritis).

TABLE 22-3
TENDENCIES OF GLOMERULAR DISEASES TO MANIFEST NEPHROTIC AND NEPHRITIC FEATURES

Disease	Nephrotic	Nephritic
Minimal-change disease	++++	–
Membranous glomerulonephritis	+++	++
Focal segmental glomerulosclerosis	+++	++
Mesangioproliferative glomerulonephritis*	++	++
Membranoproliferative glomerulonephritis	++	++
Proliferative glomerulonephritis*	+	+++
Crescentic glomerulonephritis*	+	++++

*These histologic phenotypes can be caused by many categories of glomerular disease, including immunoglobulin A nephropathy, postinfectious glomerulonephritis, lupus glomerulonephritis, antineutrophil cytoplasmic autoantibody glomerulonephritis, anti–glomerular basement membrane glomerulonephritis and C3 glomerulopathy.

Some glomerular diseases tend to cause the nephrotic syndrome, but others lead to the nephritic syndrome (Table 22-3). However, except for minimal-change disease (which almost always causes nephrotic syndrome), all glomerular diseases may occasionally cause mixed nephritic and nephrotic manifestations that confound clinical diagnosis. ***Renal biopsy evaluation is the only means of definitive diagnosis for most glomerular diseases, although clinical and laboratory data may provide presumptive evidence for a specific disease.***

PATHOPHYSIOLOGY: Glomerulonephritis is often caused by immunologic mechanisms. Antibody- and cell-mediated immunity may both lead to glomerular inflammation, but three types of antibody-induced inflammation have been incriminated as the major pathogenetic processes in most forms of glomerulonephritis (Fig. 22-14). A less frequent cause of

TABLE 22-2
PATHOLOGIC FEATURES OF IMPORTANT CAUSES OF THE NEPHROTIC SYNDROME

	Minimal-Change Disease	Focal Segmental Glomerulosclerosis	Membranous Glomerulnephritis	Membranoproliferative Glomerulonephritis
Light microscopy	No lesion	Focal and segmental glomerular consolidation	Diffuse global capillary wall thickening	Capillary wall thickening and endocapillary hypercellularity
Immunofluorescence microscopy	No immune deposits	No immune deposits	Diffuse capillary wall immunoglobulin	Diffuse capillary wall complement with or without immunoglobulin
Electron microscopy	No immune deposits	No immune deposits	Diffuse subepithelial deposits	Subendothelial dense deposits; intramembranous dense deposits (dense deposit disease)

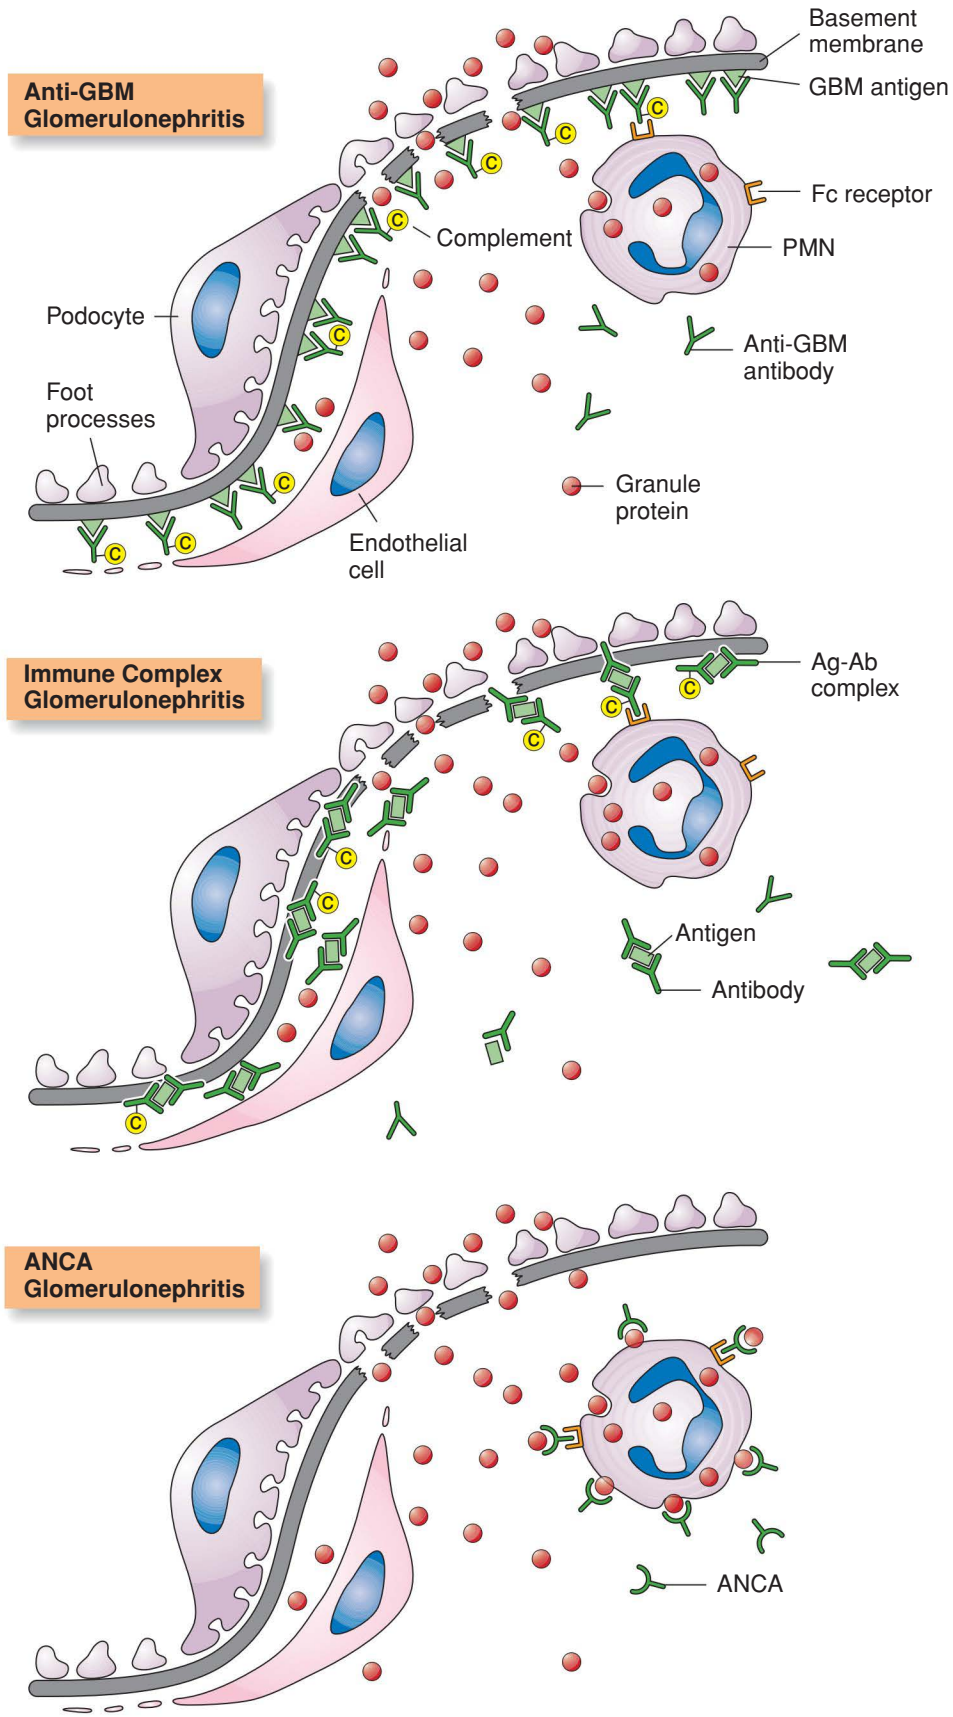

FIGURE 22-14. Antibody-mediated glomerulonephritis. Top panel. Anti–glomerular basement membrane (GBM) antibodies cause glomerulonephritis by binding in situ to basement membrane antigens. This activates complement and recruits inflammatory cells. PMN = polymorphonuclear neutrophil. **Middle panel.** Immune complexes that deposit from the circulation also activate complement and recruit inflammatory cells. Ag-Ab complex = antigen–antibody complex. **Bottom panel.** Antineutrophil cytoplasmic antibodies (ANCAs) cause inflammation by activating leukocytes by direct binding of the antibodies to the leukocytes and by Fc receptor engagement of ANCA bound to antigen.

glomerulonephritis is dysregulation and uncontrolled activation of the alternative complement pathway.

- In situ immune complex formation
- Deposition of circulating immune complexes
- Antineutrophil cytoplasmic autoantibodies (ANCAs)
- Alternative pathway complement dysregulation

Immune complex formation in situ involves circulating antibodies binding to intrinsic antigens or foreign antigens within glomeruli. For example, anti-GBM autoantibodies bind a very specific epitope on the α4 chain of type IV collagen in GBMs. Resultant immune complexes in glomerular capillary walls attract leukocytes and activate complement and other humoral inflammatory mediators, resulting in inflammatory injury. In the most common form of primary membranous glomerulonephritis, immune complexes form in situ between an antigen produced by podocytes, phospholipase A_2 receptor (PLA_2R) and anti-PLA_2R antibodies from the circulation.

Circulating immune complexes may deposit in glomeruli and incite inflammation like that produced when immune complexes form in situ. For example, circulating antibodies can bind to antigens released into the blood by bacterial or viral infection to produce immune complexes. If these complexes escape phagocytosis, they can deposit in glomeruli and incite inflammation. Immunofluorescence microscopy detects such immune complexes in glomeruli. Anti-GBM antibodies produce linear staining of GBMs, but other immune complexes produce granular staining in capillary walls, mesangium or both.

Antineutrophil cytoplasmic autoantibodies cause severe glomerulonephritis with little or no glomerular immunoglobulin deposition. Such patients often have circulating autoantibodies specific for antigens in the cytoplasm of neutrophils, which activate them and so mediate glomerular inflammation. Most ANCAs are directed against myeloperoxidase (MPO-ANCA) or proteinase-3 (PR3-ANCA). Even minor stimulation of neutrophils and monocytes, such as by increased circulating levels of cytokines during viral infection, causes them to express surface MPO and PR3, which then can interact with ANCAs. This interaction activates neutrophils and causes them to adhere to microvascular endothelial cells, especially glomerular capillaries. There, they release products that promote vascular inflammation, including glomerulonephritis, arteritis and venulitis. This inflammation is amplified by release of factors from ANCA-activated neutrophils that activate the alternative complement pathway.

Formation of glomerular immune complexes in situ, deposition of immune complexes and interaction of ANCAs with leukocytes all initiate glomerular inflammatory injury, with attraction and activation of leukocytes (Fig. 22-14).

A fourth immunopathology category of glomerulonephritis **(C3 glomerulopathy)** is mediated by dysregulation of the alternative complement pathway caused either by the genetic absence or dysfunction of complement regulatory proteins (e.g., complement factor H, complement factor I), autoantibodies that inhibit complement regulatory proteins or autoantibodies that stabilize the alternative pathway C3 convertase (C3 nephritis factor).

PATHOLOGY: Specific glomerular diseases have distinctive pathologic features, as well as different natural histories and appropriate treatments. ***Accurate pathologic diagnosis of glomerular diseases requires examination of renal tissue by light, immunofluorescence and electron microscopy, and integration of these findings with clinical information.*** Table 22-4 lists pathologic features useful in diagnosing glomerular diseases (see Table 22-2 for a

TABLE 22-4
DIAGNOSTIC FEATURES OF GLOMERULAR DISEASES

I. Light microscopic features
A. Increased cellularity
Infiltration by leukocytes (e.g., neutrophils, monocytes, macrophages)
Proliferation of "endocapillary" cells (i.e., endothelial and mesangial cells)
Proliferation of "extracapillary" cells (i.e., epithelial cells) (crescent formation)
B. Increased extracellular material
Localization of immune complexes
Thickening or replication of GBM
Increases in collagenous matrix (sclerosis)
Insudation of plasma proteins (hyalinosis)
Fibrinoid necrosis
Deposition of amyloid
II. Immunofluorescence features
A. Linear staining of GBM
Anti-GBM antibodies
Multiple plasma proteins (e.g., diabetic glomerulosclerosis)
Monoclonal immunoglobulin chains
B. Granular immune complex staining or complement staining alone
Mesangium (e.g., IgA nephropathy)
Capillary wall (e.g., membranous glomerulonephritis)
Mesangium and capillary wall (e.g., lupus glomerulonephritis, C3 glomerulopathy)
C. Irregular (fluffy) staining
Monoclonal light chains (AL amyloidosis)
AA protein (AA amyloidosis)
III. Electron microscopic features
A. Electron-dense immune complex deposits or complement deposits
Mesangial (e.g., IgA nephropathy)
Subendothelial (e.g., lupus glomerulonephritis)
Subepithelial (e.g., membranous glomerulonephritis)
B. GBM thickening (e.g., diabetic glomerulosclerosis)
C. GBM remodeling (e.g., membranoproliferative glomerulonephritis)
D. Collagenous matrix expansion (e.g., focal segmental glomerulosclerosis)
E. Fibrillary deposits (e.g., amyloidosis)

GBM = glomerular basement membrane; IgA = immunoglobulin A.

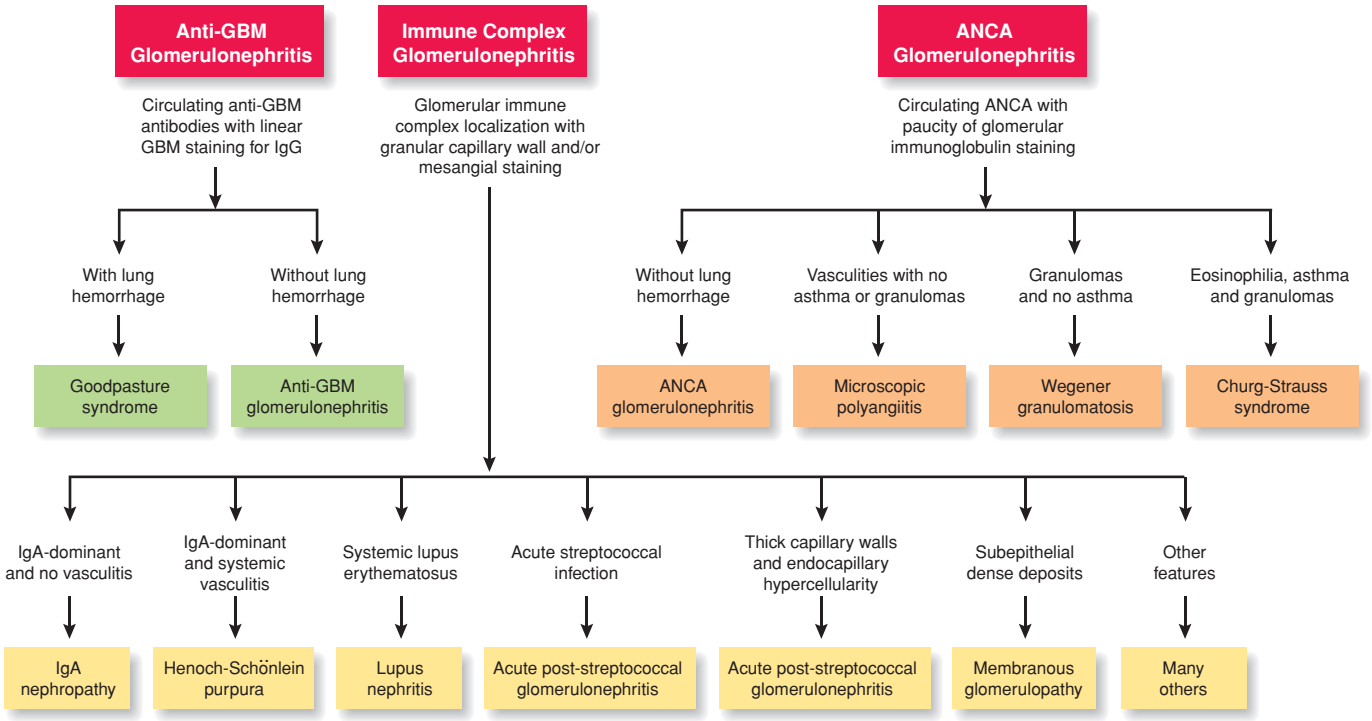

FIGURE 22-15. Algorithm demonstrating the integration of pathologic findings with clinical data to diagnose specific forms of primary or secondary glomerulonephritis. Note that an important initial categorization is as immune complex, anti–glomerular basement membrane (GBM), C3 or antineutrophil cytoplasmic autoantibody (ANCA) glomerulonephritis. Once this determination is made, more specific diagnoses depend on additional clinical or pathologic observations.

summary of pathologic features of important causes of the nephrotic syndrome). The algorithm in Fig. 22-15 shows how pathologic and clinical data mesh to diagnose specific glomerular diseases.

In general, pathologic features of acute inflammation, such as endocapillary and extracapillary hypercellularity, leukocyte infiltration and necrosis, are more common in disorders characterized mainly as nephritic than in those that are more typically nephrotic. **Glomerular crescent formation** (extracapillary proliferation) correlates with a more rapidly progressive course. Crescents are not specific for a particular cause of glomerular inflammation. They are, rather, markers of severe injury causing extensive rupture of capillary walls, which allows inflammatory mediators to enter the Bowman space, where they stimulate macrophage infiltration and epithelial proliferation.

Minimal-Change Disease Causes Nephrotic Syndrome

Pathologically, this disease entails effacement of podocyte foot processes.

PATHOPHYSIOLOGY: The pathogenesis of minimal-change disease is unknown. The immune system may be involved: the disease may remit with corticosteroid treatment, and it may occur in association with an allergic disease or a lymphoid neoplasm. Occasional associations with Hodgkin disease (in which there is T-cell dysfunction) and with thymomas and T-cell lymphomas has led to speculation that minimal-change disease may reflect a disorder of T lymphocytes, possibly involving production of a cytokine that increases glomerular permeability via effects on podocytes. The heavy proteinuria of minimal-change disease is accompanied by loss of GBM and podocyte polyanionic sites. This allows anionic proteins, especially albumin, to pass more easily across capillary walls. There may be a pathogenic relationship between minimal-change disease and some forms of FSGS, with the potential for the former to evolve into the latter in some patients, but this has not been confirmed.

PATHOLOGY: ***Glomeruli in minimal-change disease appear essentially normal on light microscopy*** (Fig. 22-16). Proteinuria leads to hypoalbuminemia, and a compensatory increase in lipoprotein secretion by the liver results in hyperlipidemia. Loss of lipoproteins through glomeruli causes lipids to accumulate in proximal tubular cells, reflected histologically as glassy (hyaline) droplets in tubular epithelial cytoplasm. Such droplets are not specific for minimal-change disease but are seen in any glomerular disease causing nephrotic syndrome.

Electron microscopy shows extensive **fusion of podocyte cell foot processes** (Figs. 22-17, 22-18). This occurs in almost all cases of nephrotic range proteinuria; it is not specific for minimal-change disease. Immunofluorescence studies for immunoglobulin and complement deposition are most often negative, but there is occasional weak mesangial staining for IgM and the complement component C3.

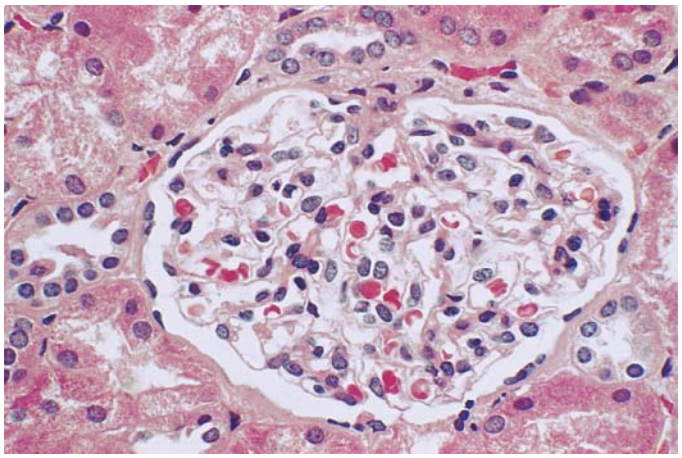

FIGURE 22-16. Minimal-change disease. A light micrograph shows no abnormality.

CLINICAL FEATURES: ***Minimal-change disease causes 90% of primary nephrotic syndrome cases in children younger than 5, 50% in older children and 15% in adults.*** Proteinuria is generally more selective (albumin > globulins) than in the nephrotic syndrome caused by other diseases, but there is too much overlap for this to be used as a diagnostic criterion. In more than 90% of children and in fewer adults with minimal-change disease, proteinuria remits completely within 8 weeks of initiating corticosteroid therapy. Adults often require a longer course of steroids for remission. If corticosteroids are withdrawn, most patients have intermittent relapses for up to 10 years. A small subgroup of patients has only partial remission with corticosteroid therapy and continues to lose protein in the urine. An even smaller group is totally resistant to corticosteroid therapy. In such cases, the diagnosis of minimal-change disease may not be accurate, and FSGS that was not sampled in the initial biopsy specimen may be present.

In the absence of complications, the long-term outlook for patients with minimal-change disease is no different from that of the general population. Development of azotemia in a patient previously diagnosed as having minimal-change disease should suggest failure to sample FSGS in the original biopsy. It may also reflect evolution into FSGS or perhaps a complication such as drug-induced interstitial nephritis.

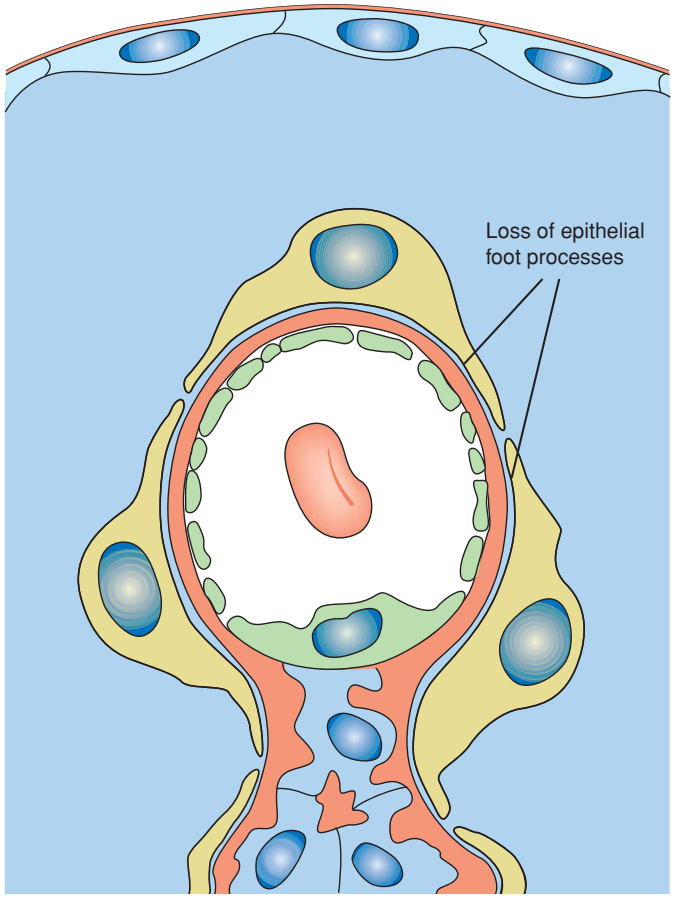

FIGURE 22-17. Minimal-change disease. This condition is characterized predominantly by epithelial cell changes, particularly effacement of foot processes. All other glomerular structures appear intact.

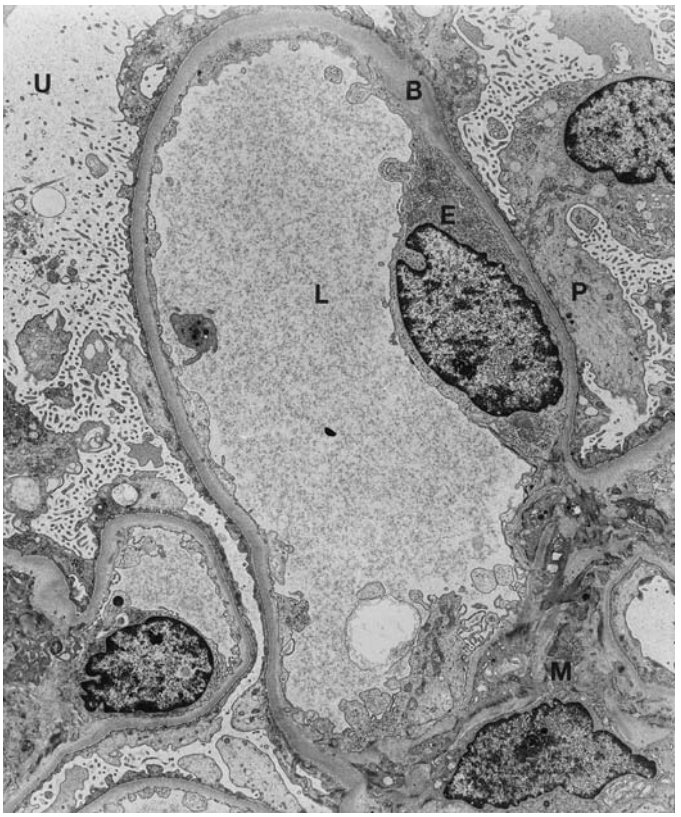

FIGURE 22-18. Minimal-change disease. In this electron micrograph, the podocyte (P) displays extensive effacement of foot processes and numerous microvilli projecting into the urinary space (U). B = basement membrane; E = endothelial cell; L = lumen; M = mesangial cell. Compare with Figure 22-3.

Focal Segmental Glomerulosclerosis May Reflect Diverse Etiologies and Pathogenetic Mechanisms

In FSGS, glomerular consolidation affects some (focal), but not all, glomeruli and initially involves only part of an affected glomerular tuft (segmental). Consolidated segments often show increased collagenous matrix (sclerosis; Fig. 22-19). There are primary (idiopathic) and secondary forms of FSGS.

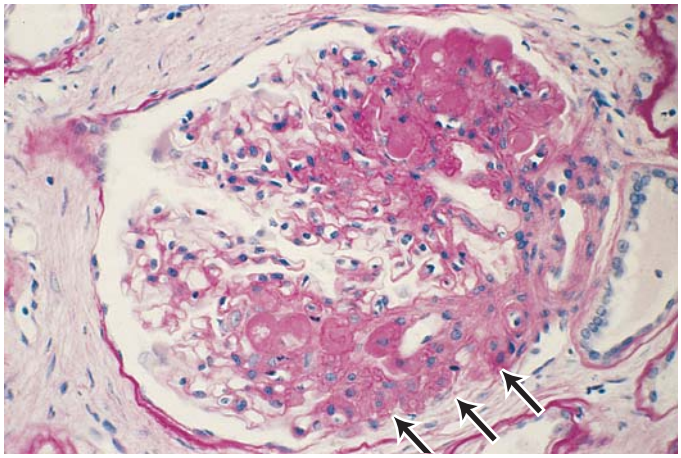

FIGURE 22-19. Focal segmental glomerulosclerosis. Periodic acid–Schiff (PAS) staining shows perihilar areas of segmental sclerosis and adjacent adhesions to the Bowman capsule (*arrows*).

MOLECULAR PATHOGENESIS AND ETIOLOGIC FACTORS: The term **FSGS** describes a heterogeneous group of glomerular diseases with different causes, pathologies, responses to treatment and outcomes. It may be idiopathic (primary) or secondary to several conditions (Table 22-5). Multiple factors probably lead to a final common pathway of injury. Pathologic features and genetic evidence suggest that injury to podocytes may be common to all types of FSGS.

Several hereditary forms of FSGS reflect genetic abnormalities in podocyte proteins (e.g., podocin, nephrin, α-actinin-4 and TRPC6). This implicates injury to, or dysfunction of, podocytes in FSGS.

Congenital (e.g., unilateral agenesis with contralateral hypoplasia) and acquired (e.g., reflux nephropathy) reductions in renal mass place adaptive stress on the reduced number of nephrons. In turn, this strain appears to cause FSGS from overwork, with increased glomerular capillary pressure and filtration, and glomerular enlargement. A normal amount of renal tissue can also be stressed by excessive body mass (obesity), resulting in FSGS. Reduced blood oxygen (e.g., as in sickle cell disease or cyanotic congenital heart disease) also causes a similar pattern of glomerular injury. In all of these settings, glomerular enlargement reflects functional overwork, placing undue stress on podocytes because of their limited proliferative capacity.

Viruses, drugs and serum factors are implicated as causes of FSGS. Infection with HIV, especially in blacks, is associated with a variant of FSGS with a collapsing pattern of sclerosis (Fig. 22-20). Such an appearance may also occur in idiopathic FSGS. Collapsing FSGS may also be caused by viral infection of podocytes. Pamidronate, a drug used to treat osteolytic bone disease in patients with cancer, causes collapsing FSGS in some patients. The drug probably causes FSGS by injuring podocytes. A serum permeability factor has been detected in some patients with FSGS, which suggests a systemic cause for the glomerular injury. This is further supported by the recurrence of FSGS in renal transplants, especially in patients who have the permeability factor. Sequence variants in the gene encoding apolipoprotein 1 (*APOL1*) have been linked to FSGS in blacks, who are known to have a high incidence of FSGS and hypertension-related ESRD. Apparently, these variants provide protection against African sleeping sickness (trypanosomiasis), which may explain their prevalence in blacks. As in sickle cell disease, this is an example of how a genetic variant can cause a common disease while providing protection against a major infectious disease.

TABLE 22-5
CATEGORIES OF FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Primary (idiopathic) focal segmental glomerulosclerosis (FSGS)
Secondary FSGS
Hereditary/genetic (e.g., mutations in podocyte genes)
Obesity (perihilar variant)
Reduced renal mass (perihilar variant)
Cyanotic congenital heart disease (usually perihilar variant)
Sickle cell nephropathy (usually perihilar variant)
Infection induced (e.g., HIV; collapsing variant)
Drug induced (e.g., pamidronate; collapsing variant)

Note: Primary and secondary FSGS can have various histologic patterns of injury: perihilar, tip lesion, cellular, collapsing, not otherwise specified (NOS).

PATHOLOGY: Varying numbers of glomeruli show segmental obliteration of capillary loops by increased matrix or accumulation of cells, or both. Insudation of plasma proteins and lipid gives lesions a glassy appearance, called **hyalinosis**. Adhesions to the Bowman

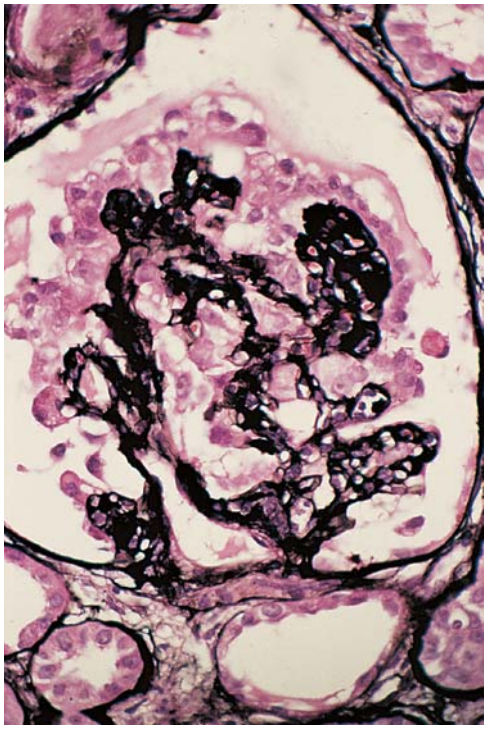

FIGURE 22-20. HIV-associated nephropathy. Silver staining shows a collapsing pattern of focal segmental glomerulosclerosis (FSGS), with collapse of glomerular capillaries, increased matrix material (sclerosis) and hypertrophy of podocytes.

capsule occur adjacent to sclerotic lesions. Uninvolved glomeruli may look entirely normal, although mild mesangial hypercellularity is occasionally present. Because uninvolved glomeruli usually appear normal, FSGS can be mistaken for minimal-change disease in small biopsy specimens that contain only nonsclerotic glomeruli.

Several histologic variants of FSGS are recognized. Particularly in patients with reduced renal mass or obesity, the sclerosis localizes in **perihilar** segments within glomeruli and in deep cortical (juxtamedullary) glomeruli (Fig. 22-19). A **collapsing** pattern of sclerosis with hypertrophied and hyperplastic podocytes adjacent to sclerotic segments is typical of HIV-associated nephropathy and also occurs with intravenous drug abuse, with pamidronate-induced disease and as an idiopathic process. This collapsing variant has a poor prognosis, and 1/2 of patients reach end-stage disease within 2 years. Sclerosis limited to glomerular segments adjacent to the origin of the proximal tubule has been designated **tip lesion** and is more likely to respond to steroid therapy than other forms of FSGS. A **cellular variant** of FSGS has prominent lipid-laden cells within the sites of glomerular consolidation.

By electron microscopy, epithelial cell foot processes are diffusely effaced in FSGS, with occasional focal detachment or loss of podocytes from the GBM. Sclerotic segments show increased matrix material, wrinkling and thickening of basement membranes and capillary collapse. Accumulation of electron-dense material in sclerotic segments represents insudative trapping of plasma proteins and corresponds to hyalinosis seen by light microscopy. ***Immune complexes are absent.***

Immunofluorescence microscopy shows irregular trapping of IgM and C3 in the segmental areas of sclerosis and hyalinosis. IgG, C4 and C1q are less often found in sclerotic segments. Nonsclerotic segments do not stain or do so weakly, usually for IgM and C3 in the mesangium.

CLINICAL FEATURES: FSGS causes 1/3 of primary nephrotic syndrome in adults and 10% in children. It is more common in blacks than in whites and is the leading cause of primary nephrotic syndrome in blacks. Its frequency has been increasing over the past few decades for unknown reasons. Clinical presentations and outcomes vary among the different patterns of injury. Most often, asymptomatic proteinuria begins insidiously and progresses to the nephrotic syndrome. Many patients are hypertensive. Microscopic hematuria is frequent.

Most people with FSGS show persistent proteinuria and progressive decline in renal function. Many progress to ESRD after 5–20 years. Some, but not all, patients improve with corticosteroid therapy. Although renal transplantation is the preferred treatment for ESRD, FSGS recurs in 1/2 of transplanted kidneys.

Patients with FSGS due to obesity or reduced renal mass usually have a more indolent course with lower levels of proteinuria that benefits from treatment with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs). People with the tip lesion variant often present with severe nephrotic syndrome. This variant resembles minimal-change disease and responds better to corticosteroids than do other forms of FSGS. HIV-associated and idiopathic collapsing FSGS have the worst prognoses. They typically have severe nephrotic syndrome and renal failure, often progressing to ESRD within a year.

HIV-1–Associated Nephropathy Is a Severe, Rapidly Progressive Collapsing Form of FSGS

ETIOLOGIC FACTORS: The occurrence of nephropathy in patients with HIV-1 infection has raised the possibility that it is caused by HIV-1 within the renal parenchyma. A different hypothesis proposes that the nephropathy is caused by another virus that has infected the kidney of an immunocompromised person.

PATHOLOGY: HIV-1–associated nephropathy shows a segmental or global collapsing pattern of focal sclerosis (Fig. 22-20). Capillaries in sclerotic segments collapse, often with adjacent swollen podocytes that have numerous protein droplets. Interstitial fibrosis and infiltration by mononuclear leukocytes are common. Tubular epithelial atrophy and degeneration are conspicuous; cystically dilated tubules contain proteinaceous casts. By electron microscopy, many tubuloreticular inclusions are seen in endothelial cells, similar to those in lupus nephritis.

CLINICAL FEATURES: Some 5% of HIV-positive patients, of whom more than 90% are black, develop collapsing FSGS. Idiopathic collapsing FSGS also occurs mainly in blacks. It presents with severe proteinuria (often >10 g/day) and renal insufficiency. More than 1/2 of patients progress to ESRD in less than 2 years.

Membranous Glomerulonephritis Is a Disease of Immune Complex Deposition

Membranous glomerulonephritis is a common cause of nephrotic syndrome in adults. It reflects subepithelial immune complex accumulation in glomerular capillaries.

PATHOPHYSIOLOGY: Immune complexes localize in the **subepithelial zone** (between podocytes and the GBM) as a result of immune complex formation in situ or deposition of circulating immune complexes. Formation in situ occurs in the animal model of membranous glomerulonephritis called **Heymann nephritis,** in which rats are immunized with a renal epithelial antigen and develop autoantibodies. The antibodies cross GBMs and bind antigens on podocytes. Resultant immune complexes are shed into the adjacent subepithelial zone to cause membranous glomerulonephritis. A rare form of neonatal membranous glomerulonephritis is caused by transplacental passage of antibodies that react with an alloantigen on neonatal podocytes (neutral endopeptidase) that is not shared by the mother. Most patients with primary membranous glomerulonephritis have circulating autoantibodies against a podocyte transmembrane receptor, PLA_2R. PLA_2R and anti-PLA_2R can be isolated from the immune complexes, supporting in situ subepithelial immune complex formation.

Repeated experimental exposure to foreign proteins elicits antibodies, which form circulating immune complexes. A subpopulation of these complexes deposits in glomerular capillary walls. Sometimes, free antigens and antibodies cross the GBM independently and form subepithelial immune complexes in situ.

General causes of membranous glomerulonephritis are:

- Primary membranous glomerulonephritis
  - Anti-PLA_2R autoantibodies
  - Anti–neutral endopeptidase alloantibodies
- Secondary membranous glomerulonephritis
  - Autoimmune disease (SLE, autoimmune thyroid disease)
  - Infectious disease (hepatitis B, malaria, syphilis, schistosomiasis)
  - Therapeutic agents (penicillamine)
  - Neoplasms (lung, prostate and gastrointestinal cancers)

PATHOLOGY: Glomeruli are usually normocellular. Depending on the duration of the disease, capillary walls may be normal or thickened (Fig. 22-21). In intermediate disease stages, silver stains (which highlight basement membranes) reveal multiple "spikes" of argyrophilic material on the epithelial side of the basement membrane (Fig. 22-22). These spikes are projections of basement membrane material around subepithelial immune complexes (which do not stain with silver). As disease progresses, capillary lumens narrow, and glomerular sclerosis eventually ensues. Advanced membranous glomerulonephritis cannot be distinguished from other forms of chronic glomerular disease. Atrophy of tubules and interstitial fibrosis parallel the degree of glomerular sclerosis.

By electron microscopy, immune complexes appear in capillary walls as electron-dense deposits (Figs. 22-23, 22-24). The progressive ultrastructural changes caused by subepithelial immune complexes are divided into stages:

- **Stage I:** Subepithelial dense deposits without adjacent projections of GBM material
- **Stage II:** Projections of GBM material adjacent to dense deposits (Fig. 22-24)
- **Stage III:** Enclosure of dense deposits within GBM material
- **Stage IV:** Rarefaction of deposits within a thickened GBM

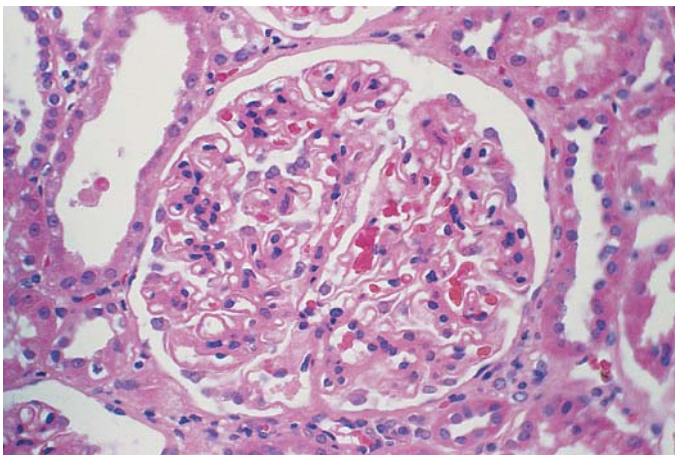

FIGURE 22-21. Membranous glomerulonephritis. The glomerulus is slightly enlarged and shows diffuse thickening of the capillary walls. There is no hypercellularity. Compare capillary walls to those shown in Fig. 22-15.

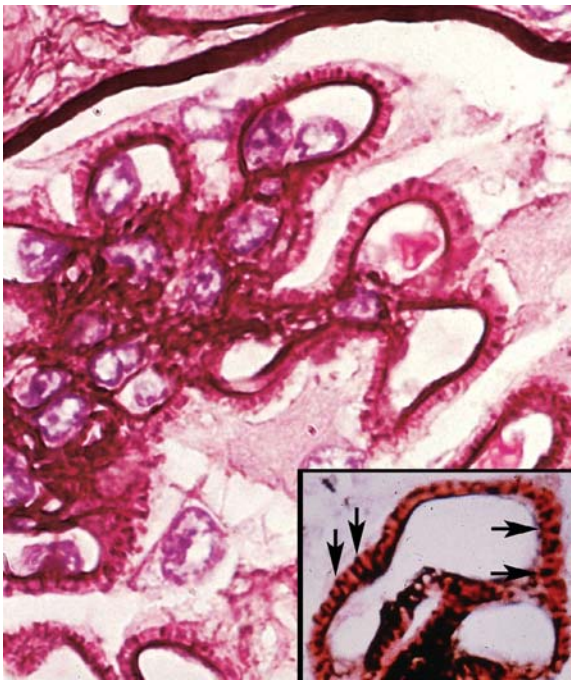

FIGURE 22-22. Membranous glomerulonephritis. Silver staining reveals multiple "spikes" diffusely distributed in the glomerular capillary basement membranes. This pattern corresponds to the stage II lesion illustrated in Figs. 22-23 and 22-24. The appearance is produced by the deposition of silver-positive basement membrane material around silver-negative immune complex deposits.

Mesangial electron-dense deposits are rare in primary membranous glomerulonephritis but are more common in secondary disease (e.g., in lupus nephropathy). This difference may reflect the fact that primary disease is caused by antigens normally present in the subepithelial zone (e.g., podocyte PLA_2R and neutral endopeptidase), but the secondary type is produced by circulating antigens (e.g., hepatitis B virus antigens) in complexes with circulating antibodies that can localize in mesangial as well as subepithelial locations.

Immunofluorescence reveals diffuse granular staining of capillary walls for IgG and C3 (Fig. 22-25). There is intense staining for terminal complement components, including the membrane attack complex, which participate in inducing glomerular injury, especially to podocytes.

CLINICAL FEATURES: Membranous glomerulonephritis is the most common primary glomerular cause of nephrotic syndrome in white and Asian adults in the United States (the most common secondary glomerular cause is diabetic glomerulosclerosis). The course of membranous glomerulonephritis is highly variable. Spontaneous remission occurs in 1/4 of patients within 20 years, and 10-year renal survival rate is greater than 65%. Lower survival correlates with male gender, age above 50, proteinuria of more than 6 g/day, extensive glomerular sclerosis and chronic tubulointerstitial disease. Patients with progressive renal failure receive corticosteroids and/or immunosuppressive drugs. The prognosis is better in children because of a higher rate of permanent spontaneous remission.

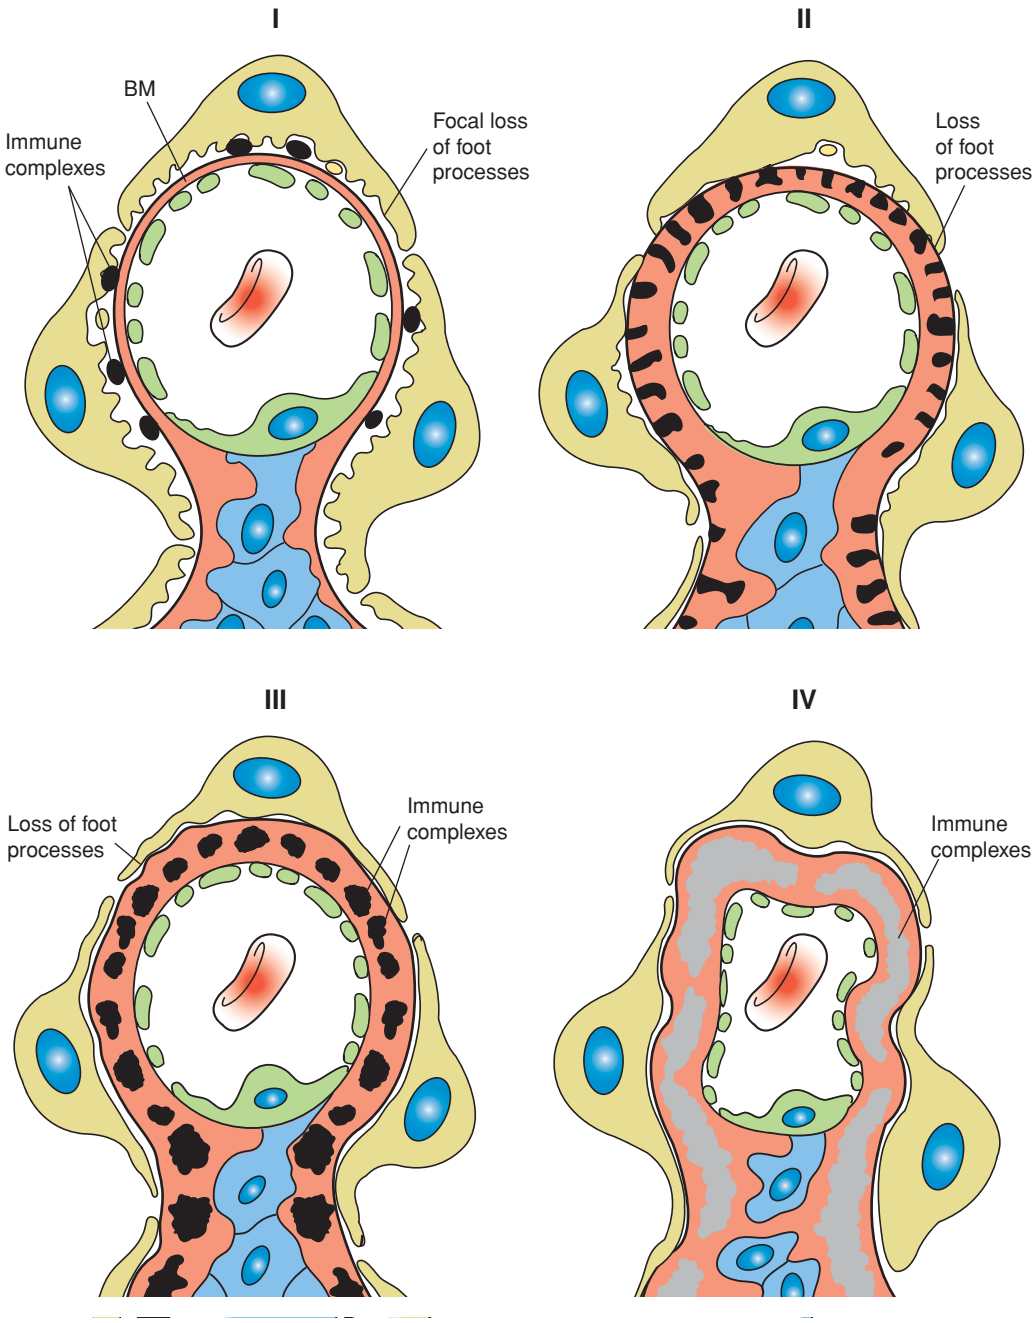

FIGURE 22-23. Membranous glomerulonephritis. This disease is caused by the subepithelial accumulation of immune complexes and the accompanying changes in the basement membrane (BM). Stage I exhibits scattered subepithelial deposits. The outer contour of the basement membrane remains smooth. Stage II disease has projections (spikes) of basement membrane material adjacent to the deposits. In stage III disease, newly formed basement membrane has surrounded the deposits. With stage IV disease, the immune complex deposits lose their electron density, resulting in an irregularly thickened basement membrane with irregular electron-lucent areas.

Diabetic Glomerulosclerosis Causes Proteinuria and Progressive Renal Failure

PATHOPHYSIOLOGY: Glomerulosclerosis is a part of vasculopathy that affects small vessels throughout the body in diabetic patients (see Chapter 13). The abnormal metabolic state leads to a general increase in synthesis of basement membrane material in the microvasculature. One hypothesis proposes that increased **oxidative injury** and abnormal **nonenzymatic glycosylation** of plasma proteins (e.g., immunoglobulins) and matrix proteins (including those of the GBM and mesangial matrix) induce excessive matrix production and podocyte injury.

PATHOLOGY: The earliest lesions of diabetic glomerulosclerosis are glomerular enlargement, GBM thickening and mesangial matrix expansion (Fig. 22-26). Numbers of podocytes decline. Mild mesangial hypercellularity may be present along with the increase in mesangial matrix. In patients who develop symptomatic disease, GBM thickening and especially mesangial matrix expansion result in changes visible on light microscopy. In diabetic glomerulosclerosis, diffuse global GBM thickening and diffuse mesangial matrix expansion are accompanied by sclerotic **Kimmelstiel-Wilson nodules** (Fig. 22-27). Insudated proteins form rounded nodules between the Bowman capsule and the parietal epithelium ("capsular drops") or subendothelial accumulations along capillary loops ("hyaline caps"). Tubular basement membranes are thickened. Sclerosing and insudative changes in afferent and efferent

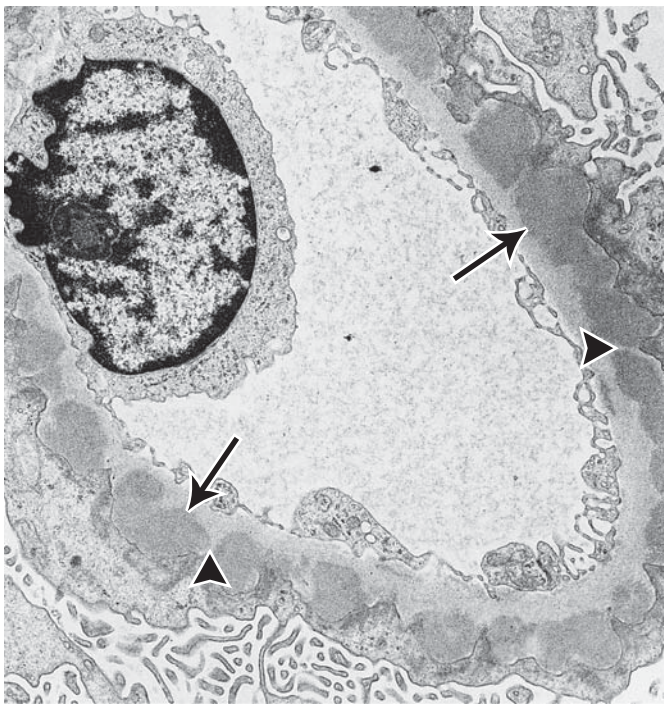

FIGURE 22-24. Stage II membranous glomerulonephritis. An electron micrograph shows deposits of electron-dense material (*arrows*), with intervening delicate projections of basement membrane material (*arrowheads*).

arterioles cause hyaline arteriolosclerosis. Generalized renal arteriosclerosis is usually present. Vascular narrowing and reduced blood flow to the medulla predispose to papillary necrosis and pyelonephritis.

By electron microscopy, the basement membrane lamina densa may be thicker by 5–10-fold. Mesangial matrix is increased, particularly in nodular lesions (Fig. 22-28). The hyaline insudative lesions appear as electron-dense masses that contain lipid debris. By immunofluorescence, there is diffuse linear trapping of IgG, albumin, fibrinogen and other plasma proteins in the GBM. This reflects nonimmunologic adsorption of these proteins to the thickened GBM, possibly due to nonenzymatic glycosylation of GBM and plasma proteins.

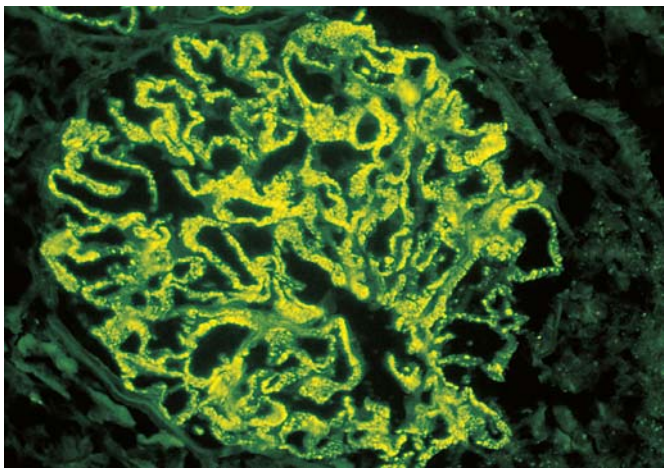

FIGURE 22-25. Membranous glomerulonephritis. Immunofluorescence microscopy shows granular deposits of immunoglobulin G (IgG) outlining the glomerular capillary loops.

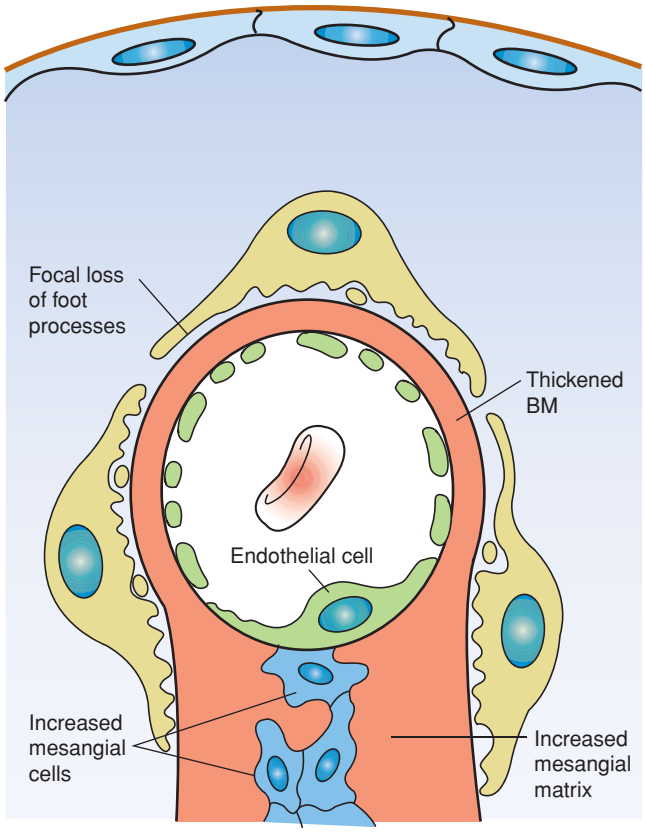

FIGURE 22-26. Diabetic glomerulosclerosis. The lamina densa of the glomerular basement membrane is thickened, and there is an increase in mesangial matrix material.

CLINICAL FEATURES: ***Diabetic glomerulosclerosis accounts for 40% of ESRD and thus is the leading cause of ESRD in the United States.*** It occurs in type 1 and type 2 diabetes mellitus. Approximately 25% of patients with diabetes develop diabetic glomerulosclerosis.

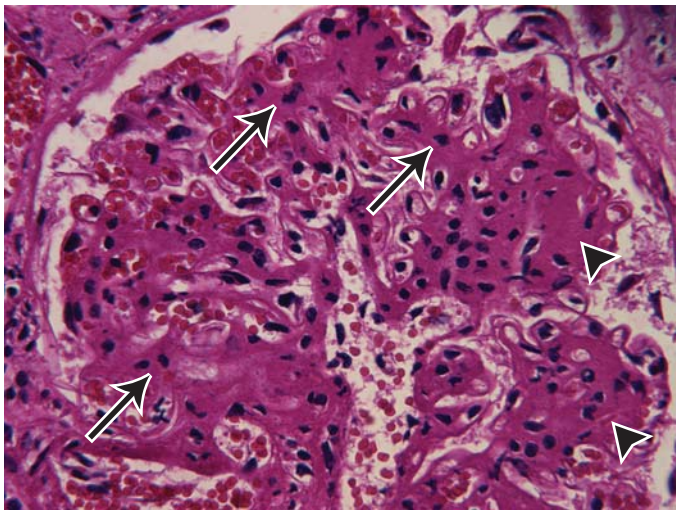

FIGURE 22-27. Diabetic glomerulosclerosis. There is a prominent increase in the mesangial matrix (*arrows*), forming several nodular lesions (*arrowheads*). Dilation of glomerular capillaries is evident, and some capillary basement membranes are thickened.

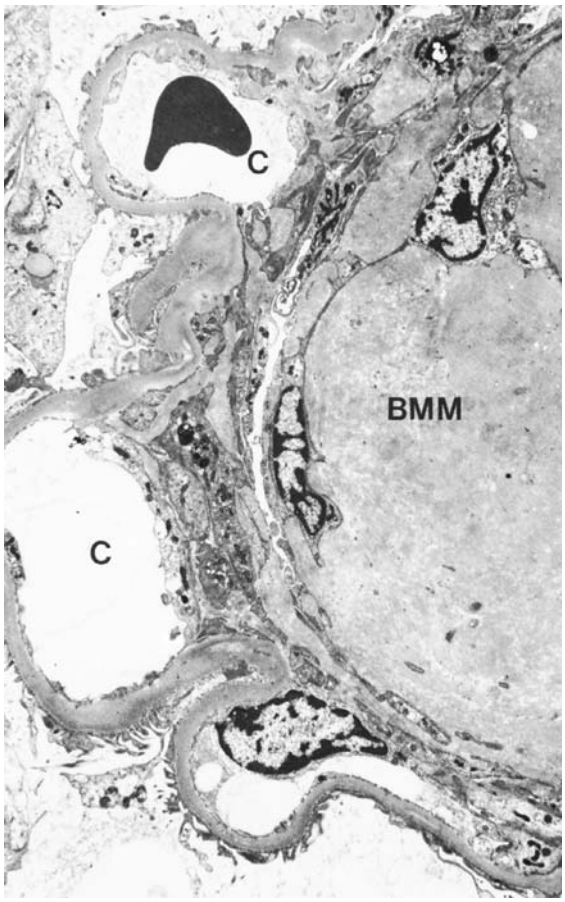

FIGURE 22-28. Advanced diabetic glomerulosclerosis. An electron micrograph shows a nodular aggregate of basement membrane–like material (BMM). The peripheral capillary (C) demonstrates diffuse basement membrane widening but a normal texture.

The earliest manifestation is microalbuminuria (slightly increased proteinuria). Overt proteinuria occurs between 10 and 15 years after the onset of diabetes and often becomes severe enough to cause the nephrotic syndrome. In time, diabetic glomerulosclerosis progresses to renal failure. Strict control of blood glucose reduces the incidence of diabetic glomerulosclerosis and retards progression once it develops. Control of hypertension and dietary protein restriction also slow progression of the disease.

Amyloidosis Leads to Nephrotic Syndrome and Renal Failure

Renal disease is a frequent complication of AA and AL amyloidosis (see Chapter 15).

MOLECULAR PATHOGENESIS: Amyloid may be formed from a number of different polypeptides. In North America, AL amyloidosis accounts for 80% of renal amyloidosis, 10% of AA amyloidosis and 10% of all other types of amyloidosis (e.g., composed of fibrinogen, leukocyte chemotactic factor 2, apolipoprotein). AA is more common is areas with high rates of endemic infections. All forms of amyloidosis appear similar histologically and ultrastructurally. Immunohistochemical tests are required to differentiate among the different types. **AA amyloid** is derived from serum amyloid A (SAA) protein, which increases markedly during inflammation. Thus, AA amyloid is often associated with chronic inflammatory disorders (e.g., rheumatoid arthritis, chronic infections, familial Mediterranean fever). **AL amyloid** is derived from immunoglobulin light chains made by neoplastic clones of B cells or plasma cells. Thus, it often occurs in, or presages, multiple myeloma.

PATHOLOGY: Amyloid is an eosinophilic, amorphous material (Fig. 22-29) with a characteristic apple-green color under polarized light in sections stained with Congo red (Fig. 22-30). Acidophilic deposits are initially most apparent in the mesangium but later extend into capillary walls and may obliterate capillary lumens (Figs. 22-29, 22-31). Glomerular structure is completely obliterated in advanced amyloidosis, and glomeruli appear as large eosinophilic spheres.

Amyloid is composed of nonbranching fibrils, about 10 nm in diameter. These are initially most abundant in the mesangium but often extend into capillary walls, especially in advanced cases (Figs. 22-31, 22-32). Podocyte foot processes overlying the GBM are effaced.

CLINICAL FEATURES: Renal involvement is prominent in most cases of systemic AL and AA amyloidosis. Proteinuria is often the initial manifestation. Proteinuria is nonselective (i.e., albumin and globulins are in the urine) and nephrotic syndrome occurs in 60% of patients. Eventually, severe infiltration of glomeruli and

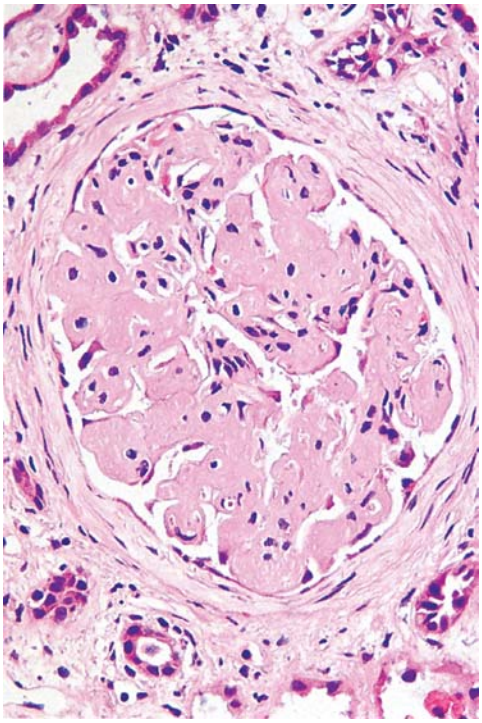

FIGURE 22-29. Amyloid nephropathy. Amorphous acellular material expands the mesangial areas and obstructs the glomerular capillaries. The deposits of amyloid may take on a nodular appearance, somewhat resembling those of diabetic glomerulosclerosis (see Fig. 22-27). However, amyloid deposits are not periodic acid–Schiff positive and are identifiable by Congo red staining.

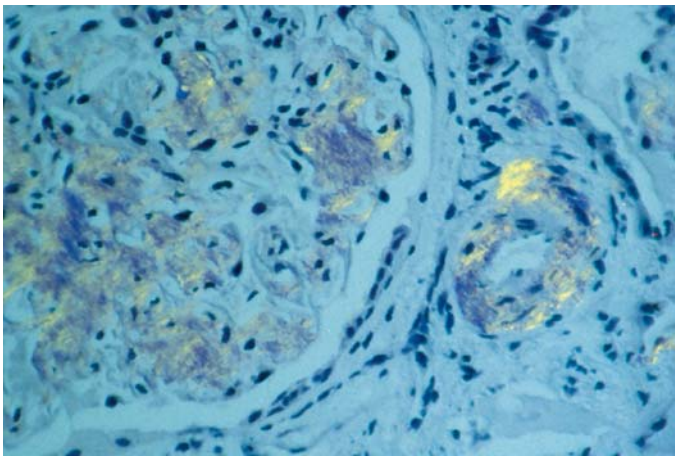

FIGURE 22-30. Amyloid nephropathy. In a section stained with Congo red and examined under polarized light, the amyloid deposits in the glomerulus and the adjacent arteriole show a characteristic apple-green birefringence.

blood vessels by amyloid results in renal failure. AL amyloidosis is treated with chemotherapy for multiple myeloma. AA amyloidosis, especially when caused by familial Mediterranean fever, is ameliorated by colchicine therapy.

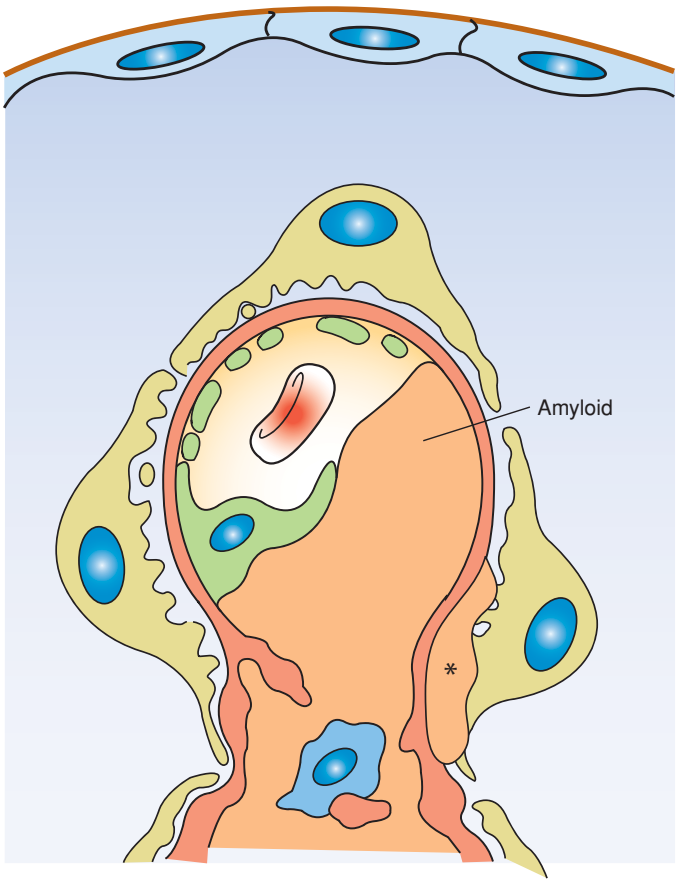

FIGURE 22-31. Amyloid nephropathy. This disorder is initially associated with the accumulation of characteristic fibrillar deposits in the mesangium. These inert masses, which are fibrillar by electron microscopy, extend along the inner surface of the basement membrane, frequently obstructing the capillary lumen. Focal extension of amyloid through the basement membrane (*) may elevate the epithelial cell.

FIGURE 22-32. Amyloid nephropathy. Deposits of fibrils (10 nm in diameter) in a glomerulus adjacent to podocyte cytoplasm with effaced foot processes.

Nonfibrillary Monoclonal Immunoglobulin Deposition in Kidneys Can Cause Disease

Such deposition may be in GBMs, glomerular mesangial matrix, capillary walls and tubular basement membranes. Unlike the deposits of AL amyloid, these do not form fibrils. The two major phenotypes are nodular sclerosing glomerular disease with granular deposits by electron microscopy and proliferative (or membranoproliferative) glomerulonephritis with homogenous dense deposits by electron microscopy.

PATHOLOGY: The underlying B-cell dyscrasia may be occult, or there may be overt multiple myeloma or lymphoma. Monoclonal immunoglobulin deposition stimulates increased glomerular matrix production and/or mesangial hyperplasia. Nodular expansion of mesangial regions resembles diabetic glomerulosclerosis. The increased extracellular material does not stain with Congo red, which distinguishes monoclonal immunoglobulin deposition disease from amyloidosis. Immunofluorescence microscopy demonstrates staining for monoclonal immunoglobulin

chains. Monoclonal immunoglobulin deposition disease with nodular sclerosis usually manifests clinically as nephrotic syndrome, whereas proliferative glomerulonephritis with monoclonal immunoglobulin often manifests as mixed nephritic and nephrotic syndrome.

Hereditary Nephritis (Alport Syndrome) Reflects Abnormal Glomerular Basement Membrane Type IV Collagen

Hereditary nephritis is a proliferative and sclerosing glomerular disease, often accompanied by defects of the ears or the eyes. It is caused by mutations in type IV collagen. In Alport syndrome, a hereditary hearing deficit accompanies nephritis.

MOLECULAR PATHOGENESIS: Several genetic mutations cause molecular defects in the GBM that lead to the renal lesions of hereditary nephritis. The most common, accounting for 85% of hereditary nephritis, is X-linked and is caused by a mutation in the gene for the α5 chain of type IV collagen (*COL4A5*). A deletion at the 5′ end of *COL4A5* that extends into the *COL4A6* gene, which codes for the α6 chain of type IV collagen, causes hereditary nephritis and multiple leiomyomas in the gastrointestinal and genital tracts. An autosomal recessive form of hereditary nephritis is caused by mutations in *COL4A3* and *COL4A4*.

As basement membrane structure is disturbed in hereditary nephritis, serum from patients with anti-GBM disease (e.g., Goodpasture syndrome) fails to react with GBMs from patients with hereditary nephritis. Conversely, patients with hereditary nephritis who have renal transplants are at risk for developing antibodies to allograft GBMs.

PATHOLOGY: Early glomerular lesions of hereditary nephritis show mild mesangial hypercellularity and matrix expansion. Renal disease progression is associated with increasing focal and eventually diffuse glomerular sclerosis. Tubular atrophy, interstitial fibrosis and foam cells in tubules and interstitium accompany advanced glomerular lesions. Electron microscopy makes the diagnosis, demonstrating an irregularly thickened GBM with splitting of the lamina densa into interlacing lamellae that surround electron-lucent areas (Fig. 22-33).

CLINICAL FEATURES: Hematuria develops early in boys with X-linked hereditary nephritis, and proteinuria and progressive renal failure usually follow in the second to fourth decades of life. In females, the X-linked disease is generally milder, with the rate of progression varying substantially among patients, possibly due to the degree of random inactivation (lyonization) of the mutated X chromosome. Autosomal recessive hereditary nephritis resembles X-linked disease except that males and females are affected equally. Autosomal dominant hereditary nephritis with progressive renal failure is rare and difficult to distinguish from severe thin basement membrane disease (see below). Sensorineural, high-frequency hearing loss affects 1/2 of males with X-linked disease and a higher proportion of males and females with autosomal disease. Ocular defects, largely of the lens, occur in 1/4 to 1/3 of patients.

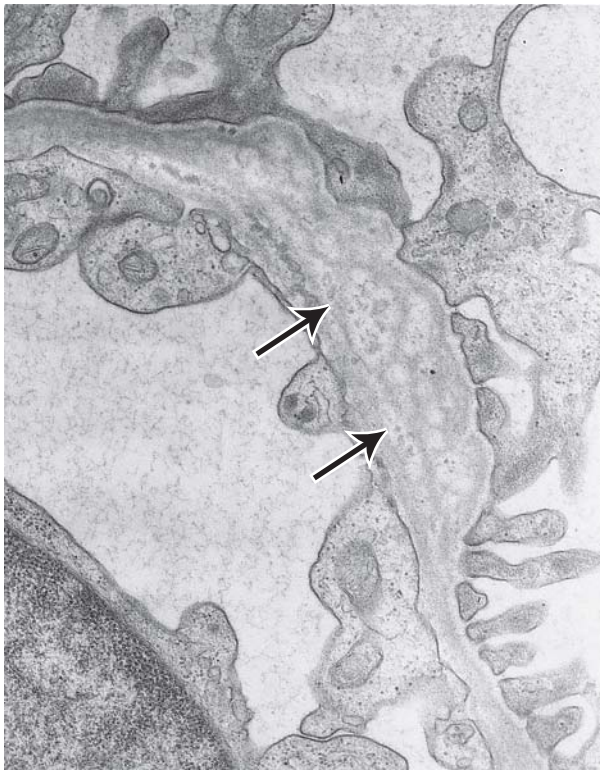

FIGURE 22-33. Hereditary nephritis (Alport syndrome). The lamina densa of the glomerular basement membrane is laminated (*arrows*) rather than forming a single dense band (compare this electron micrograph with Fig. 22-5).

Thin Glomerular Basement Membrane Nephropathy Is a Common Cause of Hereditary Benign Hematuria

This nephropathy, also called **benign familial hematuria,** often presents as asymptomatic microscopic hematuria, with occasional intermittent gross hematuria. This disease and IgA nephropathy are common diagnostic considerations in patients with asymptomatic glomerular hematuria. Patients with thin basement membrane nephropathy usually do not develop renal failure or substantial proteinuria. By light microscopy, glomeruli are unremarkable. Electron microscopy shows reduced thickness of the GBM (150–300 nm; normal is 350–450 nm). The most common mode of inheritance is autosomal dominant. Heterozygous mutations in *COL4A3* and *COL4A4* genes lead to thin basement membrane disease, and homozygous ones lead to Alport syndrome.

Acute Postinfectious Glomerulonephritis Usually Follows Acute β-Hemolytic Streptococcal or Staphylococcal Infection

Complement-rich immune complex deposits in glomeruli cause this disease.

PATHOPHYSIOLOGY: Nephritogenic strains of group A streptococci or staphylococci usually cause acute postinfectious glomerulonephritis. Rare cases result from viral (e.g., hepatitis B) or parasitic (e.g., malaria) infections. The mechanism by which

infection causes the characteristic glomerular inflammation is not completely understood. Similarities to experimental acute serum sickness suggest that postinfectious glomerulonephritis reflects deposition in glomeruli of immune complexes containing antibody plus bacterial antigens. Poststreptococcal glomerulonephritis in patients and experimental acute serum sickness have 9–14-day latent periods between antigen exposure and glomerulonephritis. Both show granular immune complex deposits with similar ultrastructural appearance (dense deposits) (see below). Immune complexes could form in the circulation and deposit in glomeruli, or they may form in situ when bacterial antigens trapped in glomeruli bind to circulating antibodies. Potentially culpable (but not yet convicted) streptococcal antigens include glyceraldehyde phosphate dehydrogenase and cationic proteinase exotoxin B. Both can localize in glomerular capillary walls and activate complement even without antibodies. Alternatively, nephritogenic bacteria may release factors that activate complement without requiring immune complex formation. This would explain why complement—but not immunoglobulin—is sometimes present in glomerular deposits.

Complement activation, as well as activation of other humoral and cellular inflammatory mediators, causes glomerular inflammation. Complement activation is so extensive that more than 90% of patients develop hypocomplementemia. The inflammatory mediators attract and activate neutrophils and monocytes, and stimulate mesangial and endothelial cell proliferation. These effects result in marked glomerular hypercellularity, which defines acute diffuse proliferative glomerulonephritis.

PATHOLOGY: In the acute phase, glomeruli are diffusely enlarged and hypercellular (Fig. 22-34). The latter reflects proliferation of endothelial and mesangial cells (Fig. 22-35), and infiltration by neutrophils and monocytes. Crescents are uncommon. Interstitial edema and mild mononuclear infiltration parallel the glomerular changes.

The acute phase begins 1–2 weeks after the onset of the nephritogenic infection and resolves in more than 90% of patients after several weeks. Neutrophils and endothelial hypercellularity disappear first. Mesangial hypercellularity and matrix expansion remain, but all of these changes resolve completely in most patients after several months.

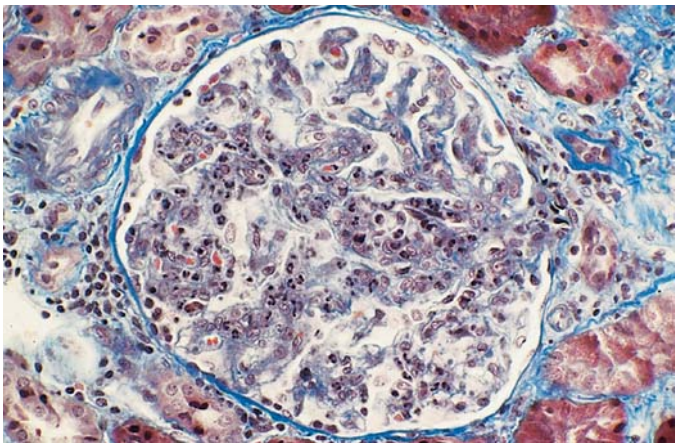

FIGURE 22-34. Acute poststreptococcal glomerulonephritis. A glomerulus of a patient who developed glomerulonephritis after a streptococcal infection contains many neutrophils (Masson trichrome stain).

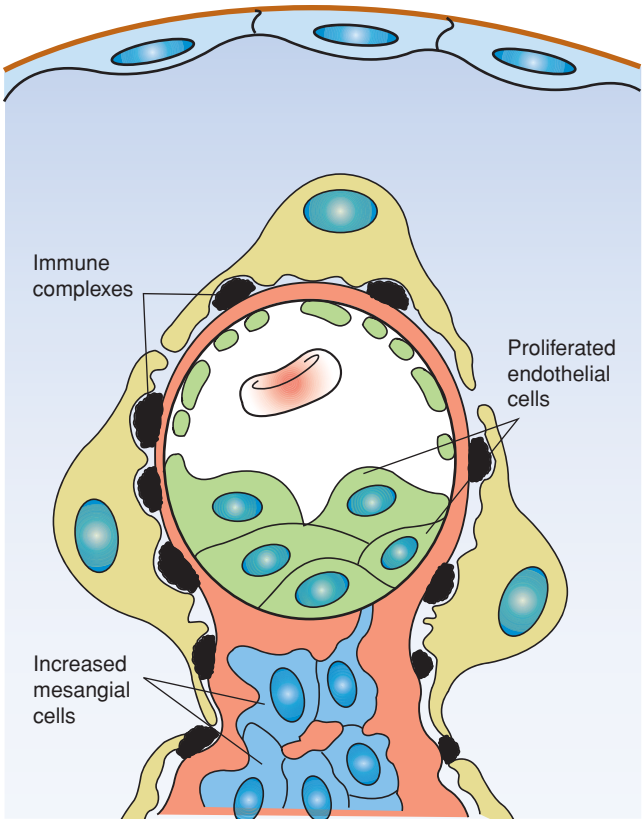

FIGURE 22-35. Postinfectious glomerulonephritis. Accumulation of numerous subepithelial immune complexes as hump-like structures is a characteristic feature. Less prominent subendothelial immune complexes are associated with endothelial cell proliferation and are related to increased capillary permeability and narrowing of the lumen. Frequently, proliferation of mesangial cells and a thickened mesangial matrix (BM) result in widening of the stalk and conspicuous trapping of immune complexes.

Ultrastructurally, acute postinfectious glomerulonephritis shows distinctive **subepithelial dense deposits** shaped like **"humps"** (Figs. 22-35, 22-36). These are invariably accompanied by mesangial and subendothelial deposits, which may be more difficult to find but are probably more important in pathogenesis by virtue of their proximity to inflammatory mediator systems in the blood. The variably sized, dome-shaped humps are on the epithelial side of the GBM. They are not as widely distributed as the deposits of membranous glomerulonephritis (compare Figs. 22-23 and 22-35). Granular deposits of C3 with or without immunoglobulin are observed by immunofluorescence microscopy in capillary walls, corresponding to the humps (Fig. 22-37). A rare variant of postinfectious glomerulonephritis, usually caused by methicillin-resistant staphylococcus, has conspicuous IgA in the immune deposits.

CLINICAL FEATURES: The incidence of acute postinfectious glomerulonephritis is declining in most developed countries but remains high because of higher rates of nephritogenic infections. It is still

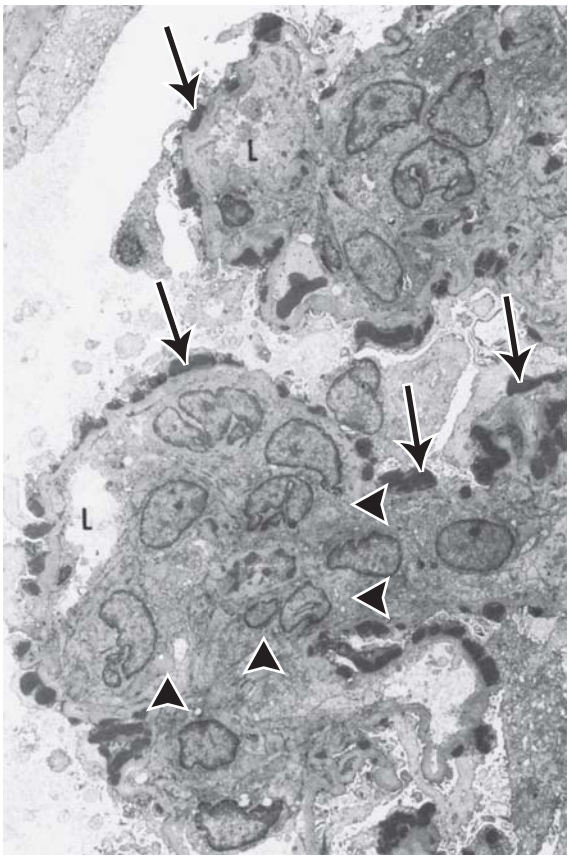

FIGURE 22-36. Acute postinfectious glomerulonephritis. An electron micrograph demonstrates numerous subepithelial humps (*arrows*) and mesangial hypercellularity (*arrowheads*). The capillary lumina (L) are markedly narrowed.

one of the most common childhood renal diseases. Primary infection involves the pharynx (pharyngitis) or, especially in hot and humid environments, the skin (pyoderma). In recent years, the proportion of cases following staphylococcal infection has been increasing. Because organisms may not be present at the time nephritis develops, the diagnosis may depend on serologic evidence of increasing antibody titers to streptococcal antigens. The nephritic syndrome begins abruptly with oliguria, hematuria, facial edema and hypertension. Serum C3 levels are lower during the acute syndrome but return to normal within 1–2 weeks. Overt nephritis resolves after several weeks, but hematuria and especially proteinuria may persist for several months. A few patients have abnormal urinary sediment for years after the acute episode, and rare patients (particularly adults) develop progressive renal failure.

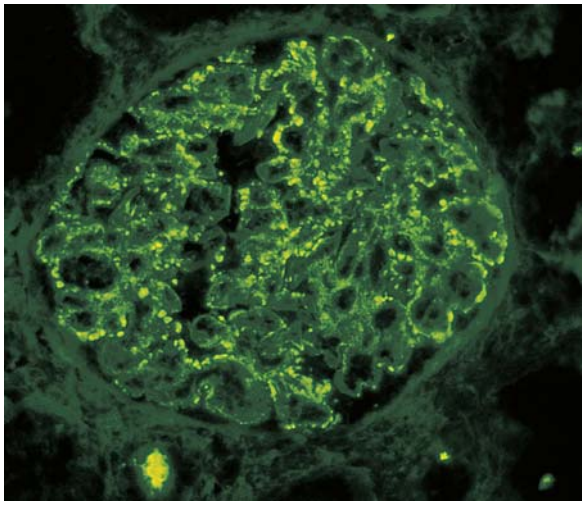

FIGURE 22-37. Acute postinfectious glomerulonephritis. An immunofluorescence micrograph demonstrates granular staining for C3 in capillary walls and the mesangium.

Immune Complex Membranoproliferative Glomerulonephritis Has Multiple Causes

MPGN is a pattern of glomerular inflammation with hypercellularity and capillary wall thickening caused by multiple different etiologies.

PATHOPHYSIOLOGY: MPGN is caused by deposits in the mesangium and subendothelial zone of capillary walls containing immune complexes or activated complement without immunoglobulin. Subepithelial deposits may also occur. The two major immunopathologic categories are immune complex MPGN and C3 glomerulopathy MPGN (Table 22-6). The nephritogenic antigens in immune complex MPGN are usually unknown. However, the apparent sources of the antigens may be infectious or autoimmune conditions (Table 22-6). C3 glomerulopathy MPGN is caused by genetic or autoimmune disruption of regulatory mechanisms that normally hold the alternative complement pathway in check. C3 glomerulopathy is discussed in the next section.

Eliminating the associated condition (e.g., bacterial endocarditis or osteomyelitis) may be followed by resolution of immune complex MPGN, thus suggesting a causal relationship between the two. Unlike the pathogens of

TABLE 22-6
CLASSIFICATION OF MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

Primary Immune Complex (idiopathic) Membranoproliferative Glomerulonephritis (MPGN)
Secondary Immune Complex MPGN caused by:
Subacute bacterial endocarditis
Infected ventriculoatrial shunt
Osteomyelitis
Hepatitis C virus infection
Cryoglobulinemia
Monoclonal immunoglobulins
Neoplasia
C3 Glomerulopathy
Dense deposit disease
C3 glomerulonephritis

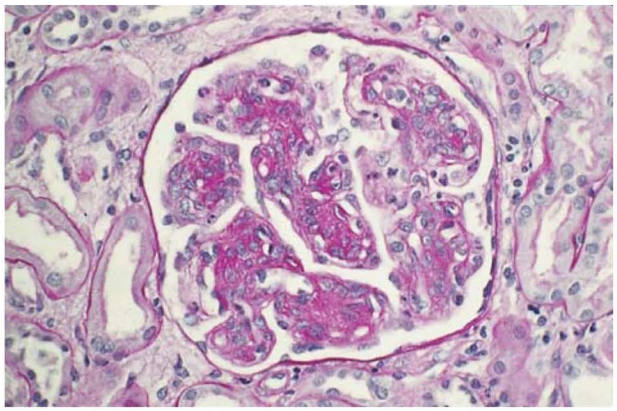

FIGURE 22-38. Type I membranoproliferative glomerulonephritis. The glomerular lobulation is accentuated. Increased cells and matrix in the mesangium and thickening of capillary walls are noted.

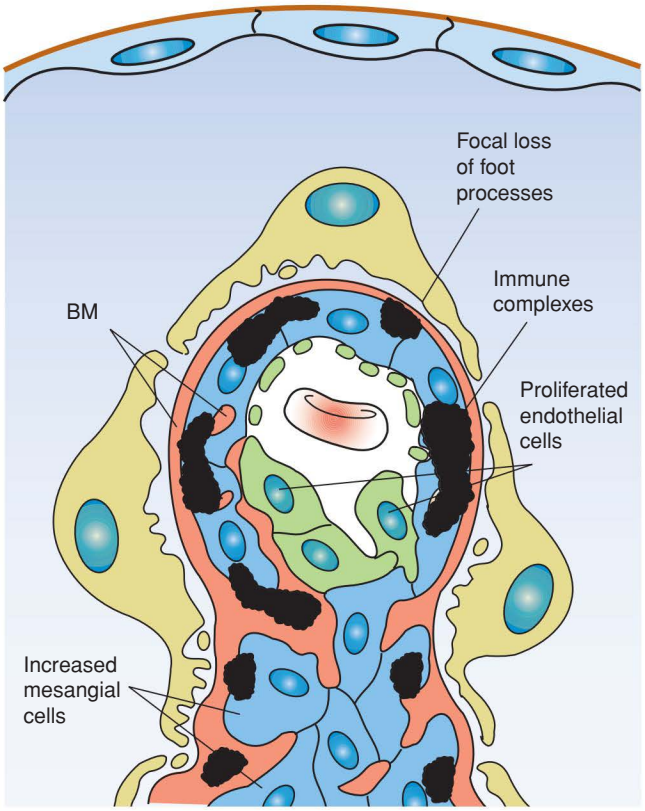

FIGURE 22-39. Type I membranoproliferative glomerulonephritis. In this disease, the glomeruli are enlarged. Hypercellular tufts and narrowing or obstruction of the capillary lumens are seen. Large subendothelial deposits of immune complexes extend along the inner border of the basement membrane (BM). The mesangial cells proliferate and migrate peripherally into the capillary. Basement membrane material accumulates in a linear fashion parallel to the basement membrane in a subendothelial position. The interposition of mesangial cells and basement membrane between the endothelial cells and the original basement membrane creates a double-contour effect. The accumulation of mesangial cells and stroma in the tufts narrows the capillary lumen. The proliferation of mesangial cells and the accumulation of basement membrane material also widen the mesangium. The entire process leads progressively to lobulation of the glomerulus. Note the proliferation of endothelial cells and focal effacement of foot processes.

acute postinfectious glomerulonephritis, those associated with immune complex MPGN cause persistent, indolent infections with chronic antigenemia. This condition leads to chronic localization of immune complexes in glomeruli and resultant hypercellularity and matrix remodeling.

PATHOLOGY: Glomeruli in MPGN are diffusely enlarged, with florid mesangial cell proliferation and infiltration of monocytes/macrophages. The resultant glomerular lobular distortion ("hypersegmentation"; Fig. 22-38) was once called **lobular glomerulonephritis**. Of these patients, 20% have crescents, usually involving only a minority of glomeruli. Capillary walls are thickened, and silver stains show a doubling or complex replication of GBMs.

Electron microscopy reveals thickening and replication of GBMs probably caused by endothelial cell activation as well as extension of mesangial cytoplasm into the subendothelial zone and deposition of new basement membrane material between the mesangial cytoplasm and endothelial cell (Figs. 22-39, 22-40). Subendothelial and mesangial electron-dense deposits, corresponding to immune complexes or complement deposits, are the likely stimuli for the endothelial and mesangial response. Variable numbers of subepithelial dense deposits may also be seen. Immunofluorescence microscopy shows granular deposition of immunoglobulins

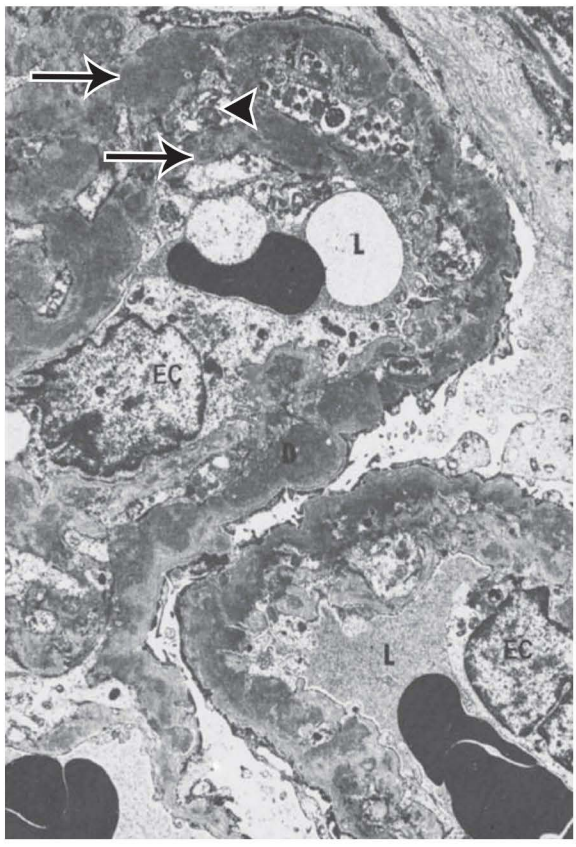

FIGURE 22-40. Type I membranoproliferative glomerulonephritis. An electron micrograph demonstrates a double-contour basement membrane (*arrows*), with mesangial interposition (*arrowhead*) and prominent subendothelial deposits. EC = endothelial cell; L = capillary lumen.

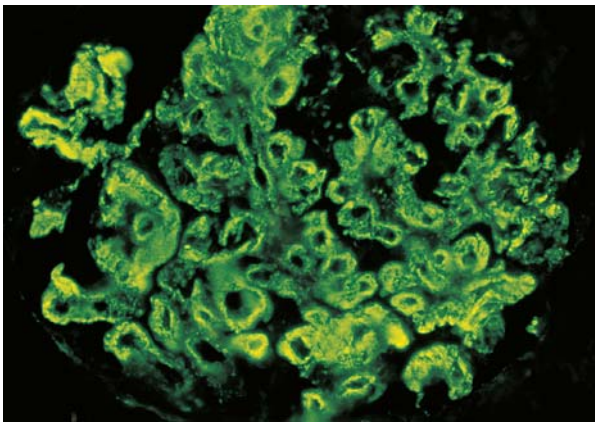

FIGURE 22-41. Type I membranoproliferative glomerulonephritis. An immunofluorescence micrograph demonstrates granular to band-like staining for C3 in the capillary walls and mesangium.

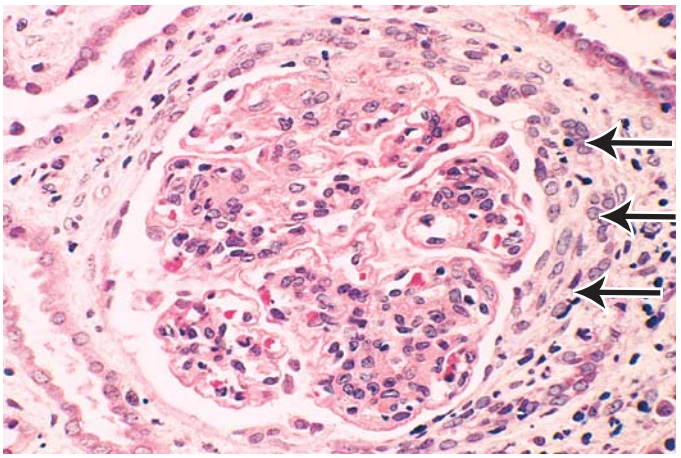

FIGURE 22-42. C3 glomerulopathy (dense deposit disease). Capillary wall thickening, hypercellularity and a small crescent (*arrows*) are evident.

and complement in glomerular capillary loops and mesangium in immune complex MPGN and complement alone in C3 glomerulopathy (Fig. 22-41).

CLINICAL FEATURES: Immune complex MPGN can occur at any age but is most frequent in older children and young adults. It may manifest as nephrotic or nephritic syndromes, or a combination of both. MPGN accounts for 5% of primary nephrotic syndrome in children and adults in the United States. Immune complex MPGN occurs much more commonly in countries where chronic infections are more prevalent. Patients often have low C3 levels. The differential diagnosis includes acute postinfectious glomerulonephritis and lupus glomerulonephritis, both of which can cause nephritis with hypocomplementemia. MPGN is usually a persistent, slowly progressive disease. After 10 years, 1/2 of patients reach ESRD.

C3 Glomerulopathy Is Caused by Dysregulation of the Alternative Complement Pathway

C3 glomerulopathy is a rare glomerulonephritis caused by complement dysregulation that includes **dense deposit disease** (formerly called *type II MPGN*) and **C3 glomerulonephritis** (including a variant with an MPGN pattern).

PATHOPHYSIOLOGY: The extensive glomerular localization of complement *without* immunoglobulin indicates that complement activation is a major mediator of the structural and functional abnormalities. Deficient or ineffective alternative pathway complement regulatory factors (e.g., complement factor H, complement factor I) cause C3 glomerulopathy. Complement activation abnormality results from genetic mutations or autoantibodies that impair alternative pathway regulatory mechanisms. Some patients have a serum IgG autoantibody, **C3 nephritic factor,** which stabilizes activated C3 convertase (C3bBb) of the alternative complement pathway and prolongs C3 activation. C3 glomerulopathy often recurs in renal transplants because the defect in complement regulation is in the recipient.

PATHOLOGY: The two pathologic types of C3 glomerulopathy are dense deposit disease and C3 glomerulonephritis. C3 glomerulopathy histologically resembles immune complex MPGN, with capillary wall thickening and increased cellularity (Fig. 22-42). However, in many patients, hypercellularity or capillary wall thickening may assume a different pattern. The distinctive pathologic feature of dense deposit disease is a ribbon-like zone of increased density in the center of a thickened GBM and in the mesangial matrix (Fig. 22-43). There are areas of density in peritubular capillary membranes and arteriolar elastic laminae. C3 deposits linearly in capillary walls, with little or no antibody (Fig. 22-44). C3 glomerulonephritis lacks intramembranous dense deposits. It has dense deposits like those of immune complex glomerulonephritis, except that they have no immunoglobulin.

CLINICAL FEATURES: C3 glomerulopathy is rare (<5/1,000,000), and 80% of patients are children. Patients usually present with proteinuria (often nephrotic range), hematuria, hypertension and impaired renal function. Hypocomplementemia with low C3 and normal C4 is common. Prognosis is sobering, as 40% reach ESRD within 10 years.

Lupus Glomerulonephritis Includes Diverse Patterns of Immune Complex Deposition

SLE (see Chapter 11) is an autoimmune disease with generalized B-cell dysregulation and hyperactivity, and production of autoantibodies to many nuclear and nonnuclear antigens, including DNA, RNA, nucleoproteins and phospholipids. SLE is most common in women, especially of child-bearing age. Blacks, Asians and Hispanics generally have more severe disease than do whites. Nephritis is one of the most common complications of SLE.

Immune complexes in the mesangium cause less inflammation than subendothelial immune complexes. The latter are more exposed to cellular and humoral inflammatory mediator systems in blood and are, therefore, more likely to initiate inflammation. Subepithelial localization of immune complexes causes proteinuria but does not stimulate overt glomerular inflammation.

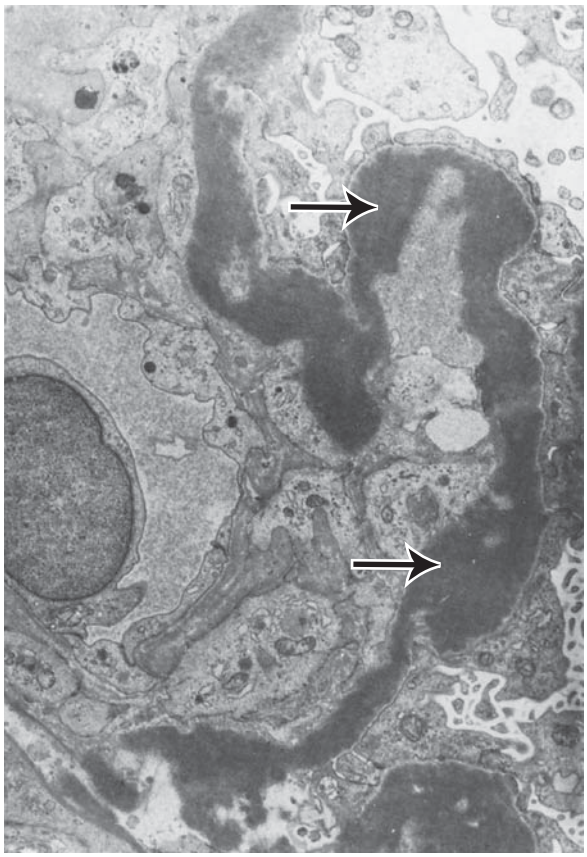

FIGURE 22-43. C3 glomerulopathy (dense deposit disease). An electron micrograph demonstrates thickening of the basement membrane with intramembranous dense deposits (*arrows*).

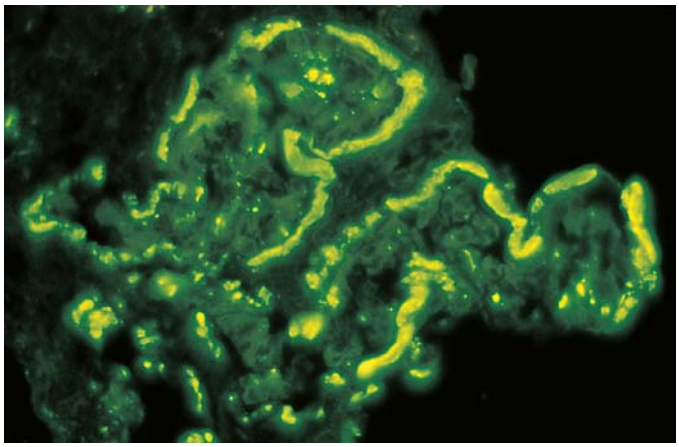

FIGURE 22-44. C3 glomerulopathy (dense deposit disease). An immunofluorescence micrograph demonstrates bands of capillary wall staining and coarsely granular mesangial staining for C3.

PATHOPHYSIOLOGY: Defective apoptosis and impaired clearance of chromatin fragments may contribute to the genesis of antinuclear autoimmune responses and provide target antigens for nephritogenic immune complex formation. Immune complexes may localize in glomeruli by deposition from the circulation, formation in situ or both. Circulating immune complexes formed by high-avidity antibodies deposit in subendothelial and mesangial zones; low-affinity antibodies form immune complexes in situ in the subepithelial zone. Immune complexes formed in situ may involve antigens such as double-stranded DNA and nucleosomes that accumulate on GBMs or in mesangial matrix due to charge interactions. Glomerular immune complexes activate complement and initiate inflammation. Complement activation often causes hypocomplementemia. Immune complexes also localize in the renal interstitium, walls of interstitial vessels and tubular basement membranes, where they may activate the tubulointerstitial inflammation seen in patients with lupus nephritis.

PATHOLOGY: The pathologic and clinical manifestations of lupus nephritis vary with the diverse patterns of immune complex accumulation in different patients (Table 22-7) and in the same patient over time.

- **Class I (minimal mesangial lupus glomerulonephritis):** Immune complexes are confined to mesangium and cause no changes by light microscopy.
- **Class II (mesangial proliferative lupus glomerulonephritis):** Immune complexes are confined to mesangium

TABLE 22-7
PATHOLOGIC AND CLINICAL FEATURES OF LUPUS NEPHRITIS

Location of Immune Lupus Nephritis Class	Location of Immune Clinical Complexes	Clinical Manifestations
I: Minimal mesangial	Mesangial	Mild hematuria and proteinuria
II: Mesangial proliferative	Mesangial	Mild hematuria and proteinuria
III: Focal	Mesangial and subendothelial	Moderate nephritis
IV: Diffuse	Mesangial and subendothelial	Severe nephritis
V: Membranous	Subepithelial and mesangial	Nephrotic syndrome
VI: Chronic sclerosing	Variable	Chronic renal failure

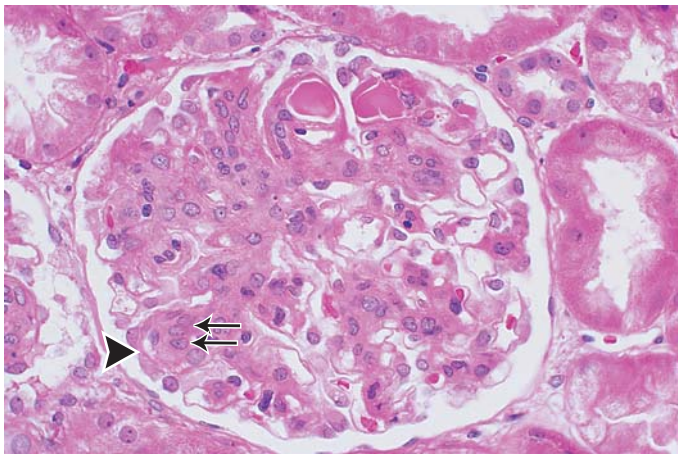

FIGURE 22-45. Proliferative lupus glomerulonephritis. Segmental endocapillary hypercellularity (*arrows*) and thickening of capillary walls (*arrowhead*) are present.

and cause varying degrees of mesangial hypercellularity and matrix expansion (Fig. 22-45).

- **Class III (focal lupus glomerulonephritis):** Subendothelial immune complexes accumulate, together with mesangial immune complexes. These trigger mesangial and endothelial cell proliferation, inflammation and influx of neutrophils and monocytes. This overt glomerular inflammation is called **focal proliferative lupus glomerulonephritis** if it involves less than 50% of glomeruli.
- **Class IV (diffuse lupus glomerulonephritis):** This type is similar to class III but involves more than 50% of glomeruli. Glomerular involvement may be predominantly global (IV-G) or predominantly segmental (IV-S).
- **Class V (membranous lupus glomerulonephritis):** Immune complexes are mostly in the subepithelial zone. Some patients have a background of class V injury and a concurrent class III or IV injury. Even pure class V lupus nephritis has mesangial immune complexes that can be detected by electron microscopy.
- **Class VI (advanced sclerosing lupus glomerulonephritis):** Advanced chronic disease.

Immune complex dense deposits occur in mesangial, subendothelial and subepithelial locations. Class I and II lesions have mainly mesangial deposits. Classes III and IV-G have mesangial and subendothelial deposits, and usually scattered subepithelial deposits (Fig. 22-46). Class IV-S tends to show fewer glomerular immune complexes and more segmental necrosis. Class V lesions contain many subepithelial dense deposits. In 80% of cases, endothelial cells have **tubuloreticular inclusions** (Fig. 22-46). These reflect high levels of interferon. Lupus nephritis and HIV-associated nephropathy are the only renal diseases that feature such inclusions.

By immunofluorescence, subepithelial complexes are granular; subendothelial deposits may be granular or band-like (Fig. 22-47). The immune complexes often stain most intensely for IgG, but IgA and IgM are also almost always present, as are C3, C1q and other complement components. Granular staining along tubular basement membranes and interstitial vessels occurs in more than 1/2 of patients.

FIGURE 22-46. Diffuse proliferative class IV-G lupus glomerulonephritis. An electron micrograph reveals large subendothelial and mesangial dense deposits (*M*) and a few subepithelial (*SE*) deposits. Endothelial tubuloreticular inclusions (*arrows*) are present.

CLINICAL FEATURES: Renal disease develops in 70% of patients with SLE and is often the major cause of morbidity and mortality. Clinical manifestations and prognosis of renal dysfunction vary (Table 22-7), depending on the pathology of the underlying renal disease. ***Renal biopsy specimens from patients with lupus are used to assess disease category, activity and chronicity, as well as to diagnose lupus glomerulonephritis.*** Class III and class IV

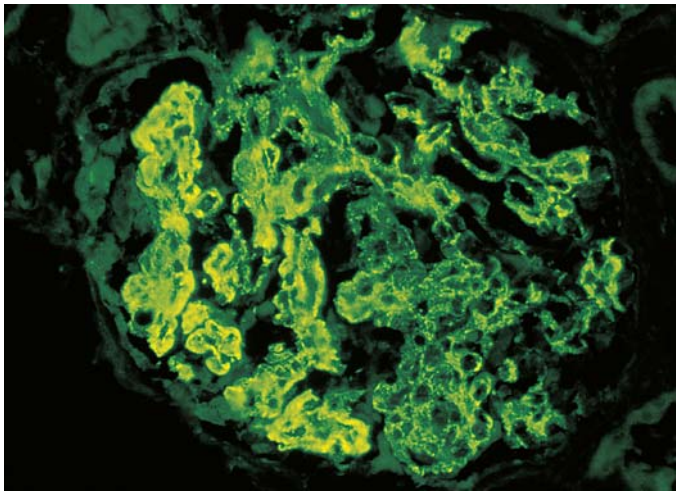

FIGURE 22-47. Diffuse proliferative lupus glomerulonephritis. An immunofluorescence micrograph demonstrates segmental staining for immunoglobulin G in the capillary walls and mesangium.

lupus nephritis have the poorest prognosis and are treated most aggressively, usually with high doses of corticosteroids and immunosuppressive drugs. Over time, sometimes due to treatment, lupus nephritis may change from one type to another, with parallel changes in clinical manifestations. Fewer than 20% of patients with class IV disease reach ESRD within 5 years.

IgA Nephropathy Is Caused by IgA1 Immune Complexes

PATHOPHYSIOLOGY: Deposition of IgA-dominant immune complexes is the cause of IgA nephropathy, but what the constituent antigens are and how they accumulate (deposition vs. formation in situ) are uncertain. Patients with IgA nephropathy often have aberrant IgA1 molecules, elevated blood levels of IgA1 and circulating IgA1-containing immune complexes or aggregated IgA1. Mesangial accumulation of IgA-dominant immune complexes may entail several mechanisms.

Respiratory or gastrointestinal infections often trigger exacerbations of IgA nephropathy. Mucosal exposure to viral, bacterial or dietary antigens stimulates IgA-dominant immune responses, leading to glomerular immune complex accumulation. Abnormal glycosylation of the IgA1 hinge region appears to be an important factor in many patients with IgA nephropathy. The immune deposits contain mainly IgA1 rather than IgA2. IgA1, but not IgA2, has a hinge region with O-linked glycan chains. In IgA nephropathy, serum IgA1 has less terminal galactosylation and sialylation of these chains. Autoantibodies against these abnormal chains may develop.

As well, the abnormal IgA1 galactosylation may lead to lack of receptor engagement of the abnormal IgA1, reducing clearance of immune complexes containing IgA1 from the blood. As a result, IgA forms aggregates in the circulation. The mesangium traps these aggregates. Immune complexes form between the abnormal IgA1 and IgG antibodies against the abnormal IgA1.

IgA-containing immune complexes in the mesangium most likely activate complement by the alternative pathway. The demonstration of C3 and properdin, but not C1q and C4, in the IgA deposits supports this hypothesis.

PATHOLOGY: Immunofluorescence microscopy is essential for diagnosis of IgA nephropathy. The diagnostic finding is mesangial immunostaining for IgA more intense than, or equivalent to, staining for IgG or IgM (Fig. 22-48). This is almost always accompanied by staining for C3. IgA deposited in the glomerular capillary wall (in addition to the mesangium) may be present in more severe cases and suggests a less favorable prognosis.

Depending on the severity and duration of the disease, a continuum of histologic findings is seen in IgA nephropathy, from (1) no discernible light microscopic changes to (2) focal or diffuse mesangial hypercellularity to (3) focal or diffuse proliferative glomerulonephritis (Fig. 22-49) to (4) chronic sclerosing glomerulonephritis. At the time of initial renal biopsy diagnosis, focal proliferative glomerulonephritis is the most frequent manifestation. Crescents are not common, except in unusually severe cases. This spectrum of pathologic changes is analogous to that seen with lupus nephritis but tends to be less severe.

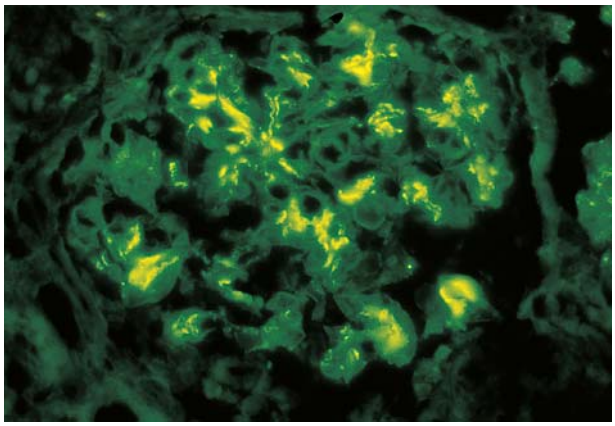

FIGURE 22-48. Immunoglobulin A (IgA) nephropathy. An immunofluorescence micrograph shows deposits of IgA in the mesangial areas.

Ultrastructural examination reveals mesangial electron-dense deposits (Figs. 22-50, 22-51). Dense deposits in capillary walls are usually seen in patients with severe disease.

CLINICAL FEATURES: ***IgA nephropathy is the most common form of glomerulonephritis in developed countries.*** It accounts for 10% of cases in the United States, 20% in Europe and 40% in Asia. IgA nephropathy is common in Native Americans and rare in blacks. It occurs most often in young men, with a peak age of 15–30 years at diagnosis. Clinical presentations vary, which reflects the varied pathologic severity: 40% of patients have asymptomatic microscopic hematuria, 40% have intermittent gross hematuria, 10% have nephrotic syndrome and 10% have renal failure. The disease rarely resolves completely but may follow an episodic course, with exacerbations often coinciding with upper respiratory tract infections. IgA nephropathy is slowly progressive, with 20% of patients reaching end-stage renal failure after 10 years. In systemic IgA vasculitis (Henoch-Schönlein purpura), the IgA deposits and resultant

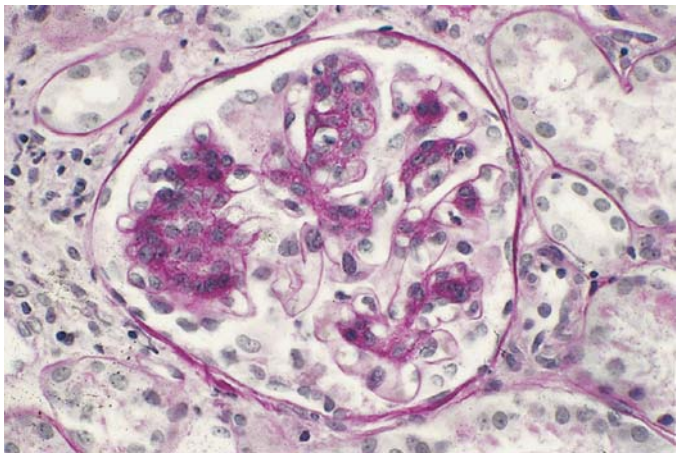

FIGURE 22-49. Immunoglobulin A nephropathy. Segmental mesangial hypercellularity and matrix expansion caused by the mesangial immune deposits (periodic acid–Schiff stain).

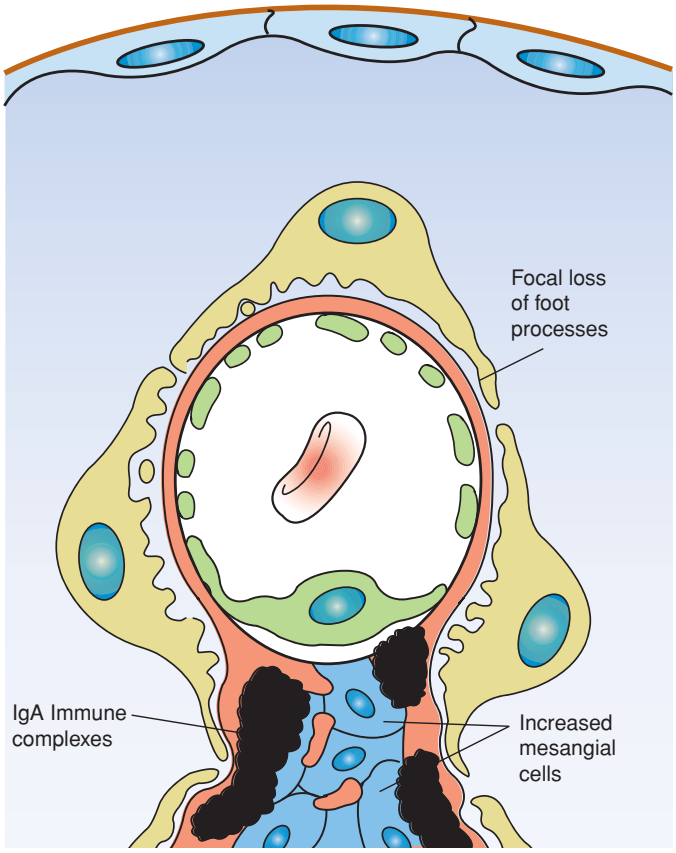

FIGURE 22-50. Immunoglobulin A (IgA) nephropathy. Significant accumulation of IgA is seen in the mesangium, most commonly between the mesangial cells and the basement membrane.

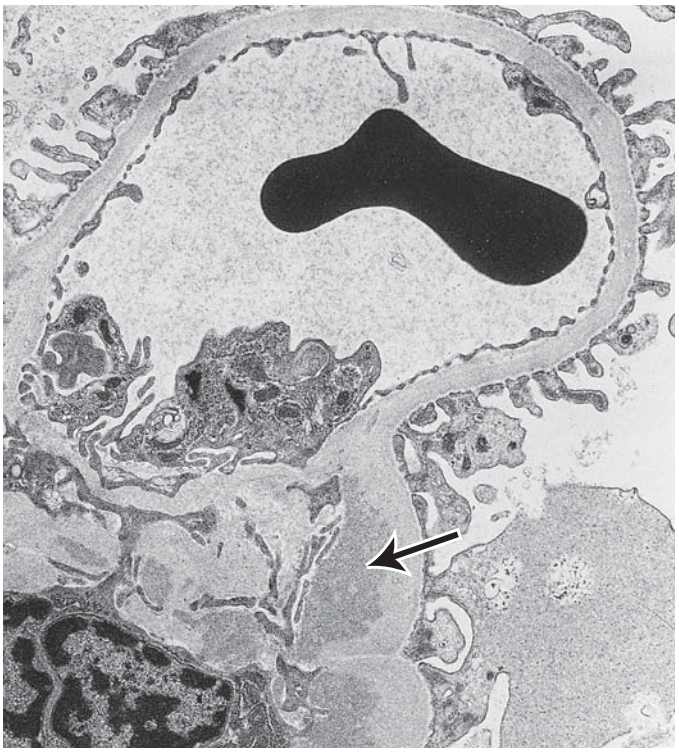

FIGURE 22-51. Immunoglobulin A nephropathy. An electron micrograph demonstrates prominent dense deposits in the mesangial matrix (*arrow*).

inflammation affect small vessels throughout the body including the skin (causing purpura) and gut (causing abdominal pain). When patients with IgA nephropathy are treated by renal transplantation, IgA deposits may recur in the allograft, although graft function is usually not impaired.

Anti–Glomerular Basement Membrane Glomerulonephritis May Be Accompanied by Pulmonary Hemorrhage

Anti-GBM antibody disease is an uncommon but aggressive glomerulonephritis that may only affect the kidneys, or it may be combined with pulmonary hemorrhage (Goodpasture syndrome).

MOLECULAR PATHOGENESIS: ***Anti-GBM glomerulonephritis is mediated by an autoimmune response against type IV collagen in the GBM.*** The specific epitope is in the globular noncollagenous domain of the α3 chain of type IV collagen. Disturbance of the tertiary structural conformation of type IV collagen is required to expose the epitopes that are targeted by anti-GBM antibodies. Because the target antigen is also expressed on pulmonary alveolar capillary basement membranes, 1/2 of patients also have pulmonary hemorrhages and hemoptysis, sometimes severe enough to be life-threatening. If lungs and kidneys are both involved, the eponym **Goodpasture syndrome** is used (Fig. 22-15). Anti-GBM antibodies, anti-GBM T cells or both may mediate the injury. The antibodies bind the autoantigens in situ, initiating acute inflammation by activating mediator systems, such as complement. Experimental studies suggest that T cells specific for GBM antigens may also mediate vascular injury. Genetic susceptibility to anti-GBM disease is strongly associated with human leukocyte antigen (HLA)-DRB1. Disease onset often follows viral upper respiratory tract infections, and pulmonary involvement appears to require synergistic injurious agents, such as cigarette smoke.

PATHOLOGY: ***The pathologic hallmark of anti-GBM glomerulonephritis is diffuse linear GBM immunostaining for IgG, indicating autoantibodies bound to the basement membrane*** (Fig. 22-52). This finding is not, however, entirely specific. For example, binding of IgG to basement membranes occurs in diabetic glomerulosclerosis and monoclonal immunoglobulin deposition disease based on mechanisms other than antigen recognition. More than 90% of patients with anti-GBM glomerulonephritis have glomerular crescents **(crescentic glomerulonephritis)** (Figs. 22-53, 22-54), usually involving more than 50% of glomeruli. Focal glomerular fibrinoid necrosis is common. Involved lungs have marked intra-alveolar hemorrhage. By electron microscopy, GBMs show focal breaks, but no immune complex–type electron-dense deposits.

CLINICAL FEATURES: Anti-GBM glomerulonephritis typically presents with rapidly progressive renal failure and nephritic signs and symptoms. ***It accounts for 10%–20% of rapidly progressive (crescentic) glomerulonephritis*** (Table 22-8). Anti-GBM

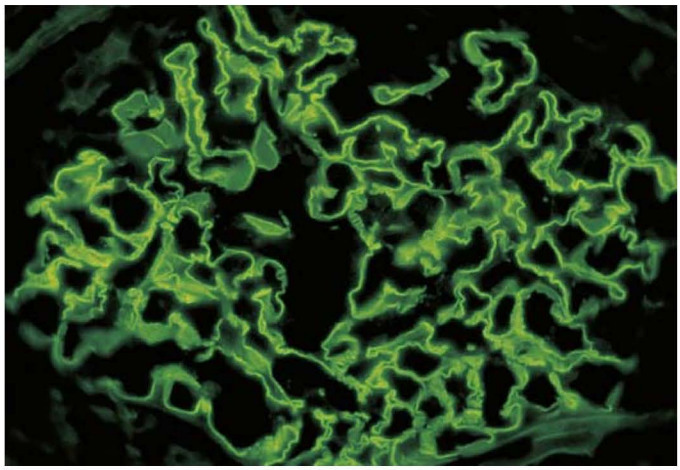

FIGURE 22-52. Anti–glomerular basement membrane (GBM) glomerulonephritis. Linear immunofluorescence for immunoglobulin G is seen along the GBM. Contrast this linear pattern of staining with the granular pattern of immunofluorescence typical for most types of immune complex deposition within capillary walls (see Fig. 22-36).

antibodies are detectable in approximately 90% of patients. Treatment consists of high-dose immunosuppressive therapy and plasma exchange, which are most effective at an early stage of the disease, before severe renal failure supervenes. If end-stage renal failure develops, renal transplantation is successful with little risk of losing the allograft to recurrent glomerulonephritis if transplantation is done after anti-GBM antibodies have disappeared.

Antineutrophil Cytoplasmic Autoantibody Glomerulonephritis Is an Aggressive Disease Mediated by Neutrophils

ANCA glomerulonephritis is characterized by glomerular necrosis and crescents.

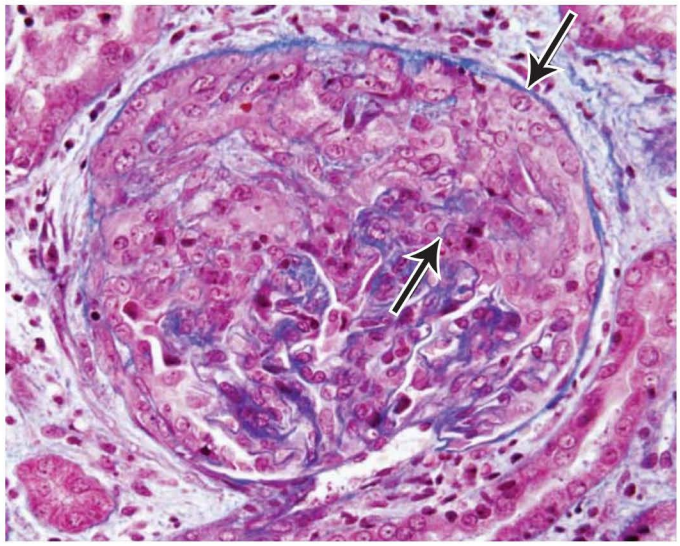

FIGURE 22-53. Crescentic anti–glomerular basement membrane glomerulonephritis. The Bowman space is filled by a cellular crescent (*between arrows*). The injured glomerular tuft is at the bottom (Masson trichrome stain).

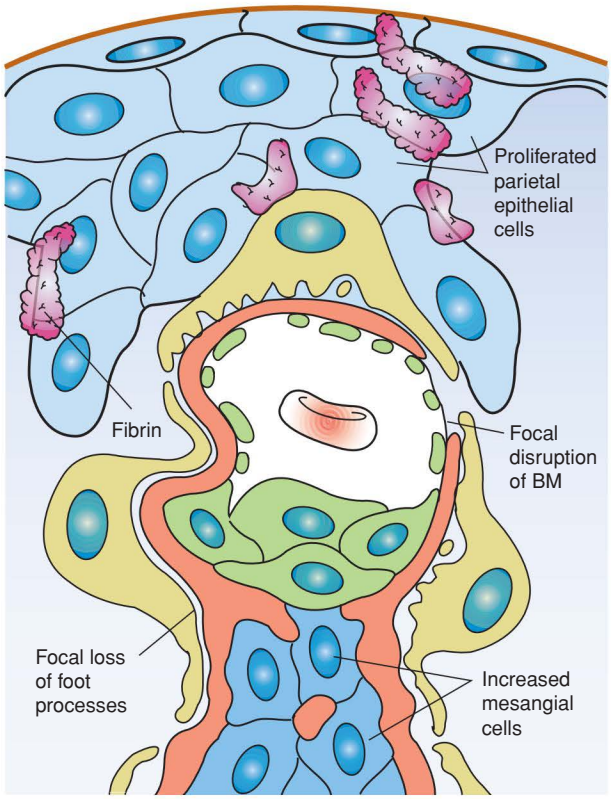

FIGURE 22-54. Crescentic (rapidly progressive) glomerulonephritis. A variety of different pathogenic mechanisms cause crescent formation by disrupting glomerular capillary walls. This allows plasma constituents into the Bowman space, including coagulation factors and inflammatory mediators. Fibrin forms, and there is proliferation of parietal epithelial cells and influx of macrophages (not shown), resulting in crescent formation.

PATHOPHYSIOLOGY: ANCA glomerulonephritis was once called *idiopathic crescentic glomerulonephritis* because there was no evidence of glomerular deposition of anti-GBM antibodies or immune complexes. The discovery that 90% of patients with this pattern of glomerular injury have circulating ANCAs led to the demonstration that these autoantibodies cause the

TABLE 22-8
FREQUENCY (%) OF IMMUNOPATHOLOGIC CATEGORIES OF CRESCENTIC GLOMERULONEPHRITIS* IN DIFFERENT AGE GROUPS

	Age (years)		
Category	**<20**	**20–64**	**>65**
Anti–glomerular basement membrane	10	10	10
Immune complex	55	40	10
Antineutrophil cytoplasmic autoantibody	30	45	75
No evidence for the three categories above	5	5	5

*Glomerulonephritis with crescents in more than 50% of glomeruli.

disease. ***ANCAs are specific for cytoplasmic proteins in neutrophils and monocytes, usually myeloperoxidase (MPO-ANCA) or proteinase 3 (PR3-ANCA).*** These autoantibodies activate neutrophils to adhere to endothelial cells, release toxic oxygen metabolites, degranulate and kill endothelial cells. Neutrophils activated by ANCAs also activate the alternative complement pathway, which further amplifies the inflammation.

PATHOLOGY: More than 90% of patients with ANCA glomerulonephritis have glomerular necrosis (Fig. 22-55) and crescent formation (Fig. 22-56), often in more than 1/2 of glomeruli. Nonnecrotic segments may appear normal or have slight neutrophil infiltration or mild endocapillary hypercellularity. There is little or no immunoglobulin or complement deposition, which distinguishes ANCA glomerulonephritis from anti-GBM and immune complex glomerulonephritides. Some patients with crescentic glomerulonephritis have serologic and pathologic evidence of ANCAs, anti-GBM antibodies and/or immune complexes.

CLINICAL FEATURES: ANCA glomerulonephritis most commonly presents with rapidly progressive renal failure, with nephritic signs and symptoms. The disease accounts for 75% of rapidly progressive (crescentic) glomerulonephritis in patients older than 60, 45% in middle-aged adults and 30% in young adults and children (Table 22-8). ***In 3/4 of patients with ANCA glomerulonephritis, systemic small vessel vasculitis is present (see below), which has many systemic manifestations, including pulmonary hemorrhage.*** ANCA glomerulonephritis with pulmonary vasculitis causes **pulmonary–renal vasculitic syndrome** much more often than does Goodpasture syndrome. More than 80% of patients with ANCA glomerulonephritis develop ESRD within 5 years if untreated. Immunosuppressive therapy reduces this to less than 20%. Once remission is induced with high-dose immunosuppression, patients are at risk for recurrent disease. The disease recurs in 15% of renal transplant recipients.

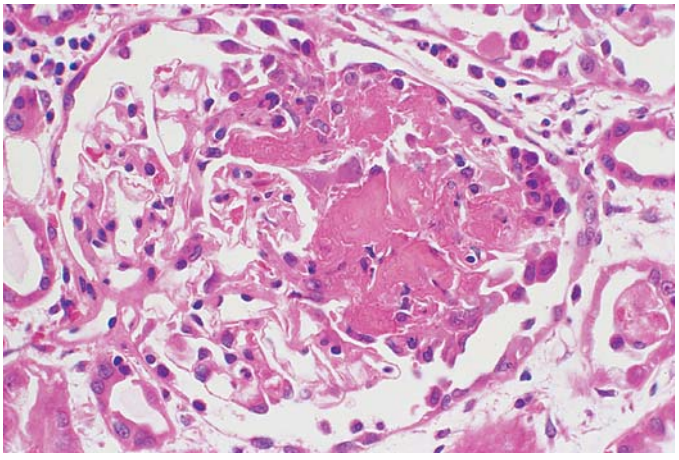

FIGURE 22-55. Antineutrophil cytoplasmic autoantibody glomerulonephritis. Segmental fibrinoid necrosis is illustrated. In time, this lesion stimulates crescent formation.

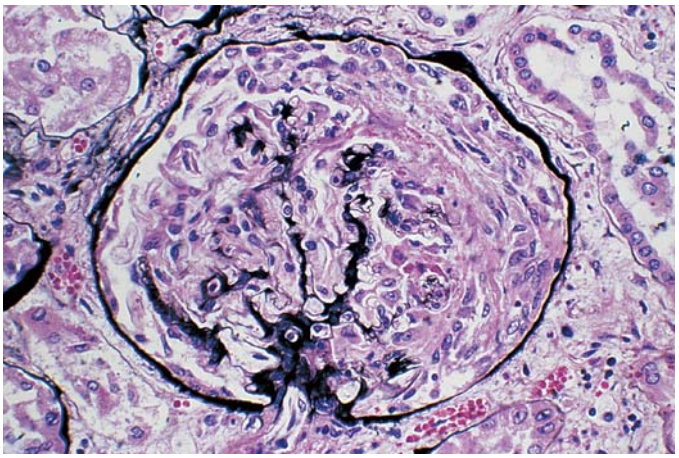

FIGURE 22-56. Antineutrophil cytoplasmic autoantibody glomerulonephritis. Silver staining shows focal disruption of glomerular basement membranes and crescent formation within the Bowman space.

VASCULAR DISEASES

Renal Vasculitis May Affect Vessels of All Sizes

Many types of systemic vasculitis affect the kidney (Table 22-9). ***In a sense, glomerulonephritis is a local form of vasculitis that involves glomerular capillaries.*** Glomeruli may be the only site of vascular inflammation, or the renal disease may be a component of a systemic vasculitis.

Small Vessel Vasculitides

Small vessel vasculitis affects small arteries, arterioles, capillaries and venules. Involvement of any of these can lead to glomerulonephritis. Other common manifestations include purpura, arthralgias, myalgias, peripheral neuropathy and pulmonary hemorrhage. Immune complexes, anti–basement membrane antibodies or ANCAs (Table 22-9) can cause small vessel vasculitides.

IgA vasculitis (Henoch-Schönlein purpura) is the most common childhood vasculitis. It is caused by vascular localization of immune complexes containing mostly IgA. The glomerular lesion is identical to that of IgA nephropathy.

Cryoglobulinemic vasculitis causes proliferative glomerulonephritis, usually type I MPGN. By light microscopy, aggregates of cryoglobulins ("hyaline thrombi") are often seen within capillary lumens (Fig. 22-57).

ANCA vasculitis involves vessels outside the kidneys in 75% of patients with ANCA glomerulonephritis. Based on clinical and pathologic features, patients with systemic ANCA vasculitis are classified as follows (Fig. 22-15):

- **Microscopic polyangiitis,** if there is pauci-immune vasculitis with no asthma or granulomatous inflammation
- **Granulomatosis with polyangiitis (formerly Wegener granulomatosis),** if there is necrotizing granulomatous inflammation, usually in the respiratory tract
- **Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome),** if there is eosinophilia and asthma

In addition to causing necrotizing and crescentic glomerulonephritis, ANCA vasculitides often entail necrotizing inflammation in other renal vessels, such as arteries (Fig. 22-58), arterioles and medullary peritubular capillaries.

TABLE 22-9
TYPES OF VASCULITIS THAT INVOLVE THE KIDNEYS

Type of Vasculitis	Major Target Vessels in Kidney	Major Renal Manifestations
Small Vessel Vasculitis		
Immune complex vasculitis		
IgA vasculitis (Henoch-Schönlein purpura)	Glomeruli	Nephritis
Cryoglobulinemic vasculitis	Glomeruli	Nephritis
Anti-GBM vasculitis		
Goodpasture syndrome	Glomeruli	Nephritis
ANCA vasculitis		
Granulomatosis with polyangiitis (Wegener granulomatosis)	Glomeruli, arterioles, interlobular arteries	Nephritis
Microscopic polyangiitis	Glomeruli, arterioles, interlobular arteries	Nephritis
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)	Glomeruli, arterioles, interlobular arteries	Nephritis
Medium-Sized Vessel Vasculitis		
Polyarteritis nodosa	Interlobar and arcuate arteries	Infarcts and hemorrhage
Kawasaki disease	Interlobar and arcuate arteries	Infarcts and hemorrhage
Large Vessel Vasculitis		
Giant cell arteritis	Main renal artery	Renovascular hypertension
Takayasu arteritis	Main renal artery	Renovascular hypertension

ANCA = antineutrophil cytoplasmic autoantibody; GBM = glomerular basement membrane.

Medium-Sized Vessel Vasculitis

Medium-sized vessel vasculitides affect arteries, but not arterioles, capillaries or venules (see Chapter 16). The necrotizing arteritides, such as **polyarteritis nodosa,** which occurs mainly in adults, and **Kawasaki disease,** which principally afflicts young children, rarely cause renal dysfunction. However, they may involve renal arteries and cause pseudoaneurysm formation and renal thrombosis, infarction and hemorrhage.

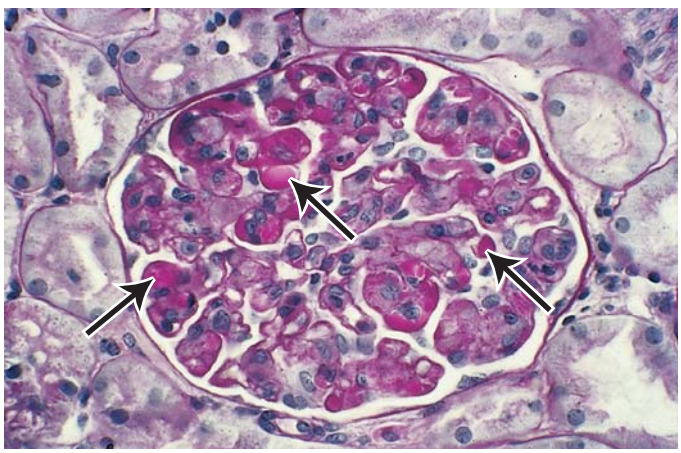

FIGURE 22-57. Cryoglobulinemic glomerulonephritis. The pattern of glomerular inflammation is similar to that of type I membranoproliferative glomerulonephritis. However, as in this specimen, there typically are conspicuous glassy aggregates ("hyaline thrombi," *arrows*) in the capillary lumina and subendothelial spaces. These are not true thrombi but rather are large aggregates of cryoglobulins (periodic acid–Schiff stain).

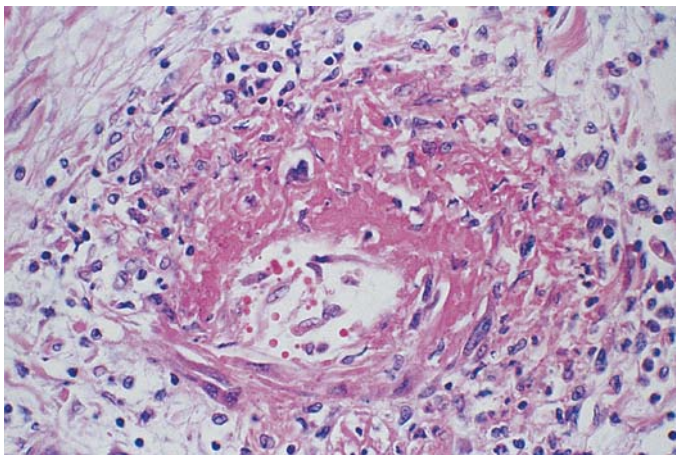

FIGURE 22-58. Antineutrophil cytoplasmic autoantibody necrotizing arteritis. Fibrinoid necrosis and inflammation involve an interlobular artery in the renal cortex.

Large Vessel Vasculitis

Large vessel vasculitides, such as **giant cell arteritis** and **Takayasu arteritis,** affect the aorta and its major branches. These disorders may cause renovascular hypertension by involving the main renal arteries or the aorta at the origin of the renal arteries (see Chapter 16). Narrowing or obstruction of these vessels results in renal ischemia, which stimulates increased renin production and consequent hypertension (Table 22-9).

Hypertensive Nephrosclerosis May Obliterate Glomeruli
